All antidepressants are indicated for the treatment of acute major depressive episodes. The major depressive disorder is, most likely, a variety of neuropsychological disorders that have in common their negative effects on mood, thought and vegetative symptoms. There is much room for variation, with phenomenology ranging from anxiety and irritability to anergy and melancholia. The heterogeneity of the diagnosis is recognized in the Diagnostic and Statistical Manual of Mental Disorders (DSM), of which the DSM-IV-Text Revision (DSM-IV-TR) (American Psychiatric Association 2000a) is the most recent edition. DSM-IV-TR lists nine possible symptoms. Of these, either depressed mood or loss of interest is required for the diagnosis, with at least four other symptoms present during a 2-week period.

Though there have been some attempts to match different types of depression with different medications, there is no convincing evidence to suggest that there is a preferential efficacy between specific presentations of depression and certain medications. Some investigators have suggested that certainly personality types may differentially respond to different agents (Tranter et al. 2002); however, it is not clear whether these data reflect actual differences in efficacy or personality differences that then affect adherence.

Prevention of Relapse and Recurrence

Beyond the acute period, there is also evidence for the use of antidepressants in the prevention of relapse and recurrence. However, the further one gets from the initial episode, the sparser the data. Most of the commonly used antidepressants have at least one placebo-controlled study justifying their use in relapse prevention. However, few studies go beyond a year of treatment (these are discussed later in this chapter).

Other Depressive Disorders

There are a number of more minor forms of depression, many of which may also respond to antidepressant medication. Best studied of these is dysthymic disorder, which appears to be responsive to most antidepressants. There are four published placebo-controlled studies investigating the treatment of dysthymia with second-generation antidepressants. Of these, one study using fluoxetine (Devanand et al. 2005) showed no difference from the placebo group. Two studies using sertraline (Thase et al. 1996, Ravindran et al. 2000), and one with paroxetine (Barrett et al. 2001) showed positive results. To date, no studies comparing different agents in dysthymia have been published.

Other minor depressive disorders include minor depression and recurrent brief depression. Though rigorous data are largely lacking in the treatment of these disorders, they seem to show an at least modest response to antidepressant medications.

Other Disorders

Antidepressants are used in an ever-increasing number of nondepressive disorders: such uses are discussed under the appropriate sections of the textbook, and are listed in Table 101–2.

Various Uses of Antidepressants

Assessing the Need for Intervention

This involves assessing the likely result if pharmacological treatment is not given. It is essential in making a useful risk–benefit assessment.

Longitudinal Factors

The physician should consider the course and duration of previous episodes of depression. Such episodes can predict the potential severity of the current episode, the likely time to recovery, and the probability of a subsequent recurrence. The physician should also consider the likely complications of depression for the individual patient, which may include substance abuse and suicide.

Cross-Sectional Factors

The physician should consider the severity of symptoms and the degree of functional impairment. Suicidal ideation is of particular concern and needs rapid and intensive treatment. Such treatment often includes hospitalization. Even with less pressing symptoms, but significant occupational or social impairment, the risk–benefit ratio generally still favors a trial of antidepressants, particularly now that safer and more easily tolerated agents are available.

Assessing the Likelihood of Success

The ability to predict the likely response to pharmacotherapy would be invaluable for planning a treatment strategy. Such an assessment is difficult.

A number of symptoms have been suggested as predictors of good and poor response. In the past, depressive illness was distinguished by whether it was “endogenous” or “exogenous.” Endogenous depression was thought to have a primary biological etiology, whereas exogenous depression implied a reactive response to environmental stressors. It was assumed that endogenous depression would respond better to somatic therapy and exogenous to psychosocial interventions. This distinction proved excessively simplistic. The categories did not have adequate construct validity. Usually, the attribution of cause was assigned retrospectively, and it was subject to various interpretations. As a result, these subgroups did not adequately predict treatment response.

A refinement of such categories has been the concept of “melancholic depression.” This subtype contains many of the criteria thought to describe the endogenous type of depression, but it does not imply any specific etiology. Melancholic depression is, by definition, highly responsive to somatic therapy. Individuals in this subgroup tend to have a positive family history for depression and a 2:1 female–male ratio.

Another subtype, “atypical depression,” describes a group of patients who differ from the melancholic type, primarily with neurovegetative symptoms: they have hypersomnia, hyperphagia, and psychomotor agitation and are more likely to be anxious or irritable. Earlier studies suggested a preferential response to certain classes of antidepressants, with MAOIs often suggested as the drug of choice. However, studies that are more recent have not supported a differential effect on depression among different classes of antidepressants (McGrath et al. 2000).

Additional possible predictors of poor response include personality features (such as neurotic, hypochondriacal, and hysterical traits), multiple prior episodes, delusions, and psychomotor agitation.

Selection of a Particular Agent

Although, as noted earlier, the various antidepressants seem to have equal efficacy in the treatment of depression, a given patient may respond preferentially to one, or a class of agents. Again, cross-sectional and longitudinal factors should be taken into account.

Longitudinal Factors
Longitudinal factors include a history of response to a particular agent, a family history of good response, a history of prior side effects (particularly if they resulted in drug discontinuation), and a history of symptoms that could suggest mania (or more minor variants of manic episodes). TCAs are less desirable for patients with prior manic episodes, as they may precipitate manic episodes. Although less well understood, MAOIs may produce the same effect (Keller et al. 1986).

Cross-Sectional Factors
Cross-sectional factors would include data from the physical examination and laboratory work-up, which might suggest susceptibilities to certain antidepressant agents or contraindications based on physical illness. For instance, an examination that revealed prostatic hypertrophy or an electrocardiogram that showed a conduction abnormality should influence the physician against a TCA. A seizure disorder would be a relative contraindication against using bupropion. Aspects of the psychiatric examination are useful as well. For example, the presence of manic symptoms, indicative of a mixed bipolar illness, argues for treatment with lithium or anticonvulsants over standard antidepressants.

Anxiety has been often used as a predictive symptom. Specifically, there is often a belief that patients with anxiety symptoms do better with more sedating antidepressants. Even though an early sedating effect may increase adherence in patients with prominent anxiety, there is no evidence that more sedating agents are more effective in patients with comorbid depression and anxiety.

The presence of psychotic symptoms requires combined treatment with antidepressants and antipsychotics, as either agent alone is less effective for these symptoms. An alternative is to use electroconvulsive therapy.

An issue often neglected is that of cost. Older agents that are available in generic form are 10–100 times less expensive than newer agents are. Although older agents tend to have more side effects, cost can also influence compliance. In 2001, fluoxetine became the first SSRI to be available in the US in generic form. By the year 2010, all but one of the currently available antidepressants will be off patent and eligible to be produced generically. Table 101–1 lists the relative costs of antidepressants, as of the first quarter of 2007.

Pharmacokinetic Concerns

First-Generation Antidepressants
The pharmacokinetics of TCAs is complex. This complexity is reflected in the diversity of half-lives reported, which vary roughly from 10 to 40 hours. TCAs are primarily absorbed in the small intestine. They are usually well absorbed, and reach peak plasma levels 2–6 hours after oral administration. Absorption can be affected by changes in gut motility. The drugs are extensively metabolized in the liver on first pass through the portal system. They are lipophilic, have a large volume of distribution, and are highly protein bound (85–95%). TCAs are metabolized in the liver by hepatic microsomal enzymes, via demethylation, oxidation, or hydroxylation. They are generally metabolized to active metabolites, and are excreted by the kidneys. There is a large range of elimination half-lives among the antidepressants. MAOIs are also well absorbed from the gastrointestinal tract. Their metabolism, although quite efficient (they have a half-life of 1–2 hours), is not well understood. The short half-life of these compounds is not entirely relevant however, as they bind irreversibly with MAO. Thus, the activity of these drugs depends less on pharmacokinetics, and more on the synthesis of new MAO to restore normal enzyme activity. This synthesis requires approximately 2 weeks.

Second-Generation Antidepressants
All of the available SSRIs are well absorbed, and not generally affected by food administration. Sertraline is an exception to this rule, and its blood level may be increased by food. All SSRIs have large volumes of distribution and they are extensively protein bound. They are metabolized by hepatic microsomal enzymes and are potent inhibitors of these enzymes (a fact that will be discussed later in detail). The only SSRI with an active metabolite is fluoxetine, whose metabolite norfluoxetine has a half-life of 7–15 days. Thus, it may take several months to achieve steady state with fluoxetine. This is considerably longer than citalopram, which has a half-life of about 1.5 days, or sertraline and paroxetine, which have half-lives of about a day.

As previously discussed, there is no correlation between half-life and time to onset. Drugs with shorter half-lives have an advantage in cases where rapid elimination is desired (e.g., in the case of an allergic reaction). Drugs with a longer half-life may also have advantages: fluoxetine, for example, is available in a once-weekly formulation. All SSRIs are eliminated in the urine as inactive metabolites. Both fluoxetine and paroxetine are capable of inhibiting their own clearance at clinically relevant doses. As such, they have nonlinear pharmacokinetics: changes in dose can produce proportionately large plasma levels.

As with most of the other antidepressants, buproprion undergoes extensive first pass metabolism in the liver. Although the parent compound has a half-life of 10–12 hours, it has three metabolites that appear to be active. One, threohydrobupropion, has a half-life of 35 hours and is relatively free in plasma (it is only 50% protein bound). There is considerable individual variability in the levels of bupropion and its metabolites. In addition, the drug is available in an immediate release, intermediate release, and extended release formulation. Trazodone has a half-life that is relatively short, having a range of 3–9 hours. Given this, and its apparent lack of active metabolites, the plasma levels of trazodone can be quite variable during a day. For this reason, the medication requires divided dosing.

Third-Generation Antidepressants
Venlafaxine has a short half-life (4 hours); however, it is available in an extended release formulation that allows once-daily dosing. It appears to have a dual effect, in which at lower doses it primarily acts on the serotonin transporter, and clinically significant norepinephrine reuptake inhibition is not seen until higher doses are used (150 mg/day and above). Nefazodone has relatively low bioavailability, and a short half-life (2–8 hours), and thus it is usually given in twice-daily doses. Mirtazapine has a half-life of 13 to 34 hours. Duloxetine is absorbed over a 2-hour period, although this absorption is delayed if the medication is taken in the evening. It is highly protein bound (>90%), and undergoes
rapid metabolism after being absorbed. It has a half-life of approximately 12 hours.

The relative half-lives of available antidepressants are depicted in Figure 101–2.

**Gender, Ethnic, and Racial Issues**

**Gender**

Women may have slower gastrointestinal absorption than men, as they have less gastric acid and slower gastric emptying. A woman’s volume of distribution differs as well, given her increased ratio of adipose tissue to lean body mass. Water retention associated with the menstrual cycle may also affect the volume of distribution.

Few clinical studies specifically look at the pharmacokinetics of antidepressants in women. Existing studies show conflicting results: some studies suggest that at similar doses women will have increased plasma levels, while other studies do not show such a difference. In some of the studies, the patients used oral contraceptives, which can alter the hepatic metabolism of TCAs, and this may explain the discrepancy between studies.

There may be pharmacodynamic differences as well. Possible gender differences in responses to antidepressants have been suggested for decades, but rarely examined in detail. Kornstein et al. (2000) reanalyzed data from a study comparing imipramine and sertraline for chronic depression. They found that women responded better to sertraline than to imipramine whereas men had the opposite pattern of response. Women also had a longer time to response. Of interest was the fact that this effect was only seen in premenopausal women; postmenopausal women had similar rates of response to both medications.

**Race and Ethnicity**

As with gender, there are insufficient studies available on the effects of race and ethnicity on differential dosing, pharmacology, and treatment response. Some studies have suggested that Hispanic patients may have an increased sensitivity to antidepressants; however, there are conflicting data on this subject (Bond 1991).

Some pharmacokinetic differences are found in Asian populations; for example, Asians tend to carry the poor metabolizer trait for cytochrome P450 2C19 (Roden et al. 2006). There may be pharmacodynamic differences in Asian populations, as a number of pharmacogenetic studies have found that the associations between monoamine transporter polymorphisms and antidepressant response are not found in Asian populations (Nnadi et al. 2005).

African-Americans may differ from Caucasian Americans in their ability to metabolize certain antidepressants. Generally, it has been reported that they can be slow metabolizers of some antidepressants, particularly the TCAs (Strickland et al. 1997). One genetic study of African-Americans from the Southeastern US had a lower prevalence of the P450 2D6 poor metabolizer mutation (Evans
et al. 1993). Some differences in metabolism by racial group are illustrated in Figure 101–3.

Clearly, these issues need to be explored further. However, the greatest concern regarding race and ethnicity remains the disparities in access to treatment for African-Americans and other minority groups (Sleath et al. 2006).

Preparation of the Patient

Side Effects of Antidepressants

Good preparation and reassurance are essential. Side effects—even relatively benign ones—are a major cause of treatment nonadherence. Dropout rates ranging from 7 to 44% have been reported in various studies of TCAs, and from 7 to 23% in studies of SSRIs. Proper education and reassurance about side effects can help reduce this rate. It should reassure the patient to know that many of the side effects diminish with time, or with an adjustment of dose. It may also help frame side effects in a positive light, as they represent concrete evidence that the medication is exerting its effect on the body.

The best approach may be to consider both frequency and clinical importance. That is, one should discuss those side effects that are likely to occur, as well as considering rare but potential dangerous or irreversible side effects. A number of common, uncommon, and hypothetical side effects are discussed here.

The importance of discussing side effects as soon as possible is made particularly crucial given the wide variety of other sources of information at patients’ disposal. Many pharmacies now include printed information to accompany medications, which include comprehensive lists of side effects. Various books on medications are available and a popular offering in many bookstores and libraries. On the Internet, mental health sites have become an extremely popular source of information for patients. The information on Internet sites may range from very reputable and informative, to anecdotal, to clearly hostile and misrepresented. It should be the role of the physician to give such information context, and, if indicated, to correct misinformation.

It is useful to divide side effects into “predictable” and idiosyncratic effects. Predictable side effects result from known pharmacological actions of the drug. Idiosyncratic side effects are not well understood. What follows is a brief summary of antidepressant side effects; for a fuller discussion, the reader is referred to more comprehensive works (e.g., Schatzberg and Nemeroff 2004).

Predictable Side Effects

These side effects are the result of the action of the agent at various neurotransmitters and enzyme sites. The major neurotransmitters affected by antidepressants are as follows.

Muscarinic Acetylcholine Receptors

Blockade of this receptor produces a variety of peripheral and central effects. Gastrointestinal effects include decreased salivation and decreased peristalsis. Decreased salivation is the most common of these effects and can cause drying of the mucous membranes. Such drying can exacerbate gum disease and dental caries. Decreased peristalsis can cause constipation and, in the extreme, paralytic ileus. Contraction of the bladder wall is inhibited, causing urinary hesitancy and even urinary retention. In the case of TCAs, concomitant sympathomimetic effects that cause constriction of the bladder neck and urethra worsen this effect on urination. Inhibition of the parasympathetically mediated accommodation reflex, in which the ciliary body muscles normally contract to thicken the lens and focus near objects on the retina, results in blurry vision and mydriasis. Such accommodation paresis can occur without other anticholinergic side effects. A more serious ocular effect is the precipitation of acute narrow-angle glaucoma, through pupillary dilation. Antidepressant-induced narrow-angle glaucoma is quite rare. Anticholinergic cardiac effects include decreased vagal tone that can cause tachycardia. Central nervous effects include impaired memory and cognition. In severe cases, such cognitive impairment can reach the point of a delirium. Central anticholinergic effects can also worsen existing tardive dyskinesia.

These effects are usually dose related, and are worse in people with preexisting defects. For example, the cardiac effects are of most concern in patients with preexisting cardiac defects, and urinary blockade generally occurs only in the presence of prostatic hypertrophy. These side effects are also more common in patients taking other anticholinergic medications, which is a common feature of many over-the-counter preparations.

The relative affinities of antidepressants for blocking muscarinic receptors are compared in Figure 101–4. As MAOIs have little direct effect on receptors, and their side effects relate to enzymatic inhibition, they are discussed separately.

Histamine

Blockade of the histamine H1 receptor is typically associated with sedation. Histamine blockade may also cause
orthostatic hypotension and weight gain. It can impair psychomotor coordination and cause falls in the elderly. Cognitive impairment can occur as well. H2-receptor blockade causes decreased gastric acid production. This is the mechanism of many antiulcer medications. The relative affinities of antidepressants for blocking histaminic receptors are compared in Figure 101–5.

**Norepinephrine**

Synaptic increases in norepinephrine, through either inhibition of norepinephrine reuptake or decrease in MAO degradation, cause sympathomimetic effects. Increases in norepinephrine can cause anxiety, tremors, diaphoresis, and tachycardia. This tachycardia can potentiate anticholinergic cardiac effects. As noted, sympathomimetic effects on the bladder neck and urethra can potentiate the anticholinergic inhibition of normal urinary function. The relative potencies of antidepressants for blocking the reuptake of norepinephrine are compared in Figure 101–6.

**Receptor Blockade**

Blockade of alpha-1-receptors occurs as a chronic effect through both down regulation and desensitization of the beta- and alpha-2-receptors. Blockade of the noradrenergic

alpha-1-receptor is responsible for postural hypotension. In the elderly or medically ill, this postural hypotension can be significant, and lead to dizziness or falls. It may also be responsible for ejaculatory delay or impotence. Other potential effects include reflex tachycardia and memory dysfunction. The relative affinities of antidepressants for blocking alpha-1-adrenoceptors are compared in Figure 101–7.

Serotonin
Potentiation of serotonin can cause anorexia, nausea, vomiting, diarrhea, “jitteriness,” and anxiety. Conversely, potentiation of serotonin has also been associated with weight gain; the mechanism of this action is poorly understood. Akathisia, a syndrome of motor restlessness usually associated with antipsychotics, may also be reported: this may be due to either the general effect of serotonin potentiation or direct effects on the basal ganglia, which may also manifest as an exacerbation of Parkinsonism. Sedation, which has been reported with all SSRIs, appears to be a primary serotonin effect. Insomnia, however, is more common at higher doses, particularly with fluoxetine. Weight gain has also been associated with potentiation of serotonin. A

number of sexual side effects have been attributed to serotonin reuptake blockade, including anorgasmia, ejaculatory difficulties, and even spontaneous orgasms (Yanik 2004). The relative potencies of antidepressants for blocking the reuptake of serotonin are compared in Figure 101–8.

**Receptor Antagonism**

Blockade of the 5-HT2 receptors may result in hypotension and ejaculatory disturbances. Antagonism of serotonin receptors may also be responsible for weight gain and carbohydrate craving. Potency for blockade of this receptor (specifically of the 5-HT2A receptor) is compared in Figure 101–9.

**Dopamine**

Increases in dopamine resulting from reuptake blockade can have an anti-Parkinsonian effect. It can also cause psychomotor activation and aggravation of psychosis. The relative potencies of antidepressants for blocking the reuptake of dopamine are compared in Figure 101–10.

**Receptor Antagonism**

The blockade of dopamine receptors can result in extrapyramidal symptoms. These symptoms include cogwheel-type rigidity, tremor, dyskinesia, masked facies, and acute dystonia. Prolonged dopamine blockade appears to be responsible
for tardive dyskinesia. Dopamine receptor blockade has also been associated with endocrine changes and sexual dysfunction. The relative affinities of antidepressants for blocking dopamine receptors are compared in Figure 101–11.

Monoamine Oxidase

MAO is the main enzyme responsible for the metabolism of monoamines. There are two main types of MAOIs, identified as types A and B. Type A is selective for serotonin and norepinephrine, and accounts for 80% of the MAO in the brain. Type B selectively deaminates phenylethylamine. Both forms oxidize dopamine and tyramine.

Dietary Restrictions

The dietary restrictions required when using MAOIs represent the major limitation to widespread use of these effective antidepressants. Nonselective inhibition of MAO prevents the normal hepatic metabolism of tyramine-containing foods or sympathomimetic agents. The increased level of tyramine in the circulation stimulates the release of norepinephrine from sympathetic terminals. This sudden increase in norepinephrine is the basis for the “tyramine–cheese” reaction,
so named because cheese is the most common source of the tyramine that causes this reaction. In fact, other presor amines, such as levodopa, can also cause the reaction, but tyramine—a natural product of food fermentation and bacterial decarboxylation—is the most common in foods. The result of a tyramine–cheese reaction can be a hypertensive crisis. Thus, patients should be well educated as to the foods that must be avoided while using MAOIs. In the past, there has been a tendency toward conservative dietary restrictions, often based on single case reports or indirect analogies. More research and experience have suggested that not all the foods commonly restricted are equally likely to precipitate a reaction. Better compliance is likely if a more reasonable diet is prescribed.

Despite the best of preparation, some patients may err and suffer a hypertensive crisis. This is often experienced as a severe, pulsating, occipital headache that then generalizes. It may be alleviated with 10 mg of nifedipine, either oral or sublingual.

MAOIs can cause an increase in standing systolic blood pressure, absent of tyramine-containing foods, or sympathomimetics. Generally, this effect is not clinically significant; however, serious unprovoked hypertensive episodes have been reported (Lavin et al. 1993), and blood pressure should be monitored for 1–2 hours after beginning or increasing an MAOI. Hypotension is also a reported effect of MAO, but the mechanism is not known. MAO inhibition can also cause sedation or overstimulation. Once again, the mechanism of this is not well understood.

**Membrane Stabilizing Activity**

TCAs have effects on cardiac conduction that are independent of anticholinergic or noradrenergic effects. Destabilization of the cardiac membrane can cause dysrhythmia and asystole, particularly in overdose.

**Idiopathic Effects**

**Allergic Reactions**

Allergic reactions can occur with any of these agents. Effects include dermatological (rashes, urticaria, photosensitivity, pigment changes, and Stevens–Johnson syndrome) and hematological (agranulocytosis) sensitivities. Fluoxetine has been associated with bleeding, inflammation, and, most seriously, a fatal systemic vasculitis. It should be stopped if a rash develops.

In most cases of allergic reactions, the primary treatment is to stop the agent. On occasion, granulocyte colony stimulating factor has been used to treat allergic agranulocytosis (Rajagopal et al. 2007).

**Liver Effects**

Abnormal liver function tests have been associated with a number of antidepressants, which can be independent of dose. The risk for such effects may be worsened by chronic alcohol or anticonvulsant use.

Even though sudden liver effects are possible for most antidepressants, the greatest concern is with nefazodone, which is reported to cause liver failure resulting in death or transplant in 1 in 250,000 to 300,000 patient-years of nefazodone treatment (Schwetz 2002). This rate is approximately 3–4 times the background rate of liver failure. This can occur suddenly, and in individuals with previously normal liver functioning. In response to this information, the FDA required the manufacturer of nefazodone to add a “black box” warning to nefazodone’s prescription information. The brand version of nefazodone was subsequently discontinued. It remains available in generic formulations.

**Seizures**

A preexisting seizure disorder increases an antidepressant’s likelihood of precipitating a seizure. Other predisposing factors include a family history of a seizure, an abnormal pretreatment electroencephalogram, brain damage, previous electroconvulsive treatment, abuse or withdrawal from sedatives, alcohol or cocaine, and concurrent use of CNS-activating medications. Seizures may be more likely to occur early in treatment, or after a large escalation in dose.

The risk of seizure with TCAs is usually reported as 0.1%. This incidence applies to outpatients, without predisposing factors for seizures, receiving low to moderate doses of medications.

SSRIs appear to have a lower incidence of seizures; however, the evidence for or against an increased risk of seizures in this group is inadequate for any definitive conclusion. In one chart review of 538 patients with deliberate self-poisoning with antidepressants, seizures were more common in patients with venlafaxine overdose than in patients with TCA or SSRI overdose (Whyte et al. 2003).

Bupropion is thought to have a higher rate of seizures, approximately 2–4 times that of other antidepressants. Again, however, the data are limited. Two open-label studies of bupropion treatment for 8 weeks found rates that were similar to that reported for other antidepressants (Johnston et al. 1991, Dunner et al. 1998). Bupropion’s effect on the seizure threshold has never been directly compared with other antidepressants.

**Precipitation of Mania**

Antidepressants have been associated with the precipitation of mania and rapid cycling bipolar disorder. This appears to be most common in patients with a preexisting history of mania. For those with unipolar depression, it is thought likely that many had undiagnosed bipolar disorder (Chun and Dunner 2004). Compared with TCAs, the risk appears lower with second- and third-generation agents; however, the precipitation of mania has been reported with all antidepressants. It seems to occur coincident with the time of antidepressant effect (Wada et al. 2006). In one prospective randomized trial of second- and third-generation antidepressant use for bipolar depression, venlafaxine had the highest rate of mania switch, and bupropion had the lowest (Leverich et al. 2006). Some research points to a particular polymorphism of the serotonin transporter as predisposing to this side effect (Mundo et al. 2001).

**Sexual Dysfunction**

A variety of sexual side effects can be caused by antidepressants, and they can affect all aspects of sexual response. Thus, antidepressants can decrease libido, increase impotence and anorgasmia, and cause delayed or retrograde ejaculation.

All antidepressant have the potential to cause sexual side effects.
In a large natural study of patients in primary care, Clayton et al. (2002) found that SSRIs, mirtazapine and venlafaxine, had the highest rates of sexual dysfunction (36–43%), and bupropion had the lowest (22% for the immediate release formulation, and 25% for the sustained release). However, other studies with similar methodology have found surprisingly different rates of sexual dysfunction. It must be acknowledged that investigating the prevalence of sexual dysfunction in antidepressants is complicated by the baseline rate of sexual dysfunction in the general population and the higher prevalence in patients suffering from depression (Balon 2006). The most common antidepressant-related side effects are delayed orgasm or anorgasmia.

Though these side effects may in part be receptor mediated, at least some degree seems to be iatrogenic and not dose related. As such, sexual side effects can occur at even low therapeutic doses, and dose reduction may not be possible. A change of agent may be the only alternative.

Trazodone has been associated with penile priapism; the risk is around 1 in 6,000 to 8,000 men. Although rare, it is notable that a third of these cases required surgical intervention, and some resulted in permanent impairment. Citalopram has been reported as well (Pescatori et al. 1993). The actual cause of these sexual dysfunctions is not clear, although some of these effects may result from anticholinergic, presynaptic alpha-2-adrenergic, or serotoninergic effects.

Miscellaneous

Fine tremors have been noticed with both TCAs and SSRIs. Although the mechanism is not clear, serotonin reuptake inhibition may be involved. Excessive sweating has been associated with both fluoxetine and paroxetine. The syndrome of inappropriate secretion of antidiuretic hormone has been seen with fluoxetine, as well as with a number of other antidepressants. SSRIs have been reported to cause alopecia, usually at higher doses of the medication. Although antidepressants are often used to treat headaches, they have on occasion been reported as causing both migraine and non-migraine headaches. These reports should be tempered by the fact that headaches are a frequent nonspecific complaint both in depressed and normal individuals, and the relationship may not always be causal.

One should always be alert to the possibility of rare, undiscovered allergic reactions. For example, the subsequent discovery of serious hepatic and hematological effects caused the withdrawal of nomifensine well after the drug’s approval.

First-Generation Antidepressants

Tricyclic Antidepressants

As with any combination therapy, the side effects described previously can be additive with other similar drugs. Most problematic are the anticholinergic effects of the TCAs. Such cholinergic—particularly muscarinic—blockade is a property shared by many other medications, including numerous over-the-counter preparations. The general sedative properties of these medications can also augment any soporific. The slowing of cardiac conduction can also potentiate other medications that produce similar effects, such as type IA antiarrhythmics and anticholinergic medications. Adrenergic receptor blockade can worsen the orthostatic hypotension caused by other medications, including vasodilators and low-potency antipsychotic medications.

Pharmacokinetic Effects

Absorption of TCAs can be inhibited by cholestyramine, which therefore must be given at different time intervals than the antidepressants. TCA levels can be raised by 

Chapter 101 • Antidepressants
substances that inhibit enzyme activity, and lowered by substances that induce it. Specific substances reported to increase TCA levels include fluoxetine, antipsychotic medications, methylphenidate, and cimetidine. Enzyme “inducers” that can lower TCA levels include phenobarbital and carbamazepine. The nicotine from cigarettes can also induce enzyme activity.

Guanethidine is contraindicated with TCAs, as it relies on neuronal reuptake for its antihypertensive effect. Clonidine, a presynaptic alpha-2-receptor noradrenergic agonist, is also contraindicated, as it works in an antithetical fashion to TCAs.

**Monoamine Oxidase Inhibitors**

As with the dietary proscriptions, any medication that increases tyramine can precipitate a hypertensive crisis. Such medications include numerous over-the-counter preparations for coughs, colds, and allergies. The same rule applies to sympathomimetic drugs (such as epinephrine and amphetamines) and dopaminergic drugs (such as anti-Parkinsonian medications).

The combination of MAOIs and narcotics—particularly meperidine—can cause a reaction that varies from symptoms of agitation and hyperpyrexia to cardiovascular collapse, coma, and death. Originally, this was thought to be the result of inhibition of meperidine metabolism; however, it now appears more likely that the reaction is a type of serotonin syndrome (described in the next section), as meperidine inhibits serotonin reuptake (Latta et al. 2002). A similar reaction can occur with any potentiator of serotonin (such as an SSRI).

Similar to the dietary restrictions, some of the drug restrictions associated with MAOIs are based on little actual data. Best established are the restrictions against the combination of MAOIs with amines, meperidine, dextromethorphan, hygroscopic agents, L-Dopa, reserpine, tetrabenezine, and tryptophan. TCAs are frequently included on this list as causing a “central excitatory syndrome” in combination with MAOIs, although the two have been combined safely.

**Second-Generation Antidepressants**

**Selective Serotonin Reuptake Inhibitors**

SSRIs are potent inhibitors of the CYP2D6 pathway, and the drug–drug interactions that can result from this have been the subject of a number of books and articles. As such, an in-depth discussion is not possible in this chapter, and some concerns will be briefly discussed. The reader is also referred to our earlier discussion of CYP-related drug interactions.

SSRIs can slow the metabolism of any drug that is also metabolized by that pathway. Such drugs include TCAs, carbamazepine, phenothiazines, butyrophenones, opiates, diazepam, alprazolam, verapamil, diltiazem, cimetidine, and bupropion. Paroxetine appears to be the most potent inhibitor of this metabolic pathway, with fluoxetine also showing high potency. Sertraline is a somewhat less potent inhibitor. These pharmacokinetic interactions are best managed with dosage adjustment.

Particular caution should be used when a patient using multiple medications starts an SSRI, as the interactions with other drugs can cause dangerous increases in levels. For example, in the cardiac patient, levels of warfarin should be monitored as fluoxetine can raise the levels of these and other medications.

A single case report suggested that fluoxetine could raise lithium levels; however, this was not replicated in controlled studies combining lithium with various SSRIs (Lane et al. 1997). A more practical concern is the risk of serotonin syndrome, as lithium can potentiate serotonergic function.

**The Serotonin Syndrome**

This syndrome occurs when an SSRI is combined with another drug that can potentiate serotonin. In theory, any drug or combination of drugs that have the effect of increasing serotonin levels to the point of overwhelming normal mechanisms of metabolism or reuptake can precipitate the syndrome (Lane et al. 1997). The result is serotonin toxicity, which can include cognitive–behavioral changes (delirium, agitation), autonomic dysfunction (abdominal pain, nausea, vomiting, diarrhea, hyperpyrexia, diaphoresis, tachycardia, hypertension), and neuromuscular abnormalities (see Table 101–3). Some of the most severe reactions have been the result of combining MAOIs with SSRIs, and such a combination can result in coma, cardiovascular shock, and death. For this reason, a clearance period is required before switching between an SSRI and an MAOI. Switching from fluoxetine to an MAOI is particularly difficult, given fluoxetine’s long clearance time—about 6 weeks. Clearance is considerably more rapid for most of the other SSRIs, and a 2-week “wash-out” period is advised when changing from one of these agents to an MAOI.

**Other Second-Generation Antidepressants**

Few reports exist of interactions with other drugs and trazodone, although trazodone may increase levels of digoxin, phenytoin, and possibly warfarin. Trazodone can theoretically contribute to a serotonin syndrome, and some reports of serotonin syndromes due to the combination of trazodone and an SSRI have been reported (Lane and Baldwin 1997). Bupropion causes few drug–drug interactions. The

main interactions reported have occurred when bupropion is combined with another dopaminergic agent, the combination of which can cause restlessness and agitation.

**Third-Generation Antidepressants**

Venlafaxine does not substantially inhibit the CYP enzymes, and is not highly protein bound; thus it tends to have few clinically significant drug–drug interactions. Duloxetine is both a substrate and a moderate inhibitor of CYP2D6, and is metabolized by CYP1A2. Both venlafaxine and duloxetine can potentially contribute to a serotonin syndrome. Nefazodone is highly protein bound, and has several active metabolites. It is also a strong inhibitor of CYP3A4, and affects other drugs also metabolized by that pathway; however, it has little affinity for the CYP2D6 enzyme. Mirtazapine is highly protein bound as well, but only weakly affects the cytochrome enzymes.

**Initiation of Treatment**

**Choosing a Drug**

On average, all antidepressants are equally effective. Although an individual patient may preferentially respond to a certain antidepressant, it is difficult to predict this in advance. Without a personal or family history of such a response, side effects are the most influential factors in choosing an agent. Side effects may be particularly relevant in the following groups of patients.

**Elderly Patients**

**Pharmacokinetic Concerns**

Two pharmacokinetic changes are of great importance in aging patients: decreased efficiency of the hepatic micro-oxidase system and a decreased muscle–fat ratio. Decreased efficiency of hepatic microoxidases results in the slower metabolism of antidepressants and other drugs. Normal increases in body fat and a loss of muscle mass result in an alteration of the volume of distribution for a substance. Thus, lipophilic drugs—including all antidepressants—are more widely distributed in the elderly body.

Both the resulting slower metabolism and the increased volume of distribution increase the half-lives of the various antidepressants. The elderly, therefore, are likely to have a greater incidence of side effects. This concern is underscored by several studies that have found an increased risk of fractures in patients taking antidepressants. A meta-analysis of 16 studies estimated the relative risk to be 1.6 (Takkouche 2007), which was higher than the risk for benzodiazepines and antipsychotics.

The half-lives and steady state concentrations of the SSRIs are only minimally affected by age. Paroxetine may be an exception to this, and it may have an increased half-life in the elderly.

**Pharmacodynamic Concerns**

Numerous changes in the densities and sensitivities of various receptors have been reported; the clinical significance of most of these changes is not well understood. The assumption that elderly patients require lower blood levels of antidepressant medication is not correct. Although pharmacokinetic concerns may require lowering of the medication dose, plasma levels are comparable to those in young adults.

**Efficacy**

A number of antidepressants have been studied in the elderly. The consensus is that antidepressants are just as useful in the elderly as in younger adults. Most studies have been done in elderly patients who would be considered “young-old,” and the patients studied are generally in good health. In some cases, the definition of “elderly” in the studies is extended to as young as 55 years of age. As such, the elderly patients used in efficacy studies may not be representative of the elderly population.

Of the studies in the medically healthy elderly, there is some support—albeit limited—for the efficacy of virtually all antidepressant agents. Most TCAs (Salzman et al. 1993) and all SSRIs (Altamura et al. 1989, Guillibert et al. 1989, Cohn et al. 1990, Dunner et al. 1992) have been studied in this population. Few studies have looked at longer term results, although some studies have documented the usefulness of TCAs for the continuation (Reynolds 1992) and maintenance phases (Old Age Depression Interest Group 1993) of treatment. The SSRI paroxetine was also shown to be useful in a continuation study of depressed patients over the age of 70 (Reynolds et al. 2006). Several studies compare the use of different second- and third-generation agents in the elderly, including various combinations of fluoxetine, sertraline, paxetine, mirtazapine, bupropion, and venlafaxine. In general, most comparative studies show equal efficacy for different agents when used in the elderly.

Few studies have looked at antidepressants in the frail elderly. One controlled trial demonstrated the superiority of nortriptyline to placebo in very old and frail elderly patients (Katz et al. 1990); however, a significant percentage of the patients studied could not tolerate nortriptiline’s side effects. Another study compared venlafaxine with sertraline in frail elderly nursing home patients, and found that patients on venlafaxine had significantly more side effects and discontinuation rates (Oslin et al. 2003). The large number of patients lost to follow up limited the validity of this study.

Although these studies are promising, a number of elderly depression studies have not found antidepressant effects. One comprehensive review of antidepressant treatment in the elderly identified only 17 studies of sufficient methodological strength with a combined total of fewer than 2,000 patients. Of this group, 54% received SSRIs or placebo, 36% TCAs or placebo, and 8% received MAOIs or placebo. Pooled analysis found that each drug was superior to placebo; however, the effect sizes were often disappointingly low (Wilson et al. 2006).

In summary, it appears that antidepressants are effective in the elderly; however, there is a good deal less evidence in the elderly than in younger adult populations. An additional concern is that the elderly may have more difficulty tolerating these medications.

**Medically Ill Patients**

Few studies are available on the pharmacological treatment of depression in medically ill patients, and even less on medically ill elderly patients. At least one attempt at studying
this population was discontinued because of the difficulty in recruiting such unstable patients. Although it has been suggested that depression in the setting of medical disease (or “secondary” depression) is less responsive to antidepressants than “primary” depression, few studies exist to inform this suggestion. One systematic review published in 2003 found only 18 randomized controlled studies investigating antidepressant efficacy in depressed patients with comorbid medical illnesses (Gill and Hatcher, 2003). Until this is better understood, it seems ill advised to withhold treatment for depression because of comorbid medical illness. In initiating such treatment, the physician should understand the effects of various illnesses on pharmacokinetics and the potential side effects that may result.

**Cardiovascular Patients**

There is a high rate of depression in patients who have had a myocardial infarction, and the presence of depression adversely affects the prognosis of cardiac disease. It is important to appreciate this point, as a premorbid cardiac condition can cause concern about potential antidepressant side effects, which may delay the treatment of the depressed cardiac patient. Though some concerns may be justified, they must also be weighed against the potential morbidity from under treatment of depression in the cardiac patient.

**Tricyclic Antidepressants.** The major cardiovascular side effect of TCAs is orthostatic hypotension. This can be clinically significant in both the hypertensive patient and the elderly patient. TCAs can more than double the risk of hip fractures in these patients (Ray et al. 1987). Some of the TCAs have a lower risk of orthostatic hypotension, notably nortriptyline and doxepin.

TCAs do not show a negative inotropic effect and do not seem to worsen congestive heart failure. Patients with congestive heart failure may, however, be at a higher risk for orthostatic hypotension. Again, nortriptyline is the safest TCA in this case.

TCAs slow conduction at the bundle of His. Their effect is analogous to type 1A antiarrhythmic agents such as quinidine and procainamide. In therapeutic doses, they can slow cardiac conduction and in overdose they can cause atrioventricular blockade. These effects are of most concern in patients with preexisting cardiac conduction defects. The majority of research in this area has been done by Roose and Glassman (1989). They believe that the group at greatest risk for conduction defects from TCAs has either a bundle branch block (right or left), or a significant intraventricular conduction defect (QRS interval > 0.11 seconds). There is no evidence that any one TCA is safer than another.

Certain findings may further limit the role of TCAs in heart disease. A large multicenter study found that type 1A antiarrhythmics can increase the risk of mortality among patients with ventricular arrhythmias. Data also suggest that antiarrhythmic drugs cause increased mortality in atrial fibrillation as well (Glassman et al. 1993). As a result, Glassman et al. (1993) recommend caution when using TCAs in all patients with ischemic heart disease.

**Selective Serotonin Reuptake Inhibitors.** The SSRIs differ from the TCAs in that they do not prolong the PR or heart wave (QRS) interval. Thus, they probably lack any of the proarrhythmic and antiarrhythmic activities associated with TCAs. They do not cause orthostatic hypotension.

Several large-scale studies have investigated the safety and efficacy of SSRIs in cardiac patients. The Sertraline Antidepressant Heart Attack Randomized Trial (SADHART) tested the use of sertraline in 369 patients with acute myocardial infarctions or unstable angina (Glassman et al. 2002). They found that the antidepressant improved depressive symptoms in patients with severe depression, and found no adverse cardiac effects. The Canadian Cardiac Randomized Evaluation of Antidepressant and Psychotherapy Efficacy (CREATE) trial looked at a use of citalopram and interpersonal therapy in 284 patients with coronary heart disease, and found citalopram to be efficacious and safe in that population (Lesperance et al. 2007).

Such data are reassuring and suggest that SSRIs are likely safe in cardiac patients. What is needed next are large studies to determine whether treatment of depression improves the course of cardiac disease, as has often been suggested.

**Other Agents.** Trazodone has less proarrhythmic effect than the TCAs. However, there have been reports of trazodone-related ventricular ectopy and complete heart block (Mar- tyn et al. 1993). In patients with preexisting heart disease, bupropion does not appear to affect conduction, contractility, or orthostatic hypotension. It has rarely been reported to cause palpitations. Of most concern is that, when it is used as an antismoking agent in combination with a nicotine transdermal system, it can increase blood pressure as high as 6% (Khawaja and Feinstein 2003). Venlafaxine can rarely increase the QT interval and cause conduction defects. Its most common cardiac effect is an increase in blood pressure, which can be significant at higher doses (> 300 mg/ day). In one study, the mean diastolic increase was 7 mm of Hg after 6 weeks of treatment (Khawaja 2003). Duloxetine appears to have a similar effect as venlafaxine on blood pressure (Westanmo et al. 2005). Mirtazapine can rarely cause bradycardia and orthostatic hypotension, owing to its alpha-blocking activity.

**Poststroke Depression**

Three placebo-controlled studies of antidepressant treatment in patients who have had a cerebral vascular accident (CVA) have been published; all suggest that antidepressants are superior to placebo. Of interest is Robinson et al.’s (2000) study, which suggested that patients with CVAs preferentially responded to the TCA nortriptyline over the SSRI fluoxetine. Not all studies have confirmed this finding, and the results may in part reflect the original group assignments.

The question has also been raised whether antidepressants should be used to prevent poststroke depression. A review of 10 studies examining this question (Anderson et al. 2004) concluded that there were inadequate data to justify the preventive use of antidepressants.

**Cancer**

Although there is a good deal written about the need to treat depression in patients with cancer, there are surprisingly few studies of the pharmacotherapy of depressed patients with cancer. Of the randomized controlled studies that are available, two investigate mianserin (Van Heeringen...
and Zivkov 1996, Costa et al. 1985), one investigates the TCA imipramine (Evans et al. 1988), and one compares deserlin with fluoxetine (Holland et al. 1998). Among the SSRIs, paroxetine has been investigated in a randomized controlled study (Raison and Nemeroff, 2000), although many of the newer drugs have efficacy data from open trials and case studies. In general, all of the studies above conclude that antidepressants are safe and effective in cancer patients.

Renal Impairment
The interaction between renal impairment and TCAs is variable, with some studies reporting increased levels of TCAs in renally impaired patients and others reporting little change. Fluoxetine's, fluvoxamine's, and sertraline's blood levels are relatively unaffected by renal impairment. However, paroxetine's maximum plasma concentration was increased by 100–150% in subjects with renal disease (Rasmussen and Brosen 2000). Conclusions from these data are limited as they were all single dose studies, and all of these drugs have nonlinear pharmacokinetics. Hence, they may represent an underestimation of the effect of renal disease on drug levels.

Hepatic Impairment
Most antidepressants can cause liver abnormalities. For the TCAs, these abnormalities can range from benign aberrations in biochemical tests to potentially fatal complications, such as hepatitis and cholestasis. Most of the more severe effects are unpredictable and dose independent. As always, the potential morbidity of a depressive relapse—a likely event if effective antidepressant therapy is prematurely discontinued—must be weighed against the risk of precipitating such effects.

Also to be considered is the effect of hepatic disease on the medication. Liver disease can increase the levels of TCAs, and blood levels should be monitored. The literature suggests that the SSRIs are safe in patients with hepatic impairment, but, given their extensive liver metabolism, lower doses are required. In single dose studies, the elimination half-lives of all SSRIs were doubled in patients with cirrhosis (Rasmussen 2000). Though these higher levels may be safe in themselves, they, along with the hepatic impairment, can seriously affect drug–drug interactions in cirrhotic patients who are taking multiple medications. In practice, a one-half dose reduction in patients with cirrhosis is generally recommended by the manufacturers of each drug.

The pharmacokinetics of bupropion appears only minimally affected by alcoholic liver disease (Devane et al. 1990). There have been several reports of hepatic injury associated with trazodone, and one of trazodone-induced chronic active hepatitis in a patient with remote exposure to hepatitis B (Beck et al. 1993).

Given its association with hepatic injury, nefazodone is not recommended for patients with hepatic disease.

Endocrine Disorders
Patients who have an endocrine disorder predisposing them to depression (e.g., hypothyroidism or diabetic hypoglycemia) should first undergo medical stabilization of the disorder before attempting antidepressant treatment. To date, no large-scale trials of antidepressant treatment for depressed diabetic patients exist. Among controlled trials, there exist only two medication studies, one with nortriptyline (Lustman et al. 1997a) and one with fluoxetine (Lustman et al. 2000). Both studies show good effect in treating depression. There is also evidence that treatment of depression in patients with diabetes can improve their diabetic control (Lustman et al. 1997b). Though there has been some concern that antidepressants can cause hyperglycemia (particularly the TCAs), it has generally been shown that glycemic control improves with the use of antidepressants.

Iatrogenic Depression
The list of drugs purported to cause depression is large; however, one systematic review (Patten and Barbuib 2004) concluded that such drugs do not generally cause the symptoms of classic major depression. Several drugs can cause typical depressive symptoms, these include corticosteroids, interferon-alpha, interleukin-2, gonadotropin-releasing hormone agonists, mefloquine, progestin-releasing implanted contraceptives, and propranolol. In such cases, the most obvious first step is to try to remove the offending agent. However, at times a crucial drug has no practical substitute. An example of this is the concern over interferon-related drugs: the most common reason for discontinuation of interferon is the sudden onset of severe depression, often with suicidal ideation. In a randomized placebo-controlled study with 40 patients, Musselman et al. (2001) found that pretreatment with paroxetine reduced the emergence of interferon-alpha-induced depression in patients with malignant melanoma.

Suicidal Patients
Much concern was generated by a report of six cases documenting the emergence of sudden, violent suicidal ideation with the administration of fluoxetine (Teicher et al. 1990) and sertraline (Balon 1993). Previous reports of a theoretical relationship between serotonin and violence combined with this single uncontrolled series resulted in a wild speculation—particularly among the popular media and “antipsychiatry” groups—that fluoxetine was a “suicide pill.”

Though definitive data are lacking, more recent studies continue to raise concern about the relationship between antidepressants and suicide. Although actual mortality rates from suicide appear to be declining, meta-analyses of randomized controlled trials (Khan et al. 2003, Fergusson 2005) show small but significant associations between antidepressant use and suicidal behavior. One possible explanation of this apparent discrepancy is suggested in a study by Tiitonen et al. (2006) in Finland, who followed over 15,000 patients hospitalized in Finland through a national computerized database. They found that for those subjects who had ever used any antidepressant, the current use of an antidepressant was associated with an increased risk of suicide attempts, and yet a decreased risk of completed suicides.

Because of such studies, along with the previously noted concern over suicidal behaviors in child and adolescent patients, the FDA issued a public health advisory in June of 2005 warning of a possible risk of suicide in adults treated with antidepressants (Food and Drug Administration 2005). In December of 2006, after a further review of available data, an FDA advisory panel voted in favor
of updating “black box” warnings on antidepressants to state that there is an increased suicide risk for young adults up to age 25.

These concerns must be balanced over the well-proven and much greater risk of suicidal ideation and attempts when depression is not treated. Given this, and the propensity of suicidal patients to choose medication overdose as the method of suicide, the wide safety margin of the second- and third-generation antidepressants makes them preferable to first-generation agents when suicide is a concern. Bupropion has generally not been fatal in overdose, although about a third of such cases experience a seizure.

Starting Doses

First-Generation Antidepressants

Tricyclic Antidepressants

TCAs are usually begun at a relatively low dose. For the majority of TCAs, including imipramine, amitriptyline, desipramine, maprotiline, and doxepin, the initial starting dose is in the range of 50–75 mg/day. Notable exceptions include nortriptyline and protriptyline, which are more potent agents. In the case of nortriptyline, the usual starting dose is 25–50 mg/day, and for protriptyline, 10–15 mg/day. The lower doses are preferred in patients who are elderly. In the frail elderly, further dose reductions may be needed (about one-half or less of the usual starting dose).

Once a medication is initiated, it is gradually increased to a therapeutic level. A number of strategies have been suggested for this increase. Most TCAs can be increased to 150 mg/day by the second week, and then to a range of 300 mg/day by the third or fourth week. This can be achieved through small daily increase of 25 mg or weekly increase of 75 mg. Younger patients will tolerate larger and more rapid increases, whereas the elderly benefit from smaller (25 mg/day) and less frequent (every other day) increases with a lower target dose (150 mg/day).

Protriptyline is increased by 5–10 mg/week to a target dose of 60 mg/day. For nortriptyline, increases of 50 mg/week are usually tolerated in the young, with the elderly requiring smaller increases (25 mg/week). Of particular interest is nortriptyline’s therapeutic window: doses above and below a certain range appear to be less effective. The effective range is approximately 50–150 mg/day. Plasma blood monitoring (described later in this chapter) can aid in determining the proper level.

Monoamine Oxidase Inhibitors

Phenelzine is usually begun at a dose of 30 mg/day. It is increased by 15 mg after 3 days, then weekly to a target range of 45–90 mg/day. Tranylcypromine is started at 20 mg/day. It is increased by 10 mg after 3 days, with additional daily increases of 10 mg after 1 week, to a target range of 30–60 mg/day. Isoxparoxazid is usually begun at 20 mg/day. It is titrated in a manner similar to tranylcypromine to a target of 30 mg/day. Selegiline is administered as a transdermal patch: initial dose is 6 mg/day, and then increased to 9 mg/day after 2 weeks. The maximum dose is 12 mg/day (the patch is available in all three doses, and should not be cut).

Second-Generation Antidepressants

Selective Serotonin Reuptake Inhibitors

These agents are usually started at the lowest effective dose and increased as indicated by clinical response. Reasonable doses are 20 mg/day for fluoxetine, 50 mg/day for sertraline, 20 mg/day for paroxetine and citalopram, and 10 mg/day for escitalopram. For children, adolescents, the elderly, and patients who find medications generally difficult to tolerate, 50% reductions in these doses are reasonable starting doses.

For fluoxetine, paroxetine, and citalopram, the initial doses should be maintained for 1–2 weeks, after which they can be increased in 10 or 20 mg increments to a dose of 40 mg/day if there is no response. A maximum dose of 60 mg/day of fluoxetine is recommended for the treatment of depression. A similar strategy can be used for sertraline, which can be begun at 25–50 mg, and increased in 25–50 mg increments to a target dose of 50–150 mg. Escitalopram can be increased by 5 mg increments to a maximum of 20 mg/day. Other disorders, particularly OCD and bulimia nervosa, may require higher doses: for example, as high as 80 mg/day for fluoxetine.

As with TCAs, there is a significant delay between initiation of medication and response, and there is no reason to believe that increasing the dose prematurely hastens response.

Other Second-Generation Antidepressants

Trazodone is generally dosed in a manner similar to TCAs, with starting doses of 50–75 mg/day, and target ranges of 150–300 mg/day, with doses not exceeding 400 mg/day in outpatients and 600 mg/day in inpatients. Unlike many of the TCAs, trazodone’s short half-life requires divided doses, usually twice daily.

Bupropion, like trazodone, requires divided doses. It is available in a short acting form that requires three times a day dosing, an intermediate form that allows once-daily dosing, and a long acting form that allows once-daily dosing. The starting dose is 100–150 mg/day, and increased to a recommended dose of 300 mg/day; however, in patients not responding to that dose, it can be increased to 450 mg/day. If taking the immediate release preparation, patients should avoid taking more than 150 mg in a single dose. In the elderly, doses are usually begun at half that for adults, although full adult doses may be needed for effect.

Third-Generation Antidepressants

Venlafaxine

Originally available in a short acting form that required twice-daily dosing, it is currently available in a slow release preparation that enables once-daily dosing. Venlafaxine is usually begun at a dose of 37.5 mg and is increased within 1/2 to 1 week to a dose of 75 mg. If further increases are needed, it can be titrated at a rate of 75 mg every 4 days or more. Although a maximum dose of 225 mg per day is recommended by the manufacturer, doses as much as 300–450 mg/day have been employed to good effect in some patients.
**Mirtazapine**
Adults should be started on a dose of 15 mg/day. It is usually given as a before bedtime dose. The dosage generally needs to be increased in 15-mg intervals every 1/2 to 1 week to a target dose. The effective dose is usually between 15 and 45 mg/day; however, higher doses such as 60 mg have been useful in some patients.

**Nefazodone**
Nefazodone is given in twice-daily doses. Patients can be started at a dose of 100 mg twice daily and increased at a rate of 100–200 mg a week. The recommended effective dose is 300–600 mg/day.

**Duloxetine**
The recommended dose of duloxetine for major depressive disorder is 40–60 mg/day, given either once a day or in divided doses twice daily. Higher doses are used for diabetic neuropathy: from 60 mg/day to 60 mg twice a day.

**Therapeutic Drug Monitoring**
Although blood levels are available for many antidepressants, those for imipramine, desipramine, and nortriptyline have been best established. Imipramine and desipramine appear to have a curvilinear dose–response curve with an optimal range of 150–300 ng/mL. Nortriptyline appears to have a therapeutic window in the range of 50–150 ng/mL. These blood levels are nominal, as some patients do respond above or below these ranges, and blood level monitoring should not be a substitute for clinical observation.

Drug levels have not been well established for the MAOIs.

A review of therapeutic monitoring for SSRIs (Rasmussen et al. 2000) concluded that such monitoring is not clinically useful, as most studies have not found a correlation between plasma levels and clinical response. In addition, the studies have not shown a threshold level for toxic effects.

**Phases of Treatment**
Treatment can be divided into several phases. At each phase, the goals of treatment and the potential pitfalls differ. These phases are illustrated in Figure 101–12 and described below.

**Early, or Preresponse, Period**
Patients should initially be followed weekly to judge their response to treatment. The goal at this point is to manage the side effects of the various medications. Given realistic time and economic constraints, such contacts may at times be by telephone. However, it remains crucial that patients feel that they can communicate freely with their doctors regarding any side effects or other concerns about the medications. This is of great importance as such side effects are a primary reason for treatment nonadherence, and patients may be more inclined at this early phase to simply discontinue medications rather than to first discuss it with their physicians.

It can be difficult to persuade a depressed patient to remain on medication. Perhaps the greatest intervention at the disposal of the physician is reassurance. It is inevitable that patients will experience some side effects from their medications. Patients are able to tolerate this better when properly prepared. The patients may tolerate these side effects better when they are framed in a positive light—as a sign that the drug is present in their system.

The side effects can become intolerable, and reassurance may be inadequate. Several strategies for mitigating side effects can be considered. Many side effects are decreased or eliminated through dose reductions or changes in the dosing regimen. SSRIs, through scored capsules or liquid preparations, can be begun at one-half or one-fourth their normal starting dose in patients who are particularly sensitive to side effects. The TCAs, although often given in a single-daily dose, could be divided across the day to minimize dose-related side effects. Taking medications with food may decrease nausea. Although most physicians are aware that sedating medications should be taken in the evening, and activating ones in the morning, the patient may need these strategies reinforced. Flexibility is required as well; for example, a significant percentage of patients taking SSRIs experience sedation rather than insomnia, and this would warrant a change to evening dosing. However, the practice of starting the “less activating” SSRIs (such as paroxetine and citalopram) in the evening a priori seems unjustified as they still cause significant insomnia.

Failing these approaches, adjunctive agents may be employed to minimize the side effects. Anxiolytics can be added to treat the arousal and insomniac effects of the SSRIs. Although these adjunctive agents can be continued for the duration of treatment, discontinuation should be attempted after several weeks of treatment because many of the side effects may be limited to the early phase of treatment. The dry mouth caused by TCAs (and some newer agents) can be treated with saliva substitutes, although more mundane salivary stimulants such as sugar-free hard candy may be just as effective. Over-the-counter bulk-forming

**Figure 101–12 Phases of treatment.**
laxatives can treat the constipation caused by some agents (particularly TCAs but also seen with some newer agents). The cholinergic agonist bethanechol has been used to treat anticholinergic side effects, particularly urinary hesitancy and blurred vision. The usual adult dosage is 10–50 mg three to four times a day. Pilocarpine eye drops have been used to treat the blurred vision as well.

Intolerable side effects may warrant a change in medication. If side effects are the only reason for medication change, it is reasonable to choose a medication in the same class as the first, but with a different side effect profile. Anecdotal evidence suggests that patients can have variable reactions to different SSRIs despite their apparent similarity. For example, a patient who experiences significant anorgasmia with one SSRI may find little or no side effects with an equipotent dose of an alternative SSRI. The reasons for such an idiosyncratic response are not clear, but do encourage the physician to try to stay within a single class of drug if the initial response has been favorable. When switching from one SSRI to another, cross tapering is generally not necessary, as the substances are usually similar enough to prevent discontinuation syndromes, although occasionally patients will report discontinuation symptoms when switching; in such cases, a brief taper may be indicated.

**Response, or Acute Treatment, Period**

This period overlaps with the initial phase of treatment and continues until response is achieved, and usually lasts from 2 to 4 months. The goal during this phase is to control the acute symptoms of depression.

It is important to differentiate between partial and complete response. Complete response implies total recovery from all symptoms of depression, whereas a partial response is usually defined as a reduction in symptoms.

The time to response varies with the patient. Classically, it has been reported that patients will not show a significant response to antidepressants before 2 weeks, and often have to wait 3–6 weeks for a response. However, some recent data, based on meta-analyses of placebo-controlled trials have challenged this rule, finding that most patients show significant improvement within the first week, and then gradually continue to improve over 6 weeks (Taylor et al. 2006). This meta-analysis has been supported by other similar analyses and some prospective studies (Katz et al. 2006). If this is true, it will have enormous implications both for clinical practice, and for basic research into mood disorders (which has generally concentrated on the delayed effects of antidepressants as being the fundamental ones).

For patients who complete a satisfactory treatment regimen, the response rate for antidepressants is about 60–70% (American Psychiatric Association 2000b), although some of these responses will be partial. Response rates may be as high as 80% with antidepressants when an adequate dose is given for an adequate time.

Changes in treatment strategy should be considered after the physician is satisfied that the patient has been treated with an adequate dosage of the antidepressant for an adequate time. The American Psychiatric Association (2000b) recommends waiting at least 4 and as much as 8 weeks before changing a treatment strategy. For the patient showing inadequate response, these medications are increased to the limit of side effect tolerance before attempting a new strategy.

In patients showing an inadequate response after a reasonable time, the physician may decide whether to continue with the same medication and augment with an additional agent, or to switch medications altogether. This decision depends on an assessment of whether the patient has shown any response to the current strategy. Partial responders may be more likely to benefit from treatment augmentations, whereas patients who show no response or worsen during treatment warrant a new agent.

**Strategies for No or Inadequate Response**

There are several approaches to an incomplete or nonresponse. These include maximizing current treatment, augmenting the treatment, or switching to an alternative agent. These strategies are discussed in more detail in the Section “Treatment Failure.”

**Continuation Period**

This period usually lasts 5–8 months after the end of the acute treatment period. The goal at this phase is the prevention of relapse. There is a high risk of relapse if treatment is discontinued after the acute treatment phase. Keller et al. (1982) found that the two best predictors of relapse were a high number of previous depressive episodes (greater than 3 predicted relapses) and underlying dysthymic disorder.

Once a patient has responded to a medication, the medication should be continued for a minimum of 4–6 months, beginning from the point of initial response. The World Health Organization (1989) recommended 6 months as a minimum period for continuation of treatment after the acute phase, and the American Psychiatric Association (2000b) recommended a minimum of 16–20 weeks of treatment following the full remission of symptoms. This period should be lengthened for the patient with a history of longer depressive episodes.

Few studies exist that look at the efficacy of antidepressants for continuation therapy. However, there exists at least one placebo-controlled study for each of the SSRIs (Montgomery et al. 1988, 1993, Montgomery and Dunbar 1993, Doogan and Caillard 1992), nefazodone (Feiger et al. 1999), mirtazapine (Montgomery et al. 1998) venlafaxine (Nemeroff et al. 2002), and duloxetine (Perahia et al. 2006). These studies are summarized in Table 101–4.

In the past, it was suggested that, on achievement of euthymia, doses could be reduced. However, it is more likely that levels similar to those needed at the acute stage of treatment will be required throughout the continuation period.

**Discontinuance of Treatment**

After the continuation period, somatic therapy is usually discontinued in the patient with a single episode of major depression. Before discontinuing, however, it is important to remember that depression is often a lifelong disease with a chronic course. One should always weigh the benefits of discontinuance against the risks of recurrent depression.

In the past, a distinction between exogenous and endogenous depression was used to predict the risk of recurrence. Inferences about etiology, however, are not an accurate predictor of recurrence. More useful information is the age of onset during the initial episode and the number of episodes. Patients with a single episode of acute depression,

Tapering and Withdrawal

For the TCAs, the usual strategy is to taper the medications at a rate of 25–50 mg/day every 2–3 days. Too rapid a discontinuation may produce symptoms of cholinergic “rebound” or supersensitivity. Such a rebound includes severe gastrointestinal symptoms (nausea, vomiting, and cramping), other signs of autonomic hyperactivity (diaphoresis, anxiety, agitation, headaches), and insomnia (often with vivid nightmares). In severe cases, a full delirium may result. Cholinergic rebound may occur as early as 48 hours or as late as 2 weeks after discontinuation. These symptoms may account for some cases of presumed early relapse from antidepressant discontinuation.

MAOIs may also have a withdrawal syndrome, including symptoms of psychosis, on abrupt withdrawal; however, this syndrome is rarer than that seen with TCAs.

Fluoxetine has a long half-life, and abrupt discontinuation should be permissible. Sertraline, citalopram, paroxetine, and escitalopram, with shorter half-lives of around 1 day, may require several weeks to taper. With the shorter acting agents, a withdrawal syndrome including symptoms of fatigue, insomnia, abdominal distress, and influenza-like symptoms has been reported when they are too abruptly discontinued.

Venlafaxine and duloxetine have both been reported to have discontinuation symptoms; venlafaxine with its shorter half-life appears to have the most severe version. The symptoms are similar to SSRI discontinuation, but may include symptoms of an anticholinergic rebound as well, particularly if the patient was receiving high doses of the medication.

On discontinuance, the goal is to enable early intervention should symptoms recur. A first episode of depression has a high risk of recurrence, and the risk of recurrence is even higher in patients who show only partial response to medication. The patient should be educated to recognize symptoms of depression. The patient’s own history suggests which symptoms were prodromal to the patient’s full depressive episode.

Maintenance Period

The goal of the maintenance period is to prevent the recurrence of depression. There are a number of reasons to consider long-term prophylactic therapy for depression rather than medication withdrawal. Depression is a lifelong disease, with recurrence being the norm rather than the exception (Keller and Boland, 1998). As the number of acute episodes increases, the risk of future episodes increases as well, and the interval between episodes shortens. Each subsequent episode carries a higher morbidity and disability.

A number of factors can influence the decision of when it is appropriate to maintain long-term prophylaxis for depression. The seriousness of previous episodes, the severity of impairment caused by such episodes, the degree of response to previous treatments, and the ability of the patient to tolerate the drug all play a role. Central in the decision process is the concept of recurrent depression that some patients are more likely than others to have a recurrence of the disease. Three previous episodes of depression make recurrent depression likely. The best predictors of the likelihood of recurrence appear to be older age of onset and number of episodes. Greden (1993) proposed that long-term maintenance is the treatment of choice for the following groups of patients: (1) those who were at least 50 years old at the time of the first depressive episode, (2) those who were at least 40 years old at first episode and had at least one subsequent recurrence, and (3) anyone who had more than three episodes.

The recommended length of maintenance treatment needs further clarification as well. Recommended lengths of time vary from 5 years of treatment to indefinite continuation. There are only a handful of studies on maintenance antidepressant treatment. One study (Prien et al. 1984) compared patients successfully treated for acute major depression, who were then randomized to a medication or placebo group for 2 years. The imipramine groups (with and without lithium) had the longest time until a recurrence, with the lithium group having an intermediate time until recovery. A second study (Kupfer et al. 1992), the longest of any such study, compared medication (imipramine) with and without psychotherapy to placebo, for 3 years, with a continuation of 2 years for a subset of the group for a total of up to 5 years. This study provided strong evidence for the efficacy of antidepressant medication: by the end of 3 years, most of the placebo group had relapsed, whereas a substantial portion of those patients on imipramine (about 80%) remained well. In the 2-year extension of the study, those patients who have an onset before age 50 years, are the best candidates for discontinuance (Greden 1993).
who had remained well were randomized to imipramine or placebo, and, again, most of the patients on placebo had a recurrence of depression, whereas the majority of those on medication did not.

A more recent study looked at the use of venlafaxine in patients with recurrent depression. Subjects who continued to be treatment responders after 10 weeks of acute treatment and 6 months of continuation treatment were randomly assigned to receive either venlafaxine extended release or a placebo. After 1 year of maintenance treatment, it was found that the placebo group was twice as likely to have a recurrence of major depression as the venlafaxine-treated group (Kocsis et al. 2007).

These studies were in patients with recurrent depression. Another indication for maintenance treatment is for patients with chronic depression. Again, few studies have looked at this population for a sufficient time, but what studies exist do support the efficacy of antidepressants in this population. One such study compared sertraline with placebo for maintenance treatment of depression (Keller et al. 1998), and found that the placebo group was four times more likely to have a recurrence than the medication group.

Regarding choice of an agent, there are no rigorous studies comparing different antidepressants during the maintenance period. It is usually assumed that the same agent used in the acute and continuation period will be the preferred one in the maintenance period.

Summary
Despite limitations in data, it is reasonable to believe that most agents used for the acute treatment of depression are also effective for long-term treatment of depression.

Equally important in preventing recurrence of depression is the problem of maintaining adherence to medication long after the acute episode has resolved. Proper education and support will help with compliance. Tolerance of side effects is important and evidence suggests that patients are more likely to comply with the agents that have more favorable side effect profiles. The SSRIs are generally the best tolerated antidepressants.

Although lower doses for prophylaxis have been recommended, there are few data to support this contention. Even though lower doses may increase compliance, full doses should be used until new information indicates otherwise.

Outcome Assessment
The results of a treatment are simplest to judge when the treatment focuses on clear goals. At the time of initiating pharmacotherapy for depression, the physician should document what particular symptoms justify a diagnosis of depression. The outcome of treatment can then be judged against these symptoms. Often a patient will report still feeling “depressed” and yet show observable symptom improvement.

Although clinical judgment remains the mainstay of treatment assessment, this judgment can be reinforced with a number of well-validated scales. These scales can be either interviewer-rated or self-rated scales. Some scales are more (or less) reliable in certain groups, such as the aged, or the medically ill.

Clinic-Rated Scales
Perhaps the most widely used scale is the Hamilton Depression Rating Scale (HAM-D) (Hamilton 1960); a clinician-rated scale that requires some training to be performed properly. The Montgomery–Asberg Depression Rating Scale (MADRS) (Montgomery and Asberg 1979) has good interrater reliability and high validity for severity. It shows high sensitivity to change, which would be useful in monitoring the progress of treatment, and it appears useful in patients with comorbid somatic illnesses.

Self-Rated Scales
Self-rated scales can be easier to use and less time intensive—a patient can be filling them out while waiting for an appointment; however, they are generally less reliable than clinician-rated scales. Self-rated scales include the Beck Depression Inventory (BDI) (Beck 1978) and the Zung Depression Scale (Zung 1965). These scales, which test for a number of somatic symptoms of depression, may be less reliable in medically ill or elderly populations. The Geriatric Depression Scale (GDS) (Yesavage et al. 1983), a self-report questionnaire, is specifically intended for initial screening in the elderly. Such scales have largely been avoided in clinical practice because of added time and relative impracticality of such scales. However, the wider acceptance of computer-assisted devices, particularly palm held personal assistant devices could make such scales practical.

Treatment Failure
Failure to respond to treatment is most often due to inadequate treatment rather than “true” nonresponse. Inadequate treatment can be due to an inadequate length of treatment or an inadequate dose. These can result from the physician’s error (either improper dosing strategies or impatience in waiting an appropriate amount of time) or the patient’s error (through misunderstanding or nonadherence).

Patients may not report these errors as they fear rejection from treatment, and they certainly are unlikely to admit to it if their physician does not ask them. The best remedy for nonadherence is prevention, through proper education of the patient about likely side effects that might otherwise unnerve the patient. A flexible approach is also necessary. Gentle reassurance and encouragement can be helpful; however, dogmatic insistence on adherence to a prescription leaves the patient with no choice except to hide nonadherence, or look elsewhere for treatment.

Thus, “true” nonresponse can be defined as the lack of response to an adequate dose for an adequate time. In the case of such failure, a number of issues should be examined.

Diagnostic Issues
The physician should consider the patient’s previous medical conditions. A number of medical conditions can cause some depressive symptoms without actually causing depression. In such cases, the symptoms are unlikely to abate with treatment of the primary disorder. Similarly, many of these other diagnoses may respond to antidepressants; however, this is not always the case, and therapy targeted at the alternative disorder may be preferable.
Psychotic Depression
The physician should also consider whether the patient has a type of depression that would predict a poor response. Psychotic depression is an example of a condition less likely to respond to antidepressants alone. Psychotic depression is usually treated with either combination pharmacotherapy (an antidepressant and an antipsychotic) or electroconvulsive therapy.

Strategies for Treatment-Resistant Patients
In most cases, there should be some response by 3–4 weeks. When patients report a partial response, the treatment may simply be to wait and follow the response; as long as there remains evidence of gradual improvement, no further intervention is necessary.

In cases in which little or no response is seen, a new trial of an alternative agent should be considered. It is generally believed that the best strategy is to change to an alternative class of agent. However, in the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) trial, the particular type of switch did not seem to affect the remission rates: changing from one SSR1 to another had the same rate as a change to venlafaxine or bupropion (Rush et al. 2006). The study also suggested that a switch after a first treatment failure makes sense; however, the remission rates for single agent strategies decline significantly after two treatment failures—at that point augmentation or combination strategies should be considered.

Treatment Augmentation
For a partial response, with no sign of continued improvement, treatment augmentation can be of benefit. Possible augmentation strategies include lithium augmentation, thyroid hormone augmentation, stimulant augmentation, and the use of a second antidepressant.

Lithium Augmentation
Lithium augmentation has the best evidence as an augmentation strategy. It is generally begun in low doses (300 mg twice a day) and increased to a therapeutic blood level (0.6–1.3 mEq/L). It can take about 3–6 weeks for a response.

Thyroid Hormone
Thyroid hormone supplementation can be helpful, even in cases in which the patient is clearly euthyroid. It is usually begun at 25 μg/day of triiodothyronine, and increased to 50 μg/day if needed, and can take at least 3 weeks to show an effect. In the STAR*D trial, T3 augmentation appeared to be as helpful as lithium, and it was better tolerated (Nierenberg et al. 2006).

Stimulants
Among the stimulants, methylphenidate and dextroamphetamine have been used successfully, and there are some preliminary data supporting the use of newer agents such as modafinil to potentiate antidepressant response.

Atypical Antipsychotics
Atypical antipsychotics have also been shown useful for augmentation: one study demonstrated that olanzapine combined with fluoxetine had greater efficacy than either agent did alone in treatment-resistant patients (Shelton et al. 2001).

Combining Antidepressants
A common clinical practice is to combine antidepressants in different classes in the hope of augmenting response by combining effects. The support for this practice is limited, and mostly limited to case studies, case series, and open studies (Rojo et al. 2005). However, the data are promising. As noted earlier, the STAR*D study included an arm using combined venlafaxine and mirtazapine for patients who had failed three previous single antidepressant trials (McGrath et al. 2006). Remission rates were modest (~14%) but encouraging for this group as this was a highly treatment-resistant group of patients.

Psychotherapy
The use of nonpharmacological augmentation should be considered as well, and any patient showing an inadequate response to medication alone should be considered for psychotherapy. A large number of studies have supported the use of combination psychotherapy and medication for depression, and in some cases the combined effect is dramatically better than medication or therapy alone (Keller et al. 2000).

Electroconvulsive therapy (ECT)
ECT remains a safe and effective nonpharmacological treatment. Indications for ECT include a history of poor response to medication, a prior good response to ECT, a need for rapid response (as with life-threatening depressive symptoms, e.g., food refusal or suicide attempts), psychotic depression or a medical contraindication to antidepressants.

Other Somatic Therapies
A number of other nonpharmacological somatic therapies show promising preliminary results, including transcranial magnetic stimulation, vagal nerve stimulation, and deep brain stimulation, and these may offer additional alternatives for the treatment-resistant patient.

Strategies for treatment-refractory patients are summarized in Table 101–5.

Conclusions
There remain a number of important limitations regarding the pharmacotherapy of depression. Some of these limitations can be addressed by continued progress on current research. Other limitations await truly novel research into the mechanism of depression.

Recommendations for the Use of Antidepressants
Allowing for the many limitations, one can generalize from available data to make the following recommendations:

1. All patients with acute major depression should be considered reasonable candidates for pharmacotherapy.
2. There is adequate evidence to make the same recommendation for other forms of depression. This is particularly true for dysthymia, and may be true for other minor forms of depression as well.

3. There is good evidence for the use of antidepressants for nonmood disorders as well, particularly the anxiety disorders.

4. There remains no strong evidence from choosing one medication over another, and treatment recommendations should be made based on tolerability and, if appropriate, cost.

5. Extended treatment should be recommended both for patients with chronic depression and recurrent depression.

7. The exact length of maintenance treatment is not known. The decision for indefinite treatment should be a risk–benefit decision, made with the informed consent of the patient, who is entitled to be informed of the limitations in our knowledge.

Future Pharmacotherapies

A number of potential antidepressants are in various stages of development. Any listing of such compounds is likely to change rapidly and likely to be obsolete by the time this chapter is published: as little as 5 in 5,000 compounds that enter preclinical testing ever make it to human testing, and only 1 of these 5 is approved for sale. This list, however, does provide some insight into what types of drugs one can expect to see in the next decade.

Variations on Current Themes

Many of the new drugs will be similar to current drugs. Some will be directly based on currently available drugs (e.g., desvenlafaxine). Others will be novel chemicals that potentiate norepinephrine or serotonin. As an example, the drug Lu AA21004, is a novel compound (a bis-aryl-sulphinyl amine). Although it is the first of a new class of drug, it appears to be another approach to serotonin agonism, having action both on serotonin receptors and on the transporter molecule. Some drugs of these types that are currently in development are listed in Table 101–6.

Drugs Targeting Substance P

Substance P, a neuropeptide, is an agonist of neuropeptide-1 (NK-1) receptors in the CNS. Substance P is released in response to fear, and the NK-1 receptor is found in high concentrations along the brain's anxiety circuitry. In animal models, administration of substance P agonists can produce fearful and defensive behaviors. In humans, the administration of NK-1 receptor antagonists shows anxiolytic and antidepressants effects. The substance P agonist MK-869 showed comparable efficacy to paroxetine in a trial of patients with major depressive disorder and moderate anxiety (Kramer et al. 1998). Most significantly, the drug did not appear to interact with monoamine systems in a way typical of standard antidepressants, suggesting a novel mechanism of action. This is supported by basic research that shows increased levels of substance P in cerebrospinal fluid, and changes in those levels in response to acute stress (Geraciotti et al. 2006). Though the initial enthusiasm was dampened by some disappointing results in subsequent pharmaceutical trials, a number of NK antagonists remain in development and are listed in Table 101–6.

Drugs Targeting the HPA Axis

Investigators have looked at the role of endocrine hormones in affecting depression. This is a reasonable inquiry given the long appreciated finding of hypothalamic–pituitary–adrenal axis dysfunction in depressed patients. The HPA axis is intimately involved in the stress response. The majority of patients with depression demonstrate hyperactivity of the HPA axis, leading to increased production of corticotrophin-releasing factor (CRF) by the paraventricular nucleus of the hypothalamus. This results in reduced feedback inhibition by CRF and glucocorticoids (which is the basis of the dexamethasone suppression test). Normalization of the normal functioning of the HPA axis appears to be necessary for successful treatment of depression. Strategies at decreasing the hypercortisolemia in such cases have led to investigations with a variety of cortisol-lowering agents, including ketoconazole, metyrapone, and aminogluthethimide (Zoumakis et al. 2006), which have all had preliminary success in depressed patients, but have been limited by side effects. A preliminary open study of the CRF r-1 antagonist r-121919 showed promise as well, but the drug has been withdrawn because of potential liver toxicity (Zobel et al. 2000). Glucocorticoid antagonists can mitigate the effects of hypercortisolemia, and the agent RU486 (Murphy et al. 1993) has shown promising preliminary results. Vasopressin (VP) can also regulate the HPA axis in that stress can release VP, which then potentiates CRF. A number of CRF and glucocorticoid antagonists and at least one VP receptor antagonists are currently under development and are listed in Table 101–6.

**Drugs Targeting Glutamate**

Glutamate serves a general excitatory role in the brain, and both glutamate and glutamate receptors (e.g., NMDA) are assumed to play a central role in the expression of psychiatric illness. That NMDA antagonists may be useful in depression is supported by the observation that ketamine can rapidly improve mood in depressed individuals undergoing surgery (Goforth and Holsinger 2007). In addition, basic research suggests that treatment with antidepressants down regulate NMDA receptors. Direct NMDA antagonists are limited by their psychiatric side effects; however, weaker antagonists are being investigated. Clinical trials with such agents as memantine have had only modest effect to date (Zarate et al. 2006). Agents with a direct effect on glutamate receptors are under development. Examples of drugs targeting glutamate are listed in Table 101–6.

**Drugs Targeting Hypothalamic Feeding Peptides**

A number of the hypothalamic peptides that have a role in feeding behavior also appear to have a role in depression. For example, melanin-concentrating hormone (MCH) stimulates feeding behavior; blockade of the MCH receptor seemed to be mediated by BDNF. Depressed patients appear to have decreased levels of BDNF; infusion of BDNF (in rodents) appears to cause depression, and blockade decreases depressive behaviors (Kalueff et al. 2006). However, a variety of practical and theoretical obstacles (the size of the molecule, its multiple roles in various pathways) make direct antagonism of BDNF both difficult and potentially dangerous. Some indirect approaches may be more practical, for example, phosphodiesterases (PDEs) induce BDNF expression in the hippocampus. Agents targeting PDE have been limited by nausea (due to PDE inhibition in the brainstem); however, an attempt continues to find agents that may act preferentially in the hippocampus. Currently, to the best of our knowledge, no drugs using this mechanism have reached the stage of clinical trials.
can produce an antidepressant-like effect in rodents (evidenced by the forced swimming test) (Georgescu et al. 2005). Several other peptides involved in feeding behavior may have a role in depression, including the appetite-stimulating peptides orexin (hypocretin), neuropeptide Y (NPY), and agouti-related peptide (ARP), as well as appetite suppressant peptides, such as melanocortin, cocaine- and amphetamine-regulated transcript (CART), and CRF. The fact that peptides that both stimulate and suppress appetite can be helpful offers a potential clue to the different natures of classical and atypical depression. Examples of drugs targeting these peptides are listed in Table 101–6.

Other Lines of Development

YKP-10A, a phenylalanine derivative, is presumably being tested because of phenylalanine’s inhibitory relationship with tryptophan. Miraxion (LAX-101), a purified form of omega-3 found in fish, seems to act as a neuroprotectant. Although current data refute early hope that it may have a role in cancer prevention, some preliminary work suggests that it is useful in a number of psychiatry disorders, including major depression (Su et al. 2003).

Whether any of these particular approaches will become part of psychiatry’s clinical armamentarium is too early to say. Clearly, there is a great motivation for pharmaceutical companies to develop novel products, as it is predicted that by 2010 the many patent expirations will decrease pharmaceutical profits from antidepressants by at least 50%. Such financial predictions should not be the direct concern of the psychiatrist. It is acknowledged, however, that the considerable economic benefits reaped from contemporary antidepressants should provide a strong practical incentive for drug developers to be on the forefront of the next generations of antidepressants.

For the psychiatrist, the promise of new and different approaches to treating depression is exciting. Until recently, research into antidepressants has informed research in depression. In the future, the reverse will have to be true: in order to develop better antidepressants, researchers will have to understand the pathophysiology of depression. With the new investigatory tools available, such discoveries seem right around the corner.

Clinical Vignette

Ms. W was a 34-year-old married woman who began having depressive symptoms approximately 8 months before presented to a psychiatrist. Initially, she began to notice intense fatigue, weakness, and dizziness, to the point where she was spending a good deal of time in bed. Her primary care doctor tested her for a variety of possible medical disorders, with no abnormalities found. When he suggested an emotional disorder, she initially was reluctant; feeling convinced that her symptoms had to be medical in nature. As further months saw only worsening symptoms, she eventually agreed to psychiatric consultation.

At the time of her first psychiatric evaluation, her main complaint was of insomnia. She described herself as being constantly “on edge” during the day, often exhausted by the end of it, falling asleep briefly in the early evening, but then waking up around 3 a.m., and being unable to fall back asleep. On further discussion, she admitted feeling “miserable” all the time, frequently broke into tears “for no reason.” She had no interest in activities, and took no pleasure in anything. She also felt extremely guilty, particularly in her inability to be a mother to her 2-year-old child or a wife to her husband. In the latter case, she reported that her husband was perplexed by her emotions, but was very kind toward her, despite the fact that she frequently took out the bulk of her angry outbursts on him. In the context of her guilt, she had fleeting thoughts that her family would be better off without her, and her fantasies ranged from leaving her husband to suicide.

The diagnosis of depression was again suggested to the patient. She again had difficulty believing this diagnosis, as she saw her physical symptoms as primary. She felt that if she could only “get a decent night’s sleep” she would not be so tired, and perhaps would feel better. Antidepressant medication was discussed at that time, but she declined a trial. The agreement was made to continue meeting and discussing this further. In the interim, she approached her family doctor, and received medication for sleep (temazepam). After 2 weeks of continued misery (despite relatively good sleep) she again met with her psychiatrist. Now desperate, she reluctantly agreed to an antidepressant trial. Various options were discussed with her, and she was clearly very fearful of any medication for which anxiety might be a potential side effect. Eventually, she and her psychiatrist agreed on paroxetine (the patient had seen a television commercial that had convinced her that this medication would be preferable for anxiety). She was prescribed 20 mg/day, taking in the morning.

After 2 days, she called her psychiatrist, saying that the drug was making her mouth dry, and was making her feel tired during most of the day. She worried that this drug was going to turn her “into a zombie” and wondered whether she should stop it. She was encouraged to continue the medication, and her psychiatrist suggested that she should switch to evening dosing to decrease the apparent daytime sedation. She did so, but called again several days later, saying that she felt that the drug was making it hard for her to wake up in the morning. Again she suggested giving up, but was encouraged instead to halve the dose. When she next met with her psychiatrist, she had been on the drug for 2 weeks. At that time, the side effects seemed to have partially abated. She was discouraged all the same, as her symptoms were largely unchanged. She questioned whether this was the proper drug, and indeed whether she had been diagnosed properly. Various approaches were employed over the next few weeks. Continued education regarding the likely course of treatment was provided. The psychiatrist empathized with her frustration over what seemed a painstakingly slow trial, and gave a somewhat paternal reassurance that he had treated many patients like her. He also reassured her that her impressions were not unusual or a cause for further worry. Frequent reinforcement of these approaches was sufficient to convince the patient to continue the medication trial.

Over the next 2 weeks, the patient felt that there might have been some small improvement. She was somewhat less anxious during the days, and when asked, she admitted that she was crying less. She remained disappointed; however, her most troubling symptoms (the fatigue, weakness, and insomnia) remained, and she still reported her mood as being depressed (a word she was now more comfortably using). Her psychiatrist continued attempting to supply her with the enthusiasm she lacked, explaining that this

(continues)
response at 4 weeks of treatment was a very positive sign. She agreed to a dose increase of 20 mg/day. The patient then gradually improved over the next few weeks, and within 12 weeks of beginning treatment she could declare herself to be at her baseline. In some ways, she felt that she might even be “improved” from her baseline, saying that she was more assertive with friends and relatives than she was used to being, and would seem euphoric at times. She had more energy than she was used to, and she wondered at times if she was becoming “manic,” having heard that this could happen with antidepressants. On further questioning, however, her symptoms suggested nothing more than euthymia.

Soon after she improved, she began to suggest discontinuing medication. She admitted that she felt ashamed that she was taking psychiatric medication, and feared that her friends or relatives might discover what she was doing. The high risk of relapse at this early period was explained to her, and reasons for continuing medication during the asymptomatic period were reviewed with her. Though she agreed to continue, several weeks later she guiltily admitted that she instead discontinued her medication for 3 days, only to restart after feeling what she interpreted to be a relapse. The psychiatrist admitted that time course of her “relapse” combined with her description of the symptoms as “flu-like” made a withdrawal syndrome more likely than a relapse; however, this event was enough to convince her to remain on the medications for the full course.

Some symptoms remained during this period. Although she was largely euthymic, she admitted to continuing dissatisfaction with areas of her life, and she often reported a general sense of a lack of purpose or direction in her life. Similar dissatisfaction was reported when she discussed her marriage, though she now had great satisfaction in her role as a mother. Though psychotherapy had been suggested since the beginning of treatment, she had been even more opposed to it than she was toward medication. Now, she tentatively agreed to meet with a therapist to discuss some of these issues.

As the months passed, the patient’s initial dislike for medication changed into more of an ambivalence. Though the patient still voiced wishes to be off medication, she also admitted that she was becoming apprehensive about discontinuing it. After 9 months of medication treatment, she met with her psychiatrist to discuss future options. Though she continued to feel that her episode of depression was her first, she was not as sure whether she had been entirely well before her acute episode. She noted some longstanding, though less dramatic, feelings of pessimism and sadness before taking antidepressants. She had never considered these feelings abnormal until encountering their absence. Despite these concerns, she chose to discontinue her antidepressants, a decision that seemed reasonable to her psychiatrist as well. She again felt some symptoms of withdrawal as the medication was lowered and discontinued; however, these improved over the course of a week.

Four weeks after her discontinuation, she remained well and hopeful that she would not need medication. However, by 2 months she was beginning to notice some returning symptoms. Though she did not experience the dramatic anxiety, dysphoria, and neurovegetative symptoms that first brought her into treatment, she began to feel increasingly “moody,” irritable, and apathetic. Her husband noticed this as well, and though he originally had been skeptical of her need for antidepressants, he now began questioning her decision to discontinue them. After one particularly angry incident, in which she began inappropriately yelling at her child, she called her psychiatrist, asking to be put back on her medication. This was done, and she again responded after about 4 weeks of treatment.

In discussions with her psychiatrist now, she became despondent, wondering whether this meant that she would have to remain on medication for the rest of her life. It was admitted that this might be a possibility, particularly as many of her symptoms during the current episode seemed similar to her reported “usual state” before treatment. However, there remained the possibility that the patient had been discontinued too early from medication, and that the current symptoms represented a late relapse of the original episode. It was agreed to continue medication for a minimum of 6 months before again entertaining the idea of a discontinuation.

Though somewhat more resigned to this second period of pharmacotherapy, Ms. W became more critical of the particular medication she was taking. Initially fearful that people would discover she was on medication, she eventually was surprised to find that several of her family and friends were also taking antidepressants. The subsequent exchange of anecdotes left her curious as to whether she was on the best agent. She began to wonder whether some of the weight gain she had experienced (perhaps 5 pounds over the last year) was due to the paroxetine. An even greater complaint became apparent after a discussion between the psychiatrist and the patient’s therapist, in which the therapist felt that Ms. W was minimizing her sexual problems, and that this might be an important influence on her frequent requests for the discontinuation of medication. Previously, Ms. W had rarely voiced any sexual side effects to her psychiatrist, and when asked would relate any such problems to her ongoing marital tensions. At this time, a more detailed sexual discussion led to the admission that Ms. W had been largely anorgasmic for the entire time that she had been on the paroxetine. Though she said that she preferred this side effect to a return of her depression, it was clear that the effect was troubling both her and her husband.

Various approaches were taken to improving this side effect. Lowering the dose from 20 to 10 mg/day gave only minor improvement, and she felt that she had some increase in irritability at this lower dose. Adjunctive medications had little effect and were contrary to the patient’s reluctance to take medication. Eventually, the decision was made to switch the patient to an alternative medication. As the patient had had a good response to paroxetine, it was agreed that an alternative medication with serotonin reuptake properties would be chosen. However, trials of sertraline and venlafaxine were not successful in decreasing these side effects, and the patient felt that her response to these other medications was less robust than it has been to paroxetine. Paroxetine was eventually restarted. The psychiatrist discussed the possibility of using alternative classes of medication. After these two unsatisfactory trials, however, the patient feared any further changes.

After approximately 2 years of treatment, a second discontinuation was discussed. At this point, the patient was even more reluctant to discontinue, having enjoyed mood stability over most of this period; however, the continuing side effects of anorgasmsia and, perhaps, continued weight gain convinced her to try again. This was done, and within 2 weeks after discontinuation she reported normal sexual functioning. She continued to complain of difficulty losing weight, but as her weight seemed to be normal throughout...
the 2 years of treatment, the validity of her concerns was difficult to assess. Within 2 months of her discontinuation trial, she again relapsed. Again, her symptoms were minor, consisting of irritability and dysphoria. However, there was a clear change from her state on medication. At this time, the possibility of long-term maintenance was discussed with the patient. Frustrated with yet another relapse, she readily agreed; however, she remained concerned by side effects. Bupropion was suggested as an alternative that has relatively few sexual side effects. Within a month she was taking 150 mg twice daily of the slow release capsule. As was hoped, she did not report any sexual side effect. She did report an antidepressant response to the drug; however, she felt that the response was not as complete as that she had had on paroxetine. Although she was less dysphoric, she had somewhat greater anxiety and irritability with the bupropion.

After a trial of over several months, her psychiatrist suggested combination therapy. It was suggested that the bupropion be continued, but that a small dose of an SSRI be added in the hope that it would address some of these remaining symptoms. Experiences with medication were reviewed, and the patient felt that, of the SSRIIs tried, citalopram had had the least sexual side effects, and the closest efficacy to paroxetine. With that in mind, citalopram was begun at a dose of 10 mg/day, and with this combination the patient reported complete response with no return of her previous side effects.

Case Discussion
Many lessons can be drawn from the above case. Perhaps the most important is that medication management is not a mechanical discipline that can be diagrammed with simple algorithms. All of the skills learned in psychiatric training, both psychopharmacological and psychotherapeutic, are crucial for successful treatment of the patient. In the initial phases of this treatment, the emphasis was on fostering a trusting relationship in a skeptical and fearful patient. This effort translates into a great deal of time spent, both in person and on the telephone. Although, superficially, one might argue against the justification for so much contact during a period when the medication is unlikely to show any benefit, the effort applied was probably the most important intervention during the treatment. Not only was such an effort helpful in fostering adherence during this period, but also it made the negotiation of later challenges much simpler. In the beginning, the psychiatrist had to assume a paternal role, taking on most of the responsibility for the treatment. As the patient improved, this gradually gave way to a much more collaborative effort.

The importance of ongoing education should also be emphasized. Many, if not most, patients who present to a psychiatrist have seen another doctor before this. Education, however, is an ongoing process. Often the bulk of the information is given at the initial phases of treatment—a time when the patients’ illness makes them least able to integrate this knowledge. Throughout the treatment, the psychiatrist often had to review and reinforce the treatment strategies discussed originally. Though written material can aid this process, and the patient clearly sought external sources of information, there remains no substitute for educational power in the human interaction.

The inappropriate minimization of sexual side effects during treatment is a problem that has been improving, through education of both patients and physicians. Patients are often reluctant to bring up sexual issues, and quick or vague inquiries regarding sexual functioning may be insufficient to elicit such symptoms. Inattention to this is unfortunate, as sexual side effects are a major reason for discontinuing medication that has otherwise been very effective. In this case, the patient’s therapist first understood the importance of this side effect. This underscores another point: in cases where the medication treatment and psychotherapy are split, it is crucial that there be frequent and regular contact between the treatment team.

Finally, cases like this emphasize the art as well as the science of pharmacotherapy. Though some treatment-related decisions have a clear scientific basis, others are more rooted in judgment and experience. Certainly, the switch to bupropion to minimize sexual side effects has a clear pharmacodynamic rationale. However, the subsequent adjunctive use of an SSRI likely relied less on science, and more on the psychiatrist’s experience in interpreting the irritability as a symptom that might be more amenable to a serotonergic agent. Though the practice of clinical medicine should be informed by research, the greatest clinicians are still those unique individuals who can integrate research into their own observations and wisdom.

Introduction
The therapeutic armamentarium for the treatment of schizophrenia and related psychotic disorders has grown and diversified in the half century since the advent of chlorpromazine, the prototypical first-generation antipsychotic (FGA). A primary aim of antipsychotic drug development has been to obtain compounds with a broader efficacy profile, targeting positive, negative, cognitive, and affective symptoms while inducing fewer extrapyramidal symptoms (EPS). The introduction of clozapine and other second-generation antipsychotics (SGAs) partially achieved this aim and, at present, many clinicians prescribe SGAs (excluding clozapine) as first-choice agents for acute and maintenance therapy for psychotic disorders. A number of randomized, controlled trials (RCTs) suggest that SGAs may offer some advantages over FGAs, such as fewer acute EPS; less tardive dyskinesia (TD); and possibly improvement in negative, affective, and cognitive symptoms. The aggressive marketing of SGAs has contributed to their increased use and has expanded clinical expectations. Accordingly, SGAs are being increasingly prescribed for nonpsychiatric conditions, with or without empirical support, as happened with FGAs (Miyamoto et al. 2003a). However, recent meta-analyses and government-funded, large-scale, practical clinical trials have provided conflicting information about the relative advantages of FGAs and SGAs (Davis et al. 2003, Geddes et al. 2000, Jones et al. 2006, Leucht et al. 2002, Lewis et al. 2006b, Lieberman et al. 2005a, McEvoy et al. 2006, Rosenheck et al. 2006, Stroup et al. 2006). Of particular concern, the extrapyramidal side effects of FGAs appear not to have been eradicated with SGAs so much as replaced by such distressing adverse effects as weight gain, diabetes mellitus, and dyslipidemia. Investigators are still in the process of elucidating the impact of SGAs on a variety of domains (Miyamoto et al. 2005), including subjective well-being, quality of life (QOL), and cost-effectiveness. Meanwhile, our understanding of the neurobiology of antipsychotic treatment is rapidly expanding, and more agents with antipsychotic and/or cognitive-enhancing effects are in development. This chapter presents an updated review of the history, pharmacology, uses, efficacy, and side effects of antipsychotic drugs on the basis of currently available evidence, and discusses the benefits and limitations of individual SGAs in the management of psychosis and other disorders.

History of Antipsychotic Drug Development
The era of antipsychotic pharmacootherapy began with the serendipitous discovery of the antipsychotic properties of chlorpromazine in the early 1950s by Delay and Deniker. A “first generation” of neuroleptics was subsequently developed based on the hypothesis that schizophrenia reflects a disorder of excess dopaminergic activity and that antagonism of the dopamine D2 receptor is most strongly associated with antipsychotic response (Seeman 1992). For many patients with schizophrenia, the widely used FGAs (phenothiazines, butyrophenones, and others), which are also referred to as “conventional,” “standard,” “classical,” “traditional,” or “typical” antipsychotic drugs, are effective in the treatment of positive symptoms of the illness, and also in preventing psychotic relapse. Accordingly, these agents have permitted many patients to live independently in the community. Almost a half century of experience, however, has revealed substantial limitations with the use of these drugs. Twenty-five to sixty percent of patients treated with FGAs remain symptomatic and are considered either treatment refractory or only partially responsive (Miyamoto et al. 2003a). In particular, these drugs at best only modestly improve negative and cognitive symptoms. FGAs also cause a variety of objective and subjective side effects, both acutely and with long-term exposure. These side effects, in many instances, reduce compliance, which leads to relapse and rehospitalization.

For many years after the discovery of chlorpromazine’s therapeutic effects, drug developers held the view that any compound with antipsychotic properties must induce considerable EPS. Clozapine and other SGAs disproved this hypothesis. These newer drugs are sometimes termed “atypical” because, in contrast to most FGAs, they demonstrate substantial separation between the doses at which...
they display antipsychotic action and the doses at which they are likely to induce EPS (Lieberman 1996).

Clozapine, the prototypical SGA, underwent extensive clinical testing in the 1970s, until its development was halted in the U.S. and limited in other countries because of a relatively high incidence of a potentially fatal side effect, agranulocytosis. Nonetheless, the drug’s superior efficacy ultimately led to its reintroduction in the U.S. in 1990 (Lieberman et al. 1989). The renaissance of clozapine was based on several advantages: it is superior to FGAs for treatment-refractory schizophrenia (Kane et al. 1988); it may ameliorate some of the negative, cognitive, and mood symptoms of schizophrenia (Lieberman 1993); it may reduce the likelihood of suicidal behavior (Meltzer et al. 2003); it has very low liability for acute and chronic EPS; and it does not induce sustained hyperprolactinemia (Lieberman et al. 1989).

In the years that followed the reintroduction of clozapine, concerted research and development efforts were made to replicate the drug’s therapeutic profile while avoiding the associated risk of agranulocytosis. Although this goal was never fully realized, the initiative spawned a second generation of atypical antipsychotic medications (Table 102–1), including risperidone, olanzapine, quetiapine, ziprasidone, remoxipride, sertindole, amisulpride, perospirone, zotepine, and aripiprazole, paliperidone, iloperidone, and bifeprunox.

Remoxipride was withdrawn after approval because of rare but serious hematological adverse effects. Sertindole was voluntarily withdrawn in 1998 due to concerns about its cardiac safety, but it was relaunched in 2002 in some European countries, solely for use in clinical trials. Amisulpride and zotepine are widely used in European and other countries, but sertindole, amisulpride, and zotepine are not marketed in the U.S. Perospirone is available only in Japan. Aripiprazole is sometimes called the first of the “third-generation antipsychotics” because its mechanism of action, partial dopamine receptor agonism, distinguishes it from previously developed FGAs and SGAs (Keltner and Johnson 2002). Paliperidone, the active metabolite of risperidone, was approved by the U.S. Food and Drug Administration (FDA) in December 2006. A phase III trial of iloperidone has recently been completed in the U.S., and the results appear to be encouraging. Aripiprazole is yet another antipsychotic under development for the treatment of schizophrenia. Bifeprunox, like aripiprazole, is a partial dopamine agonist. Its manufacturer filed for FDA registration in 2006; however its expected market launch is still pending. Although none of these second- and third-generation agents have matched the singular effectiveness of clozapine, they have broadened the therapeutic repertoire available for the treatment of schizophrenia and other psychotic illnesses.

**Mechanism of Action of Antipsychotic Agents**

**Dopamine Receptor Modulation**

The role of dopamine systems in the pathophysiology and treatment of psychotic disorders has been a subject of intense investigative scrutiny for the past 50 years. Although other systems have since been implicated, the dopamine D₂ receptor is still regarded as the primary target associated with antipsychotic effect, as well as with the induction of EPS and prolactin elevation. All clinically approved, currently used antipsychotic drugs share D₂ receptor antagonism properties to some extent.

Positron emission tomography (PET) and single photon emission computed tomography (SPECT) studies support the importance of in vivo D₂ receptor occupancy as a predictor of antipsychotic response and adverse effects (for review, see Remington and Kapur 1999). Prospective studies demonstrate that, for at least some SGAs, antipsychotic effect requires a striatal D₂ receptor occupancy of 65–70%, and D₂ occupancy greater than 80% significantly increases the risk of EPS (Remington and Kapur 1999). Similarly, PET studies showing that therapeutic doses of risperidone and olanzapine produce greater than 70% occupancy of D₂ receptors suggest that D₂ receptor antagonism could be a mechanism of action of at least some SGAs (Kapur et al. 1998). However, the observations that therapeutic response occurs below this threshold for some agents and some patients, and that nonresponders can be seen in spite of adequate D₂ receptor blockade, reflect the limitations of the D₂ receptor occupancy model (Miyamoto et al. 2005).

Clozapine and quetiapine, for example, exhibit less than 70% striatal D₂ receptor occupancy at therapeutically effective doses (Farde et al. 1992, Kapur et al. 2000b), indicating that D₂ receptor antagonism alone cannot explain the superior therapeutic efficacy of clozapine. The low occupancy of striatal D₂ receptors by clozapine and quetiapine could, on the other hand, account for their low EPS liability.

Differences among antipsychotics in dopamine receptor activity have been proposed to account for the “atypicality” of SGAs, that is, their tendency to produce antipsychotic effects at considerably lower doses than those that induce EPS. For example, Kapur and colleagues proposed that low affinity for, and fast dissociation from, D₂ receptors may be the key to atypicality (Kapur and Seeman 2001). SGAs such as haloperidol and chlorpromazine bind more tightly than dopamine itself to the D₂ receptor and dissociate from it slowly in vitro and in vivo (Seeman 2002). In contrast, SGAs such as quetiapine and clozapine bind more loosely than dopamine to the D₂ receptor, with dissociation constants (expressed as “k_d”) that are higher than those for dopamine.

As a group, SGAs have higher \( k_{\text{off}} \) values (i.e., faster dissociation rates) than do FGAs, though they vary considerably on this dimension. Kapur and Seeman hypothesized that the greater the \( k_{\text{off}} \), the more quickly the drug responds to dopamine surges, allowing for a more physiological dopamine transmission (Kapur and Seeman 2001). However, this theory does not explain the apparently greater therapeutic efficacy of clozapine, compared with agents with still higher \( k_{\text{off}} \) values (e.g., quetiapine). At present, the exact relationships among the \( D_2 \) receptor dissociation rate, therapeutic effects, and adverse effects remain obscure.

Another hypothesized mechanism of SGA atypicality involves regionally selective dopamine receptor binding. It has been suggested that dopamine receptors in mesolimbic and mesocortical pathways are more relevant than striatal dopamine receptor populations for the pathophysiology of schizophrenia and that they mediate the therapeutic effects of antipsychotic drugs. A regionally selective binding of SGAs to dopamine tracts projecting to corticolimbic areas has been proposed as a contributor to atypicality. A number of animal studies have found preferential effects of SGAs on ventral tegmental area (A10) as compared to substantia nigra pars compacta (A9) dopamine neurons. In humans, several PET studies using \( ^{[123]} \text{I}\)epidepride and SPECT studies using \( ^{[123]} \text{I}\)epidepride have demonstrated this corticolimbic \( D_2 \) receptor specificity for clozapine, risperidone, olanzapine, amisulpride, quetiapine, and sertindole. However, PET studies using \( ^{[11]} \text{C}\)raclopride and \( ^{[11]} \text{C}\)FLB 457 have not supported the hypothesis of regional selectivity for clozapine, risperidone, or olanzapine. More recent PET studies with \( ^{[18]} \text{F}\)allypride found that clozapine and quetiapine, but not olanzapine, preferentially occupy temporal cortical, as compared to putamenal, \( D_2 \) receptors (Kessler et al. 2005, 2006). Further research in humans is needed to clarify the neurochemical basis of “corticolimbic selective” \( D_2 \) receptor occupancy by SGAs, as it raises the possibility of spatial targeting of antipsychotics in the future.

The concept of mesolimbic and mesocortical pathway dysfunction has also been used to update the original dopamine hypothesis of schizophrenia. Imaging studies point to a dopaminergic “imbalance” involving a primary mesocortical hypodopaminergic state associated with hypo-functioning glutamatergic signaling that results in hypostimulation of prefrontal \( D_2 \) receptors (Abi-Dargham and Moore 2003). Reduced \( D_2 \) function may lead to negative and cognitive symptoms, and later developed episodic hyperactivity of the mesolimbic \( D_2 \) receptor-mediated dopamine system may account for the emergence of psychotic symptoms (Laruelle et al. 2003).

Partial dopamine agonists, such as aripiprazole, represent a new strategy of attempting to normalize dopaminergic imbalance in psychotic disorders, without the adverse effects associated with full \( D_2 \) antagonists. These agents have lower intrinsic activity at \( D_2 \) receptors than full agonists, allowing them to act either as functional agonists or as antagonists, depending on synaptic dopamine levels (Lieberman 2004). In schizophrenia, an effective partial \( D_2 \) agonist is thought to act as a functional antagonist in the mesolimbic dopamine pathway to control positive symptoms and as a functional agonist in the mesocortical pathway to improve negative and cognitive symptoms. In addition, such an agent should ideally maintain dopaminergic tone in the nigrostriatal and tuberoinfundibular pathways, avoiding EPS and hyperprolactinemia associated with \( D_2 \) antagonism. Thus, partial \( D_2 \) agonist activity could “stabilize” the dopamine system in multiple areas of the schizophrenic brain.

**Serotonin Receptor Modulation**

Meltzer and colleagues proposed that a high ratio of serotonin 5-HT\(_{2A}\) receptor to \( D_2 \) receptor blockade might predict antipsychotic atypicality (Meltzer et al. 1989). 5-HT\(_{2A}\) antagonism can increase dopaminergic transmission in the nigrostriatal pathway, thus reducing the risk of EPS, and could theoretically improve negative symptoms and cognitive impairment in schizophrenia by increasing dopamine release in the prefrontal cortex. This “dopamine-serotonin antagonism theory” appears to apply, to some degree, for most of the SGAs, including clozapine, risperidone, olanzapine, quetiapine, ziprasidone, sertindole, perospirone, zotepine, paliperidone, and iloperidone (Table 102–2). There are, however, critical limitations to this concept (Sharif et al. 2007). First, some FGAs (e.g., chlorpromazine and loxapine) have high 5-HT\(_{2A}\) affinity (Seeman 2002) but do not have an atypical profile. Second, amisulpride has no substantial affinity for the 5-HT\(_{2A}\) receptor, and aripiprazole has higher \( D_2 \) than 5-HT\(_{2A}\) affinity, and yet both agents have atypical profiles. Third, risperidone and olanzapine exhibit high 5-HT\(_{2A}\) receptor occupancy at doses that are not antipsychotic, and as the doses of these drugs are increased beyond their usual therapeutic ranges, the risk of EPS increases despite maximal \( 5-HT_{2A} \) receptor antagonism. Fourth, the relative ratios of 5-HT\(_{2A}\)/\( D_2 \) receptor affinities of the atypicals do not always predict their clinical EPS liability. (For example, risperidone has the highest and quetiapine the lowest 5-HT\(_{2A}\)/\( D_2 \) ratio, but the EPS liability of risperidone is greater than that of quetiapine.) Finally, at equivalent \( D_2 \) receptor occupancies, risperidone and haloperidol demonstrate comparable EPS liability, despite different 5-HT\(_{2A}\) receptor affinities (Knable et al. 1997). Thus, high 5-HT\(_{2A}\) affinity may contribute to the modulation of dopamine in the striatum and prefrontal cortex, but high 5-HT\(_{2A}\) occupancy does not protect against the risk of EPS if \( D_2 \) receptor occupancy is greater than the EPS threshold (Sharif et al. 2007). The 5-HT\(_{2A}\)/\( D_2 \) hypothesis, therefore, does not satisfactorily explain atypicality (Kapur and Remington 2001). In addition, the apparent lack of efficacy of monotherapy with the selective 5-HT\(_{2A}\) receptor antagonist M-100907 indicates that 5-HT\(_{2A}\) antagonism alone does not account for the efficacy of SGAs. Further studies examining combination therapy with \( D_2 \) antagonists and M-100907 may help to elucidate the potential role of 5-HT\(_{2A}\) antagonism in the mechanism of action of SGAs.

It has been suggested that partial agonism of 5-HT\(_{1A}\) receptors, resulting in activation and blockade of pre- and postsynaptic receptors, respectively, is possible mechanism of action of some SGAs, including clozapine, ziprasidone, perospirone, quetiapine, and aripiprazole (Millan 2000). 5-HT\(_{1A}\) receptors are located presynaptically in the raphe nuclei, where they act as cell body autoreceptors to inhibit the firing rate of 5-HT neurons, and are located postsynaptically in limbic and cortical regions, where they also attenuate firing activity. 5-HT\(_{1A}\) partial agonistic properties are thought to improve negative symptoms and cognitive impairment by enhancing the release of dopamine in the prefrontal cortex. In addition, 5-HT\(_{1A}\) receptor agonists...

have been reported to possess antidepressant and anxiolytic properties and to attenuate the EPS liability of \( \text{D}_2 \) antagonists (Miyamoto et al. 2005).

**NMDA Receptor Modulation**

The ability of noncompetitive \( \text{N-methyl-D-aspartate} \) (NMDA) receptor antagonists, such as phencyclidine (PCP) and ketamine, to induce a spectrum of positive, negative, and cognitive schizophrenia-like symptoms has led to the hypothesis that hypofunction of NMDA receptors is involved in the pathophysiology of the disease (Coyle 1996, Javitt and Zukin 1991, Krystal et al. 1994).

A wide range of preclinical studies have demonstrated that acute treatment with some SGAs, but not FGAs, selectively antagonizes the consequences of experimentally induced NMDA receptor hypofunction at the cellular and behavioral levels (for review, see Duncan et al. 1999). For example, clozapine and olanzapine, but not haloperidol or raclopride, inhibit the electrophysiological effects of PCP in sectioned brain tissue and attenuate NMDA-antagonist-induced deficits in prepulse inhibition (PPI) and social behavior. In addition, ketamine-induced brain metabolic activation in rats is blocked by acute administration of clozapine and olanzapine, but not haloperidol (Duncan et al. 2000). In contrast to acute treatment with haloperidol, chronic administration of the drug blocks PCP-induced deficits in PPI and ketamine-induced brain metabolic activation. Thus, adaptive changes elicited by both FGAs and SGAs appear to attenuate the effects of NMDA antagonists (Miyamoto et al. 2005).

The well-documented effects of SGAs on responses to NMDA antagonists raise the possibility that the therapeutic action of these agents may involve a correcting of NMDA receptor hypofunction. However, since none of the SGAs has direct affinity for any of the glutamate receptors, including the NMDA receptor, the mechanism by which these effects might be mediated is poorly understood. Numerous animal studies have reported increases, decreases, or no changes in the binding site of glutamate receptors in various brain regions after chronic administration of antipsychotics (for review, see Miyamoto et al. 2005). Inconsistent and often conflicting findings have been reported regarding the gene expression of sub-units composing different glutamate receptors following long-term treatment with FGAs or SGAs. These discrepancies appear to be due to differences in treatment regimens, brain regions examined, and method of assessment. Recently, Javitt and colleagues found that clozapine inhibits synaptosomal glycine transport through system A transporters (Javitt et al. 2005). Such regulation of synaptic glycine levels may indirectly play a role in the potentiation of NMDA receptor function. Further studies are needed to determine whether the inhibition of the effects of NMDA antagonists by SGAs involves molecular modifications in glutamate receptors and/or other neurotransmitter–glutamate interactions.

**Depolarization Inactivation**

Although antipsychotic drugs can produce a high level of \( \text{D}_2 \) receptor occupancy in humans within hours of oral administration, it has traditionally been believed that antipsychotics must be taken for several weeks before their clinical effects can be fully realized in patients with schizophrenia. One possible explanation for this lag in efficacy is the hypothesis of dopaminergic neuron “depolarization inactivation.”

Acute administration of at least some FGAs (e.g., haloperidol and chlorpromazine) induces an increase in dopaminergic neuron firing in both the substantia nigra pars compacta (A9) and the ventral tectal area (A10) in rats. Repeated treatment with FGAs for 3 weeks or more, however, results in a decrease in the number of spontaneously active dopaminergic neurons in the A9 and A10 regions. After chronic treatment, dopaminergic neurons are not in a hyperpolarized, inactive state, but are instead tonically depolarized to such an extent that their spike-generating mechanism is inactive. This neuroleptic-induced inhibition of spontaneous cell firing has been termed “depolarization inactivation” or “depolarization block” (for review, see Grace 1992). The depolarization inactivation hypothesis is supported in part by studies demonstrating that systematic administration of the dopamine agonist apomorphine, which hyperpolarizes dopaminergic cells in anesthetized animals, can reverse the effects of chronic treatment with antipsychotics by causing previously nonfiring dopaminergic cells to become active (Grace 1992).

In contrast to FGAs, chronic treatment with SGAs, including clozapine, olanzapine, quetiapine, and iloperidone, results in depolarization inactivation of A10 neurons, but not A9 dopaminergic cells. It has been suggested that the inability of these drugs to decrease A9 dopaminergic neuronal activity may contribute to their lower incidence of EPS and that inactivation of mesolimbic (A10) dopamine areas may be involved in the delayed onset of therapeutic effects (White and Wang 1983).

Of note, the hypothesis that slow onset of antipsychotic effect is associated with depolarization inactivation has recently been thrown into question by work suggesting that antipsychotics may act more quickly than originally believed (Kapur et al. 2005). For example, a meta-analysis of 42 double-blind, comparator-controlled studies found that antipsychotic effect was evident within the first week of treatment and that improvement in the first 2 weeks was greater than during any subsequent 2-week period (Agid et al. 2003). Kapur and colleagues reported in a double-blind, placebo-controlled study comparing intramuscular (IM) olanzapine to IM haloperidol that onset of specific antipsychotic effect was evident within 24 hours of drug initiation and that improvement in psychosis was independent of change in agitation (Kapur et al. 2005). These observations warrant further investigation.

**Effects on Intracellular Signal Transduction and Gene Expression**

Studies suggest that antipsychotic action is associated with long-lasting adaptive modifications in neural functioning that involve changes in intracellular signal transduction and, ultimately, changes in gene expression in target neurons (for review, see Miyamoto et al. 2003a). These changes appear to be initiated by the binding of antipsychotic drugs to dopaminergic, serotonergic, muscarinic, cholinergic, adrenergic, histaminergic, or other receptors (Table 102–2). Most of these receptors belong to the G-protein-coupled receptor superfamily. Agonism of G-protein-coupled receptors stimulates specific heterotrimeric G-proteins, the subunits of which then regulate multiple downstream effectors, such as adenylate cyclase, phospholipases, and various ion channels. Some components of signal transduction, such as cyclic
with FGAs, but not SGAs, has been reported in schizophrenic patients and rats. This augmented striatal volume is accompanied by increases in the size of axon terminals, post-synaptic density, and the number of vesicles per synapse (for review see Konradi and Heckers 2001). It should be noted that neurotoxic effects may occur concurrently with the neurotrophic effects of FGAs, with the balance depending in part on factors such as dose, length of treatment, and individual sensitivity (Dean 2006). At present, it is unclear whether FGA-induced neuroplastic changes relate to the therapeutic action of these drugs and/or to their propensity to cause EPS.

### Pharmacology of Antipsychotic Agents

#### First-Generation Antipsychotic Agents

FGAs, as a class, are equally effective in the treatment of psychotic symptoms of schizophrenia, though they vary in potency, side effect risks, and other pharmacological properties (Lehman et al. 2004). Attributes common to all FGAs are a high affinity for, and full antagonist activity at, dopamine D 2 receptors (Marder and Van Putten 1995). In addition, all FGAs are capable of producing EPS and increasing serum prolactin concentration, to varying degrees, when used in the usual clinical dose range (Meltzer 1985).

Based on their chemical structure (Figure 102–1), FGAs may be divided into three groups: butyrophenones, phenothiazines, and others. The butyrophenones, represented by haloperidol, tend to be potent D 2 antagonists and to have minimal anticholinergic and autonomic effects (Marder and Van Putten 1995) (Table 102–2). The phenothiazines block D 2 , acetylcholine, serotonin, histamine, and norepinephrine receptors, each of which is associated with certain adverse effects. The phenothiazines are often subdivided into three classes, according to substitutions at position 10 (for review, see Marder and Van Putten 1995), and these classes vary in their receptor affinities. The aliphatic class (e.g., chlorpromazine) consists of medications that have relatively low potency at D 2 receptors. Compared with other FGAs, aliphatic agents have greater antimuscarinic, sympathetic, and parasympathetic activity, and more potential for sedation. The piperidine class (e.g., thioridazine) possesses a similar receptor activity profile to the aliphatic class, with somewhat reduced affinity for D 2 sites. The piperazine class (e.g., perphenazine and fluphenazine) is characterized by fewer antimuscarinic and autonomic effects, but greater potency at D 2 sites and, thus, higher EPS liability.

#### Second-Generation Antipsychotic Agents

In this chapter, SGAs refer to clozapine, risperidone, olanzapine, quetiapine, ziprasidone, serindole, amisulpride, perospirone, zotepine, aripiprazole, paliperidone, iloperidone, and bifeprunox (Figure 102–2). These drugs bind with varying affinities to a broad range of receptors (Table 102–2). Intensive research efforts by the pharmaceutical industry and the academic psychopharmacology research community continue to clarify the pharmacological properties of SGAs, especially as they compare and contrast with those of FGAs. Since clozapine is the prototypical and most efficacious SGA, investigators are particularly eager to elucidate and replicate the complex actions of this drug (Miyamoto et al. 2002).

#### Clozapine

Clozapine is a tricyclic dibenzodiazepine derivative. Distinguishing features of clozapine, as compared to FGAs, are its...

relatively high affinity for 5-HT\textsubscript{1A} receptors and lower affinity for D\textsubscript{2} receptors (for review, see Deacon et al. 1999, Lieberman 1993). Clozapine has high antagonist affinity for H\textsubscript{1}, histaminergic, muscarinic, and α\textsubscript{1}- and α\textsubscript{2}-adrenergic receptors (Bymaster et al. 1996). The drug exhibits weak partial agonist effects at 5-HT\textsubscript{1A} receptors and at muscarinic M\textsubscript{1}, M\textsubscript{2}, and M\textsubscript{4} receptors, and the latter pharmacological properties have been hypothesized to contribute to antipsychotic activity and cognitive enhancement in animal models (Bymaster et al. 2002). N-desmethyloclozapine, the major metabolite of clozapine, has potent partial agonist activity at the M\textsubscript{1} receptor and can potentiate NMDA currents in the hippocampus (Sur et al. 2003). It is possible that clozapine’s unique therapeutic profile may be due, at least in part, to such M\textsubscript{1} receptor-mediated potentiation of NMDA receptor function.

**Risperidone**

Risperidone has substantially higher affinity for 5-HT\textsubscript{2A} and D\textsubscript{2} receptors than does clozapine. A PET study found that risperidone occupies 75–80% of striatal D\textsubscript{2} receptors and 78–88% of cortical 5-HT\textsubscript{2} receptors when administered to schizophrenic patients at a dose of 6 mg/day (Farde et al. 1995). Despite high levels of D\textsubscript{2} receptor occupancy, moderate-dose risperidone treatment (4–6 mg/day) poses a somewhat lower EPS risk than treatment with some FGAs. This may be due to the 5-HT\textsubscript{2A} antagonistic properties of the drug (Meltzer et al. 1989). However, at higher doses, risperidone produces EPS consistently (Marder and Meibach 1994), indicating that 5-HT\textsubscript{2A} receptor antagonism alone cannot eliminate EPS associated with substantial D\textsubscript{2} receptor blockade. Risperidone, like clozapine, has relatively high affinity for α\textsubscript{1}- and α\textsubscript{2}-adrenergic receptors, but whether adrenergic receptor antagonism contributes to the therapeutic action of these drugs is unknown.

**Olanzapine**

Olanzapine is closely related to clozapine in chemical structure, and the two drugs share many receptor-binding characteristics (for review, see Miyamoto et al. 2001). Primary considerations in the selection of olanzapine for development were the drug’s relatively potent antagonistic effects at D\textsubscript{2} and 5-HT\textsubscript{2A} receptors (Bymaster et al. 1997). Olanzapine is more potent at 5-HT\textsubscript{2A} than at D\textsubscript{2} receptors, similar to clozapine. Other receptor-binding characteristics of olanzapine are similar to those of clozapine, but there are some notable differences between the two drugs. For example, olanzapine has substantially lower affinity for 5-HT\textsubscript{1A} and 5-HT\textsubscript{7} receptors, in comparison with clozapine. A PET study found a striatal D\textsubscript{2} receptor occupancy of 71–80% in olanzapine’s usual clinical dose range of 10–20 mg/day, while doses of 30 mg/day and higher were associated with more than 80% D\textsubscript{2} occupancy in schizophrenic patients (Kapur et al. 1998). Although olanzapine displays little physiological evidence of anticholinergic activity, it produces a substantial blockade of muscarinic sites in vivo, as demonstrated by PET imaging (Raedler et al. 2000).

**Quetiapine**

Quetiapine is another drug with greater affinity for 5-HT\textsubscript{2A} than for D\textsubscript{2} receptors. It also has some affinity for α\textsubscript{1}-adrenergic and H\textsubscript{1} receptors and weak partial agonist effects at 5-HT\textsubscript{1A} receptors. PET studies have shown that quetiapine occupies 22–68% of striatal D\textsubscript{2} receptors and 48–70% of cortical 5-HT\textsubscript{1A} receptors at therapeutic doses in schizophrenic patients (Gefvert et al. 1998). Interestingly, quetiapine produces transiently high striatal D\textsubscript{2} occupancy in schizophrenic patients, but the effect lasts for only a few hours (Kapur et al. 2000b).

**Ziprasidone**

Ziprasidone has potent 5-HT\textsubscript{2A} and D\textsubscript{2} affinities and, like clozapine, exhibits partial 5-HT\textsubscript{1A} agonist properties that may protect against the development of EPS (Ferris 2000). Ziprasidone also has significant affinity for 5-HT\textsubscript{1D}, 5-HT\textsubscript{2C}, H\textsubscript{1}, and α\textsubscript{1}-adrenergic receptors (Arnt and Skarsfeldt 1998), and it inhibits the reuptake of norepinephrine and 5-HT (Waddington and Casey 2000). Although initially ziprasidone was found to produce substantial D\textsubscript{2} receptor occupancy at low doses (20- and 40-mg single doses) in healthy volunteers (Bench et al. 1996), a subsequent study (Mamo et al. 2004) found that 60% D\textsubscript{2} occupancy was not achieved until plasma levels corresponding to a 120 mg/day dose were reached, suggesting that the optimal dose of the drug is 120 mg/day or higher. This latter finding is consistent with clinical trial data (Daniel et al. 1999, Keck et al. 1998). The surprising absence of weight gain with ziprasidone, which has relatively high 5-HT\textsubscript{2C} and H\textsubscript{1} affinities, may be related to its partial agonism at the 5-HT\textsubscript{1A} receptor.

**Sertindole**

Sertindole is a phenylindole derivative with high-affinity antagonism at 5-HT\textsubscript{2A}, 5-HT\textsubscript{3}, α\textsubscript{1}-adrenergic, and D\textsubscript{2}-like receptors (Schotte et al. 1996). In conventional preclinical models, the receptor-binding profile of sertindole accurately predicted antipsychotic efficacy with low EPS liability (for review, see Arnt and Skarsfeldt 1998). In schizophrenic patients, SPECT studies found that sertindole is similar to risperidone in occupying a high percentage of striatal D\textsubscript{2}-like receptors and cortical 5-HT\textsubscript{2A} receptors (Bigliani et al. 2000). Electrophysiologically, sertindole exhibits dose-dependent, marked limbic selectivity (for review, see Daniel and Copeland 2001).

**Amisulpride**

Amisulpride, a substituted benzamide analog of sulpiride, is a selective antagonist at D\textsubscript{2} and D\textsubscript{3} receptors, with little affinity for D\textsubscript{1}-like or nondopaminergic receptors (Waddington and Casey 2000). At low doses, the drug preferentially blocks presynaptic dopamine autoreceptors, and postsynaptic dopamine receptor antagonism arises at higher doses. The effect of low doses on negative symptoms may be attributable to the presynaptic dopamine-releasing effect, which may have a psychomotor stimulatory action. Low doses also appear to selectively block temporal cortical D\textsubscript{2} and D\textsubscript{3} receptors, whereas higher doses result in considerable striatal D\textsubscript{2} and D\textsubscript{3} receptor occupancy, with associated EPS (Xiberas et al. 2001). Amisulpride has a propensity to elevate prolactin secretion even in the absence of EPS, suggesting that the drug antagonizes tuberoinfundibular D\textsubscript{2} receptors more potently than striatal D\textsubscript{2} receptors.

**Perospirone**

Perospirone is a benzisothiazole derivative with high-affinity antagonism at 5-HT\textsubscript{2A} and D\textsubscript{2} receptors (Onrust and
McClellan 2001). It displays partial 5-HT₁A agonist properties and some affinity for D₁, α₁-adrenergic, and H₁ receptors. The drug has no appreciable affinity for muscarinic receptors. Perospirone has at least four active metabolites, but all of them have lower affinity for D₂ and 5-HT₂A receptors than the parent drug. A preliminary PET study showed that it possesses the in vivo properties of a serotonin-dopamine antagonist in healthy volunteers (Sekine et al. 2006).

**Zotepine**
Zotepine is a dibenzothiepine analog of clozapine with high affinity for 5-HT₂A, 5-HT₅, 5-HT₆, 5-HT₇, α₁-adrenergic, and H₁ receptors (Needham et al. 1996). It has modest affinity for D₁, D₂, D₃, and D₄ receptors. It is also a potent norepinephrine reuptake inhibitor (Blin 1999). Preclinical studies suggest that low-dose zotepine increases dopaminergic neurotransmission, while, at higher doses, the drug acts as a dopaminergic antagonist. In schizophrenic patients, SPECT studies indicate that zotepine occupies 68–78% of striatal D₂-like receptors at usual clinical doses (Barnas et al. 2001).

**Aripiprazole**
Aripiprazole is a partial dopamine agonist with high affinity for D₂ and D₃ receptors, and acts on both postsynaptic D₂ receptors and presynaptic autoreceptors. The drug demonstrates properties of a functional agonist and antagonist in animal models of dopaminergic hypoactivity and hyperactivity, respectively (Kikuchi et al. 1995, Lawler et al. 1999). Partial agonist activity at dopamine receptors could theoretically stabilize the aberrant dopamine system of schizophrenia by restoring dopamine function in the mesocortical pathway, reducing hyperdopaminergia in the mesolimbic pathway, and maintaining dopaminergic tone in the nigrostriatal and tuberoinfundibular pathways. It has been proposed that aripiprazole’s activity at D₃ receptors is “functionally selective,” meaning the drug may activate a specific set of D₃ receptors, which are in turn coupled to particular G proteins that mediate aripiprazole’s clinical effects (Lawler et al. 1999, Shapiro et al. 2003). In addition, aripiprazole displays partial 5-HT₁A agonism and 5-HT₂A antagonism. It also has modest affinity for α₁-adrenergic, H₁-histaminergic, 5-HT₆, and 5-HT₇ receptors, and no appreciable affinity for D₁ or muscarinic receptors (Lawler et al. 1999). The clinical significance of these in vitro receptor-binding affinities has not been determined, apart from their association with side effects.

Aripiprazole does not conform to the usual 5-HT₂A/D₂ model of atypicality. Its affinity for D₂ receptors exceeds that for serotonin receptors by an order of magnitude (Shapiro et al. 2003), and PET studies in normal humans indicate that aripiprazole occupies up to 90% of striatal D₂-like dopamine receptors at clinical doses (Yokoi et al. 2002). In spite of this, aripiprazole causes few EPS, suggesting that its inherent partial agonism properties may protect against excessive blockade of the D₂ system.

**Paliperidone**
Paliperidone is 9-hydroxy-risperidone, the active metabolite of risperidone. The pharmacological properties of paliperidone are similar to those of risperidone with respect to receptor activity, potency, and onset and duration of action (van Beijsterveldt et al. 1994). However, paliperidone displays slightly less potent in vitro affinity for D₁, D₂, 5-HT₁A, 5-HT₂A, 5-HT₅, α₁, α₂, and H₁ receptors than does risperidone (Schotte et al. 1996). A paliperidone extended-release tablet (paliperidone ER), which is associated with small 24-hour peak-to-trough fluctuations in plasma concentration, has recently been approved by the U.S. FDA for the treatment of schizophrenia. Paliperidone ER undergoes limited hepatic metabolism and, consequently, may avoid significant hepatic-related drug–drug and drug–disease interactions (Kane et al. 2006).

**Iloperidone**
Iloperidone is a piperidinyl-benzisoxazole derivative with relatively high affinity for 5-HT₂A and α₁-adrenergic receptors, and moderate affinity for D₂, D₃, and 5-HT₄ receptors. Similar to clozapine and olanzapine, it induces a depolarization blockade of A10 mesolimbic dopaminergic neurons, but not of A9 nigrostriatal neurons (Hesselink 2000). Iloperidone has also shown to increase dopamine and acetylcholine levels in the prefrontal cortex. In conventional preclinical models, the profile of iloperidone predicted antipsychotic efficacy with reduced EPS liability (Hesselink 2000).

**Bifeprunox**
In in vitro and in vivo studies, bifeprunox (DU-127090) displayed partial agonist activity at D₂ and 5-HT₁A receptors, with high affinity for both. It also demonstrates high affinity for D₁ and D₃ receptors, but has virtually no activity at 5-HT₂A, 5-HT₅, α₁, α₂, muscarinic, and histaminergic receptors (Lieberman 2004). In animal models, bifeprunox demonstrated activity consistent with antipsychotic, antidepressant, and anxiolytic effects. A preliminary PET study involving six healthy subjects found that a single 10-mg dose of bifeprunox occupied 90% of striatal D₂-like dopamine receptors after 2 hours and 79% after 24 hours (De Vries et al. 2000).

**Conditions Treated with Antipsychotic Medications**
At present, SGAs are prescribed primarily for schizophrenia; however, they are being used increasingly for other psychiatric disorders, as happened with FGAs (Glick et al. 2001, Marder 1997). A proportion of these uses are empirically well supported, but only preliminary or moderate evidence exists for others. In particular, the prescription of SGAs for nonpsychotic disorders in children and adolescents has become progressively more common, despite limited data regarding the efficacy and safety of this practice (Olfson et al. 2006).

**Schizophrenia and Schizoaffective Disorder**
Nearly all acute psychotic episodes in schizophrenia and schizoaffective disorder, including first-episode psychosis and recurrence in chronic schizophrenia, should be treated with antipsychotic medication. In these instances, the patient’s mental status and physical condition should be evaluated promptly, and then pharmacotherapy should be prescribed as early in the episode as possible (American Psychiatric Association 2004).

**First-Episode Schizophrenia**
The past decade has witnessed a rise in clinical research focused on treatment response during first-episode...
schizophrenia, in large part because of the widely held belief that early intervention with antipsychotic medication may favorably alter the subsequent course of the illness (for review, see Lieberman 1996, Wyatt 1991, 1995). Investigators have proposed a “toxic psychosis” hypothesis, asserting that a limited neurodegenerative process may be involved in the pathophysiology of schizophrenia, that this pathologic process occurs principally in the early stages of the illness, and that it is reflected in the patient’s psychotic symptoms (Lieberman 1999a, Lieberman et al. 1996, Loebel et al. 1992, Wyatt et al. 1997). Such a link between psychotic symptoms and a toxic process is supported by the finding that the duration and number of periods of psychosis prior to receiving antipsychotics appear to be significant predictors of the time to treatment response, the time to relapse, and long-term outcome (Lieberman et al. 1990, Loebel et al. 1992, Wyatt 1991). Further evidence is provided by two meta-analyses of studies involving patients with first-episode psychosis, which concluded that there is a significant association between duration of untreated psychosis and outcomes such as positive symptoms, negative symptoms, and functionality (Marshall et al. 2005, Perkins et al. 2005). These findings have stimulated enthusiasm for the idea that early detection and intervention at, or even prior to, the onset of the first episode might improve response to antipsychotic treatment and long-term outcome. Large-scale clinical trials investigating this possibility are currently under way.

The preferential use of SGAs over FGAs is now common in the treatment of first-episode patients because of their generally lower EPS burden and possible superiority in relapse prevention. It has also been hypothesized that the glutamatergic effects of some SGAs may provide a neuroprotective function, potentially resulting in better long-term outcomes (Lieberman et al. 2001b). To date, four large-scale, double-blind studies comparing an FGA and an SGA in first-episode patients have been published: clozapine vs. chlorpromazine (Lieberman et al. 2003a), risperidone vs. haloperidol (Emsley and Risperidone Working Group 1999), risperidone vs. haloperidol (Schooler et al. 2005) and olanzapine vs. haloperidol (Lieberman et al. 2003b). None has found statistically significant differences in response rates between the FGA and the SGA, but some found that more patients were retained in the SGA arm, without relapse, than in the FGA arm (e.g., Lieberman et al. 2003b, Schooler et al. 2005). Thus, SGAs may be preferable to FGAs in first-episode schizophrenia, not because of superior acute treatment efficacy but because of modestly better relapse rates.

The Prodromal Stage of Schizophrenia

The average time from onset of psychotic symptoms to first effective treatment is often 1 year or more, but when the prodromal period is taken into account, the average delay is 3 years (McGlashan 1996). In an effort to reduce this delay and to improve long-term outcomes, early intervention research has been extended to include the prodromal stage of schizophrenia. Investigators use clinically defined prodromal diagnostic criteria to identify “at-risk” subjects with a 35–40% likelihood of developing a psychotic disorder within 1 year (Keefe et al. 2006a). In all, about 85% of individuals experience prodromal symptoms prior to developing psychosis (Yung and McGorry 1996).

There have been at least two randomized, controlled studies in people with prodromal symptoms assessing the efficacy of SGAs in reducing these symptoms and delaying or preventing conversion to psychosis. The first was a nonblinded trial involving “ultra-high-risk” individuals in late prodromal stages, which compared treatment with low-dose risperidone plus cognitive–behavioral therapy to routine clinical care over a 6-month period, followed by 6 months of need-based intervention (McGorry et al. 2002). Significantly fewer subjects in the risperidone group transitioned into psychosis after 6 months, and in those subjects who were compliant with risperidone treatment, the benefits extended through the ensuing 6-month extension period, even though risperidone was discontinued. In the second study, a randomized, double-blind trial, olanzapine was superior to placebo in reducing prodromal positive symptoms and conversion to psychosis (McGlashan et al. 2006). Over the follow-up year, the conversion rate did not differ significantly between the two groups. Further prodromal recognition and intervention programs are currently being developed in several countries, and data from associated studies are needed to clarify the utility and safety of antipsychotic treatment during the prodromal stage.

Intermittent Maintenance Medication

It has been suggested that patients with schizophrenia might be better treated by administering antipsychotic medication during periods of acute symptomatology and offering medication discontinuation when symptoms remit. Such “targeted” or “intermittent” treatment was once considered a potential means of reducing the short- and long-term risks associated with antipsychotic agents. This strategy has been tested in a number of controlled studies (for review, see Gaebel 1995), all of which yielded relapse rates that were approximately twice as high as those with continuous treatment, with the possible exception of first-episode patients (Gaebel et al. 2002). Therefore, continuous antipsychotic treatment is likely to be preferable for most patients with schizophrenia, even if they are symptom free (Marder 1997).

Major Depression with Psychotic Features

Psychotic symptoms, such as delusions or hallucinations, have been observed in up to 25% of patients with major depressive disorder. Major depression with psychotic features is seen in patients of all ages, and carries a high risk of short-term morbidity and suicide. Psychosis in the context of major depression often responds poorly to antidepressant monotherapy and usually requires the use of adjuvant antipsychotic medication (Marder 1997). Some data support the use of SGAs as monotherapy in the treatment of this disorder (for review, see Buckley 2001). However, several double-blind trials have found the combination of an antidepressant and an antipsychotic to be superior to an antipsychotic alone (Muller-Siecheneder et al. 1998). In the absence of convincing evidence for the efficacy and safety of antipsychotic monotherapy in the treatment of psychotic depression, most patients with this disorder should be treated with a combination of an antidepressant and an antipsychotic agent.
Bipolar Disorder
Antipsychotic medications can effectively treat both the mood and the psychotic symptoms of mania, often demonstrating improvement more rapidly than traditional mood stabilizers (for review, see Buckley 2001, Marder 1997). During the past decade, SGAs have gained increasing favor over FGAs for the treatment of mania because of their lower risk of EPS. A large number of double-blind studies support the efficacy of olanzapine, risperidone, quetiapine, aripiprazole, and ziprasidone for the treatment of acute manic or mixed episodes, either alone or as adjuvant treatment. A meta-analysis of randomized, placebo-controlled trials of SGAs for acute bipolar mania concluded that all five of these agents are efficacious as monotherapy (Perlis et al. 2006). Pairwise comparisons identified no significant differences in efficacy among individual medications, and the magnitude of improvement was similar whether the antipsychotic was utilized as monotherapy or as adjuvant treatment. To date, there have been no double-blind, controlled, monotherapy studies of clozapine in the treatment of acute bipolar mania, but reports suggest the drug may be beneficial in the management of treatment-refractory bipolar disorder.

Antipsychotic agents have also shown efficacy in the treatment of bipolar depression, which carries a greater overall burden of suicide risk, functional impairment, and duration of active symptomatology than does bipolar mania. The findings of a large-scale, placebo-controlled, double-blind RCT of olanzapine alone and in combination with fluoxetine suggest that the drug may be efficacious in treating depressive symptoms in patients with bipolar I disorder, though the combination of olanzapine and fluoxetine was superior to monotherapy (Tohen et al. 2003). It should be noted, however, that the relatively longer half-life of fluoxetine, as compared to olanzapine, represents at least a theoretical concern with this combination, because drug discontinuation will result in a period of unopposed antidepressant exposure, which could potentially increase the risk of mania in a patient with bipolar disorder. Quetiapine monotherapy has similarly been shown to be efficacious and well tolerated in the treatment of depressive episodes in bipolar I and II disorders. Large, controlled trials are necessary to determine whether other SGAs are effective for bipolar depression.

Tourette’s Disorder
Tourette’s disorder is a neurobehavioral illness characterized by motor and vocal tics that usually begin in childhood and may persist indefinitely. The pathophysiology of the disorder is not well understood.

When motor or vocal tics interfere with functioning, an antipsychotic medication can be effective in reducing their severity. Historically, haloperidol and pimozide have been the most commonly used agents for the treatment of moderate to severe tics. SGAs also show promise in this respect. Most of these data come from placebo-controlled and active comparator trials involving risperidone. The drug appears to be comparable to pimozide in efficacy, with a lower incidence of EPS but a greater potential for weight gain. Given the risk of side effects with both agents, risperidone and pimozide should be reserved for patients with significant tic-related functional impairment or pain, which is refractory to safer treatments. One small RCT found ziprasidone to be effective and well tolerated in the treatment of Tourette’s disorder, suggesting the drug may be a viable alternative to agents with less favorable side effect profiles.

Borderline Personality Disorder
Antipsychotic agents are occasionally used in the treatment of borderline personality disorder (BPD). Although psychotherapy is the mainstay of BPD treatment, antipsychotics may be useful as adjunctive therapy in some cases. A number of studies indicate that aspects of BPD may improve with low doses of an FGA, such as thiothixene or haloperidol (Marder 1997). Case reports, open-label studies, and controlled trials have shown that some SGAs, including risperidone, olanzapine, aripiprazole, and clozapine, may also be beneficial for at least some symptoms of BPD. The largest body of evidence exists for olanzapine, which in several controlled trials has shown superiority over placebo in patients with BPD for such symptoms as anxiety, depression, paranoia, anger/hostility, impulsive aggression, and interpersonal sensitivity. There are not, however, convincing data that suggest any antipsychotic agent changes the underlying character structure of patients with BPD or alters the long-term course of the disease. Given the circumscribed utility of antipsychotics for BPD, and their potential for causing adverse effects, most patients with this condition should not routinely be treated with antipsychotic medication.

Substance-Related Disorders
A variety of substances, including amphetamines, cocaine, alcohol, cannabis, and phencyclidine, can cause psychotic symptoms during intoxication or drug withdrawal (Marder 1997). In addition, substance-use disorders are common in patients with schizophrenia, and the presence of these disorders may negatively influence response to antipsychotic medication.

FGAs are not generally helpful for patients with schizophrenia and concurrent substance-use disorders, and may even worsen the abuse of substances in this population (Green et al. 2007). In contrast, several case reports, open-label studies, and a few randomized trials suggest SGAs may have a role in reducing substance abuse when it is comorbid with a psychotic disorder. Clozapine appears to be particularly effective for reducing psychosis and substance abuse in patients with comorbid schizophrenia and substance-use disorder, though randomized studies are lacking (Green et al. 2007). When a psychotic disorder is not present, antipsychotic agents are not generally efficacious in the treatment of substance-use disorders.

Behavioral Disturbances in Patients with Dementia
Dementia, whether due to Alzheimer’s disease (AD) or other causes, is frequently associated with behavioral disturbances and psychosis. SGAs are often used to manage these symptoms, in part because of perceived safety advantages relative to FGAs. However, concerns have recently emerged regarding an increased risk of cerebrovascular adverse events (e.g., stroke and transient ischemic episodes), the metabolic syndrome (MS), cognitive decline, and mortality with at least some SGAs (Schneider et al. 2005). Because of these concerns, Health Canada issued an advisory in late 2002, and the U.S. FDA issued its own public health advisory in
April 2005, warning of an increased risk of mortality with SGAs, but not FGAs, in elderly patients with dementia. Consistent with the FDA’s assessment, a meta-analysis by Schneider and colleagues found an increased risk of death with SGA use, relative to placebo treatment, in patients with dementia (Schneider et al. 2005). In a retrospective cohort study of 22,890 elderly patients treated with FGAs or SGAs, Wang and colleagues concluded that FGAs were at least as likely as SGAs to increase the risk of death (Wang et al. 2005). The greatest increases in risk of death occurred soon after therapy was initiated and with higher dosages of FGAs. Schneider and colleagues recently reported a meta-analysis of 15 randomized, placebo-controlled trials of aripiprazole, olanzapine, quetiapine, and risperidone in 3,353 patients with AD or other dementia (Schneider et al. 2006a). Small therapeutic effect sizes supported the efficacy of aripiprazole and risperidone. Worsening of cognitive test scores was observed with SGA use, and there was a significant risk of cerebrovascular events, especially with risperidone. The authors concluded that SGA use in this population should be considered within the context of medical need and the efficacy and safety of alternatives.

Schneider and colleagues conducted a federally funded, multisite, randomized, double-blind, 36-week, placebo-controlled trial to determine the effectiveness of olanzapine, quetiapine, and risperidone, as compared with placebo, in 421 outpatients with AD and psychosis, aggression, or agitation (Schneider et al. 2006b). The primary outcome of median time to discontinuation of treatment for any reason ranged from 5 to 8 weeks, with no significant differences among the four groups.

Together, these studies suggest a modest therapeutic efficacy, if any, with the use of SGAs for psychosis and behavioral disturbances in patients with dementia, with probable small increases in the risk of cerebrovascular-related morbidity and mortality. The use of antipsychotics in this patient population should be assessed on a case-by-case basis, giving judicious consideration to the risks and benefits of neuroleptic and alternative treatment strategies. When antipsychotics are used in elderly patients, a lower dosage is indicated because of an age-related decline in drug metabolism, vulnerability to drug–drug interactions, a high incidence of comorbid physical illness, and a heightened sensitivity to EPS (Miyamoto et al. 2003a).

**Parkinson’s Disease and Huntington’s Disease**

Patients with Parkinson’s disease (PD) may experience psychotic symptoms, which are often induced by treatment with dopaminergic agents. These symptoms may improve with reduction in the dopaminergic medication dose, but this usually worsens Parkinsonism and is often not tolerated. In years past, FGAs were effectively used to alleviate psychotic symptoms in PD, but at the cost of considerable worsening of motor dysfunction (Buckley 2001). Although literature in this area is relatively sparse, a handful of open-label and double-blind, placebo-controlled studies have found that clozapine and quetiapine may offer a substantial benefit to this patient population by decreasing psychotic symptoms without significantly worsening Parkinsonism. In contrast, olanzapine and risperidone have produced mixed results regarding efficacy for PD-related psychosis, and more potential for EPS than clozapine or quetiapine.

Patients with psychiatric manifestations of Huntington’s disease (HD) may also benefit from antipsychotic medication (Marder 1997). As with PD, the use of FGAs in HD frequently worsens motor dysfunction (Buckley 2001). Several case reports and open-label studies suggest that risperidone, olanzapine, quetiapine, and ziprasidone may be efficacious and tolerable in the management of psychiatric symptoms of HD.

**Childhood Schizophrenia**

Childhood-onset schizophrenia is a rare and severe form of the disorder, characterized by the onset of psychotic symptoms before 13 years of age. Children with schizophrenia experience predominantly negative symptoms, but positive symptoms, most commonly auditory hallucinations, also occur (for review, see Masi et al. 2006). Functional decline may be marked.

Pharmacotherapy is usually necessary for the control of psychotic symptoms, and children with schizophrenia may require chronic antipsychotic treatment. One double-blind, placebo-controlled, crossover study found haloperidol to be superior to placebo for reduction of target symptoms in children with schizophrenia (Spencer et al. 1992). Unfortunately, the value of FGAs in children and adolescents is limited by this population’s sensitivity to certain adverse effects, including dysphoria, cognitive impairment, Parkinsonism, and akathisia.

SGAs have also shown efficacy in children and adolescents with schizophrenia and are felt by some to have a preferable side effect profile (for review, see Fleischhacker 2002). One double-blind, controlled trial compared clozapine and haloperidol in treatment-refractory, childhood-onset schizophrenia and found that clozapine had a striking superiority in reducing positive and negative symptoms, although observed neutropenia and seizures were major concerns with this drug (Kumra et al. 1996). Another double-blind RCT, comparing the efficacy and tolerability of treatment with risperidone, olanzapine, or haloperidol in children and adolescents with schizophrenia and/or affective psychoses and prominent positive symptoms, showed that all of the treatments were effective with similar magnitudes of improvement (Kikich et al. 2004). The majority of participants experienced at least mild-to-moderate weight gain, sedation, and/or EPS, but the two SGAs had a lower risk of acute, severe EPS than haloperidol. A double-blind RCT comparing clozapine with olanzapine in treatment-refractory childhood-onset schizophrenia demonstrated a superior clinical response with clozapine, particularly with respect to negative symptoms, though clozapine was also associated with a greater side effect burden (Shaw et al. 2006). A number of open trials and case reports indicate possible effectiveness for quetiapine, ziprasidone, and aripiprazole.

Unfortunately, as with FGAs, pediatric patients appear to have a greater susceptibility than adults to SGA-induced side effects, particularly EPS, weight gain, and dysphoria, but also hyperprolactinemia and leukocyte dyscrasias (for review, see Masi et al. 2006). SGA-associated weight gain is especially of concern in this population, given the worsening epidemic of childhood obesity and type II diabetes mellitus.
(T2DM). Metformin has shown some potential for mitigating weight gain in children treated with SGAs (Klein et al. 2006), but further research will be required to clarify the utility of this agent.

Other Conditions in Children and Adolescents

Patients with pervasive developmental disorders may demonstrate periods of hyperactivity, screaming, and agitation with combative ness. SGAs have shown some efficacy in treating these conditions. For example, in a randomized, double-blind trial involving children with autistic disorder accompanied by severe tantrums, aggression, or self-injurious behavior, risperidone was superior to placebo in reducing irritability and affecting meaningful clinical improvement (69% vs. 12%), but also caused substantially more weight gain (Mccracken et al. 2002). A number of case reports and open clinical trials with clozapine or olanzapine found an improvement in behavioral symptoms of pervasive developmental disorders with the use of these drugs. Some evidence suggests that SGAs may also be helpful in the management of conduct disorder and behavioral disturbances in children with borderline or impaired intellectual functioning.

Nonetheless, the increasingly widespread use of SGAs for the treatment of nonpsychotic disorders in children and adolescents (Olfson et al. 2006) is largely unsupported by empirical data. In particular, studies addressing the safety of this practice are limited. Further controlled studies are required to determine the role, if any, of antipsychotic agents in the treatment of nonpsychotic disorders among pediatric patients.

Effects of Antipsychotic Agents on Symptoms of Schizophrenia

Positive Symptoms

All antipsychotic agents are capable of ameliorating the “positive” symptoms of schizophrenia, including hallucinations, delusions, and disordered thought process. Control of these symptoms and associated behaviors is often critical to allowing patients to return to mainstream activities (Miyamoto et al. 2002).

In many patients with schizophrenia, FGAs are effective in alleviating positive symptoms and in preventing their recurrence (for review, see Miyamoto et al. 2002, 2003b). Approximately 30% of patients with acutely exacerbated symptoms, however, have little or no response to FGAs, and up to 50% have only a partial response (Fleischhacker 1995, Kane 1989). Because of this inconsistency in response, and because of the risk of EPS, some have argued that the only patients for whom FGAs are clearly preferable are those with a history of good response and tolerable side effects during treatment with an FGA (Schulz and McGorry 2000).

A number of double-blind, placebo- and active comparator-controlled studies have compared the efficacy and tolerability of SGAs with FGAs, or with other SGAs, in chronically schizophrenic patients with acute psychotic exacerbations (for review, see Markowitz et al. 1999, Miyamoto et al. 2003a, Remington and Kapur 2000). Despite great variation among individual trials in the proportion of patients who improve and the magnitude of therapeutic effects, these studies, and the carefully performed meta-analyses (Leucht et al. 1999) in which they were later included, suggest that SGAs as a group are at least as effective for psychotic symptoms as FGAs (for review, see Markowitz et al. 1999, Remington and Kapur 2000). The data are more equivocal, however, with regard to the hoped-for superiority of SGAs over FGAs.

Leucht and colleagues found modest to moderate efficacy advantages for SGAs over placebo, haloperidol, and low-potency FGAs, and greater tolerability for SGAs relative to haloperidol, but not relative to low-potency FGAs (Leucht et al. 1999, 2003b). Similarly, a large meta-analysis by Davis and collaborators concluded that the efficacy effect sizes for certain SGAs (clozapine, amisulpride, risperidone, and olanzapine) were significantly greater than the effect sizes for FGAs, and even those for other SGAs (Davis et al. 2003). In contrast, a meta-regression analysis by Geddes and colleagues showed no difference in efficacy between FGAs and SGAs when only trials that used 12 mg or less of haloperidol were included in the analysis, suggesting that the superior efficacy of SGAs observed in some trials may be due to a negative effect on efficacy of an excessively high dose of FGA comparator (Geddes et al. 2000).

It should be noted that, as with all meta-analyses, the studies described above were constrained by the biases and methodological limitations of the individual trials on which they were based. Most of these individual trials were sponsored and designed by the pharmaceutical industry, with narrow inclusion and exclusion criteria, moderate sample sizes, variable drug dosages, relatively short durations, and potentially bias-generating statistical methods (e.g., last-observation-carried-forward analyses), all of which could limit the generalizability of the results (Stroup et al. 2003). Furthermore, publication bias may have limited the data available for meta-analysis and potentially biased the findings in favor of SGAs.

Recently, two major, government-sponsored, multicenter RCTs succeeded in avoiding or minimizing many of these biases, and thereby provided some of the soundest evidence available for comparing FGAs and SGAs in the treatment of patients with schizophrenia. One of these, the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study, was the largest, longest, and most comprehensive independent trial ever conducted to examine existing pharmacotherapies for schizophrenia. The trial was intended to be “pragmatic,” involving a representative sample of 1,493 schizophrenic patients from numerous “real-world” outpatient settings and using a primary outcome measure—time to drug discontinuation — that captured both efficacy and tolerability. Subjects in the CATIE trial were randomized in a double-blind fashion to treatment with olanzapine (7.5–30.0 mg/day, mean dose of 20.1 mg/day), quetiapine (200–800 mg/day, mean dose of 534.4 mg/day), risperidone (1.5–6.0 mg/day, mean dose of 3.9 mg/day), ziprasidone (40–160 mg/day, mean dose of 112.8 mg/day), or the midpotency FGA perphenazine (8–32 mg/day, mean dose of 20.8 mg/day) for up to 18 months of treatment (Lieberman et al. 2005a).

In phase I of the study, a humbling 74% of patients discontinued their randomly assigned antipsychotic in less than 18 months, with olanzapine showing the lowest discontinuation rate and, thus, possibly the greatest effectiveness. All five medications displayed comparable changes in Positive
and Negative Syndrome Scale (PANSS) scores. Surprisingly, perphenazine was similar in efficacy and tolerability to the SGAs, suggesting that certain FGAs remain viable treatment options in chronic schizophrenia.

In phase II of CATIE, patients were treated in one of two pathways. Those who had discontinued their phase I drug because of insufficient therapeutic efficacy could be randomly allocated to open-label treatment with clozapine (n = 49), or blinded treatment with olanzapine (n = 19), quetiapine (n = 15), or risperidone (n = 16) (McEvoy et al. 2006). There were no significant differences in PANSS positive symptom subscores either between or within groups at baseline, 3 months, and 6 months, although the relatively small number of subjects could have affected power. Clozapine-treated patients were significantly less likely to discontinue for any reason compared to patients receiving risperidone or quetiapine, and significantly less likely to discontinue for inadequate therapeutic response compared to any other SGA.

In the other phase II pathway, 444 patients who had discontinued their phase I SGA due to intolerability or lack of efficacy were rerandomized to a different SGA (Stroup et al. 2006). Time to discontinuation for any reason was significantly longer for patients treated with olanzapine or risperidone than for those receiving quetiapine or ziprasidone. PANSS positive symptom subscale scores were significantly lower in the olanzapine group than in the other three, and in the risperidone group as compared to the ziprasidone group.

Jones and colleagues conducted the other recent, government-sponsored, multicenter RCT comparing FGAs and SGAs (Jones et al. 2006). The open Cost Utility of the Latest Antipsychotic Drugs in Schizophrenia Study (CUtLASS 1) assessed outcomes of QOL, symptoms, adverse effects, participant satisfaction, and costs of care over 1 year. CUtLASS 1 was funded by the National Health Service in the U.K. and was similar in design to CATIE (Lewis et al. 2006b). As in the CATIE trial, CUtLASS 1 found no advantage for SGAs in terms of PANSS total and positive subscale scores. In fact, patients treated with FGAs demonstrated a trend toward greater improvements in symptom scores, and neither inadequate power nor patterns of drug discontinuation accounted for the result. Like all studies, CUtLASS 1 had certain methodological idiosyncrasies that limit the generalizability of the results. For example, the protocol permitted clinicians to choose which antipsychotic agent, within the assigned class, they wished to prescribe for each patient; this resulted in the majority of patients in the FGA group receiving sulphiride, a substituted benzamide that is different from other FGAs in some respects (Lieberman 2006).

Negative Symptoms

Negative symptoms of schizophrenia include affective blunting, emotional withdrawal, poverty of speech, anhedonia, and apathy. They may be divided into three subtypes that are often difficult to distinguish clinically: (1) primary enduring (or deficit), (2) primary nonenduring, and (3) negative symptoms that are secondary to other causes, such as depression, positive symptoms, EPS or other iatrogenic effects, and substance misuse (Buchanan and Gold 1996, Murphy et al. 2006). Approximately 70% of schizophrenic patients develop primary negative symptoms before the onset of positive symptoms (Hafner et al. 1992). These represent a core feature of the illness and may be associated with long-term disability and prolonged hospitalization (Buchanan and Gold 1996).

FGAs are, in general, substantially less effective for negative than for positive symptoms of schizophrenia (for review, see Miyamoto et al. 2002). Therefore, the comparative efficacy of SGAs for negative symptoms has received much attention. Double-blind studies of individual SGAs have found evidence of efficacy for clozapine, risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, sertindole, zotepine, and amisulpride in the treatment of negative symptoms of schizophrenia. However, few of these studies have specifically examined the effect of SGA treatment on primary negative symptoms, and those that have reported little or no evidence of efficacy against this symptom domain. A notable exception is amisulpride, which does appear to demonstrate superiority over placebo and perhaps FGAs with regard to efficacy against primary or predominantly negative symptoms of schizophrenia.

In addition to these individual trials, several reviews and meta-analyses suggest that SGAs, as a group, may be more effective than FGAs against negative symptoms (Leucht et al. 1999, Tandon and Jibson 2003, Wahlbeck et al. 1999), though the effect sizes are moderate at best (Goff and Evins 1998, Leucht et al. 1999, Murphy et al. 2006). Ongoing debate exists as to whether these effects are related to a reduction in primary negative symptoms, secondary negative symptoms, or both. Path analyses have suggested that risperidone and olanzapine exert direct effects on primary negative symptoms, independent of changes in positive, depressive, or extrapyramidal symptoms (Moller 1993, Tollefson and Sanger 1997). However, these statistical approaches were performed post hoc, and only the most efficacious doses of the SGAs were used. Complicating matters further, one double-blind, placebo-controlled trial found that, in healthy individuals, single doses of haloperidol (5 mg) or risperidone (2.5 mg) produced observer-rated and self-rated negative symptoms without EPS, which may have been due to drowsiness (Artaloytia et al. 2006). This suggests that multiple properties of antipsychotic drugs may confound assessment of negative symptoms. Large, prospective studies comparing SGAs, FGAs, and placebo in patients with primary negative symptoms are needed to settle the issue.

The CATIE trial provides a notable opportunity to compare the effectiveness of multiple SGAs in the treatment of negative symptoms. In phase II of the study, there were no significant differences in PANSS negative symptom subscores either between or within treatment groups at baseline, 3 months, and 6 months (McEvoy et al. 2006). At 6 months, however, clozapine showed a trend toward greater reduction in negative symptom scores (−5.3), as compared to quetiapine (−1.1), olanzapine (−0.7), and risperidone (0.0). For patients randomized to receive olanzapine, quetiapine, risperidone, or ziprasidone in phase II, there were similarly no significant differences in PANSS negative symptom subscores among treatment groups at 12 months (Stroup et al. 2006). Thus, the results of CATIE phase II suggest only modest efficacy for SGAs in the treatment of general negative symptoms of chronic schizophrenia, with a probable small advantage for clozapine.
Encouragingly, there is growing evidence that adding certain augmentation agents to FGAs or SGAs may improve negative symptoms. Some glycine site agonists of NMDA receptors (e.g., glycine, d-cycloserine, and d-serine) and glycine transporter-1 inhibitors (e.g., sarcosine) appear to be effective in reducing negative symptoms when they are added to non-clozapine antipsychotic treatment (for review, see Miyamoto et al. 2005). Several selective serotonin reuptake inhibitors (SSRIs), including fluvoxamine, fluoxetine, and paroxetine, have shown efficacy for primary or undifferentiated negative symptoms, as adjuncts to FGAs or SGAs in placebo-controlled trials. Another antidepressant, mirtazapine, may also improve negative symptoms when used to augment haloperidol or clozapine. Double-blind, controlled trials using the neurosteroid dehydroepiandrosterone (DHEA), selegiline, Ginkgo biloba, naltrexone, or pergolide as augmenters of antipsychotic medication have suggested efficacy in the treatment of general negative symptoms of schizophrenia (for review, see Murphy et al. 2006). Many of these studies await replication.

Cognitive Symptoms
Cognitive impairment is now widely recognized as a core feature of schizophrenia, and almost all schizophrenic patients have some degree of such deficit, as compared to the level of cognitive function that would be expected of them based on premorbid factors (Keefe et al. 2005). Schizophrenics typically perform one to two standard deviations below normal on a variety of neuropsychological measures, particularly those that assess attention, verbal skills, processing speed, and executive function (for review, see Woodward et al. 2005). Progressive decline in cognitive function occurs before the onset of any other clinical manifestations of the illness, and a wide range of cognitive deficits is usually present by the time of the first psychotic episode. After the initial psychotic episode, cognitive deficits tend to remain relatively stable, or to worsen slowly (Harvey et al. 1999). Cognitive impairments are consistently and robustly associated with negative symptoms (Galderisi et al. 2002). They are also more closely related to social and vocational functioning than are positive symptoms, and may substantially impair activities of daily living and QOL (Green 1996, Harvey et al. 1998). Because cognitive deficits are among the strongest predictors of functional outcome in schizophrenia (Green et al. 2000), the targeting of these symptoms has become a major focus of treatment.

Prior to the 1990s, many believed that the cognitive deficits observed in schizophrenia are largely a side effect of FGAs (Heinrichs 2007). Cognitive performance may, in fact, be impaired by antipsychotic-induced EPS, anticholinergic effects, or sedation (Green and Braff 2001), as well as by anticholinergic or other anti-Parkinsonian agents used to treat EPS. More recent research, however, supports the century-old observation of Kraepelin and Bleuler that cognitive dysfunction is an intrinsic feature of the disease. Consequently, the view that antipsychotics are primarily unhelpful or even detrimental to cognitive performance has been replaced with optimism regarding the potential for medications to have a salubrious effect on cognition in schizophrenia (Heinrichs 2007).

A number of investigators have tested this hypothesis with FGAs and SGAs. Two quantitative reviews reported a significant advantage for SGAs over FGAs in several domains, including verbal fluency, vigilance, selective attention, secondary memory, and visuomotor skills (Harvey and Keefe 2001, Keefe et al. 1999), although these reviews have been criticized for the small number of studies they included (Woodward et al. 2005). More recently, Woodward and colleagues conducted two comprehensive meta-analyses (Woodward et al. 2005). The first of these analyzed 14 controlled studies in which patients were randomized to treatment with an SGA (clozapine, olanzapine, risperidone, or quetiapine) or an FGA. This analysis found SGAs to be superior to FGAs, haloperidol in particular, for ameliorating overall cognitive function, and specific improvements were noted in learning and processing speed. The second analysis, which included 41 uncontrolled, prospective trials of SGAs, further supported the benefits of SGAs for a wide array of cognitive functions.

It is unclear, however, whether the improvements observed with SGAs in these studies represent true cognitive enhancement or only a relative reduction in EPS- and anticholinergic-related cognitive effects, as compared with FGAs (Carpenter and Gold 2002, Harvey and Keefe 2001). This has led to debate as to whether lower doses of FGAs might show comparable efficacy to SGAs for cognitive symptoms of schizophrenia (Mishara and Goldberg 2004). Recent studies with improved methodology suggest that low doses of haloperidol may, in fact, have a less deleterious impact on cognitive function (Green et al. 2002, Keefe et al. 2004, 2006b, 2006c).

Furthermore, some studies have found mild benefits in cognitive performance with certain FGAs (Heinrichs 2007). The most compelling of these is the CATIE trial, in which the sole FGA included, perphenazine, yielded more improvement in cognition after 18 months than any phase I SGA (Keefe et al. 2007). Notably, the magnitude of cognitive improvement was small and probably not clinically significant for all agents assessed in this analysis.

Together, the variable results of the studies reviewed here suggest that FGAs and SGAs, when dosed properly, may yield at most modest improvements in the cognitive deficits of schizophrenia. Neither class appears to be clearly superior to the other.

Recognizing the need for new drugs to treat the cognitive symptoms of schizophrenia, the U.S. NIMH has introduced the Measurement and Treatment Research to Improve Cognition in Schizophrenia (MATRICS) initiative (Buchanan et al. 2005). One of the primary goals of MATRICS is to develop and facilitate the regulatory approval of novel procognitive agents. Studies in rodents, nonhuman primates, and patient populations have already revealed a number of potential molecular targets for improving cognition (Miyamoto et al. 2005).

Affective Symptoms
Depressive symptoms are common in all phases of schizophrenia, and are associated with poorer outcomes, impaired social and vocational functioning, lower QOL, and an increased risk of relapse and suicide (Burton 2006). The modal rate of comorbid depression in schizophrenia has been reported to be 25% (Siris 2000). When schizophrenic patients experience depressive features, differential diagnostic considerations should include major depression,
antipsychotic-induced side effects, demoralization, concurrent abuse of or sudden withdrawal from substances, schizoaffective disorder, and primary negative symptoms (Lehman et al. 2004).

FGAs have been found to have at least some degree of antidepressant activity in patients with schizophrenia (Siris 2000). SGAs also appear to improve affective symptoms in schizophrenia. Specifically, olanzapine, risperidone, quetiapine, amisulpride, and aripiprazole all have demonstrated greater efficacy than placebo and/or haloperidol in reducing depressive symptoms in this patient population. Clozapine has shown a significant effect on depressive symptoms in partially responsive and treatment-refractory schizophrenia. Whether there are differences among SGAs in their capacity for ameliorating depressive symptoms comorbid with schizophrenia has yet to be determined.

Antidepressants are often used in combination with antipsychotic drugs when schizophrenic patients experience depressive symptoms that meet the criteria for major depressive disorder, are causing significant distress, or are interfering with function. Several trials of tricyclic antidepressants added to FGAs support their use for acute and maintenance treatment of depressive symptoms in patients with stable schizophrenia (Hogarty et al. 1995, Siris et al. 1994). However, in one placebo-controlled trial, the addition of desipramine or amitriptyline to haloperidol in actively psychotic schizophrenic inpatients was associated with worsening of psychosis and no significant therapeutic advantage for depressive symptoms (Kramer et al. 1989). This and other studies suggest that tricyclic antidepressants may be successful for the treatment of depression in schizophrenia only once the acute psychotic episode has stabilized. As of yet, neither the use of SSRIs nor the addition of antidepressants to SGAs has been adequately studied in patients with schizophrenia and comorbid depression.

Suicidal Behavior
Suicidal behavior is common in schizophrenia. Approximately 50% of patients with schizophrenia or schizoaffective disorder attempt suicide, and about 10% “succeed” in taking their own lives. Although there is some evidence to suggest that FGAs probably reduce suicide risk to some extent, other studies suggest that side effects, especially akathisia, may be significant risk factors for suicide.

Among the SGAs, clozapine appears to possess particular antisuicidal properties. The International Suicide Prevention Trial (InterSePT), a double-blind RCT, compared suicidal behavior in 980 patients at relatively high risk for suicide, who were randomized to clozapine or olanzapine treatment and followed for up to 2 years (Meltzer et al. 2003). Approximately 25% of these patients had treatment-resistant schizophrenia. Suicidal behavior was significantly less common in patients treated with clozapine, as reflected by fewer patients attempting suicide, requiring hospitalizations or rescue interventions to prevent suicide, or requiring concomitant treatment with antidepressants, anxiolytics, or sopolitics. Although the InterSePT study has been criticized for certain methodological limitations, such as lack of blinding among patients and clinicians, the results were compelling enough to garner the U.S. FDA’s approval of an indication unique to clozapine: reduction of the risk of recurrent suicidal behavior in patients with schizophrenia or schizoaffective disorder.

Quality of Life
Marking a conceptual shift in therapeutic outcome criteria, QOL is now considered by many to be a key measure of response to antipsychotic treatment in schizophrenia (Karow and Naber 2002). Schizophrenic patients generally score very poorly on subjective and objective measures of QOL. Research suggests that several factors can affect QOL, including severity of symptoms, presence of anxiety or depression, age, antipsychotic-induced side effects, sociodemographic variables, and patients’ subjective responses to medication (Hofer et al. 2004).

The majority of recent QOL studies involve SGAs, and many use haloperidol as a comparator. Although most of these studies suffer from methodological and design limitations, a preponderance of evidence suggests a favorable impact on subjective QOL with at least some SGAs (Awad and Voruganti 1999, 2004). For example, in large double-blind trials, both clozapine and amisulpride produced greater improvements in Quality of Life Scale (QLS) scores than did haloperidol in patients with schizophrenia or schizoaffective disorder. Olanzapine, in contrast, has shown mixed QOL results relative to haloperidol.

As with other measures of antipsychotic drug response addressed above, CATIE and CUtLASS found no clear differences between SGAs and FGAs with respect to QOL. During phase I of the CATIE trial, there were no significant differences between perphenazine and any SGA, as measured by quality-adjusted life year ratings that combined measures of symptoms and side effects (Rosenheck et al. 2006). Similarly, CUtLASS 1 found no statistical advantage for SGAs in terms of QOL, symptoms, or associated costs of care across 1 year (Jones et al. 2006). In fact, patients treated with FGAs in CUtLASS 1 demonstrated a trend toward greater improvements in QLS and symptom scores, and neither inadequate power nor patterns of drug discontinuation accounted for these results.

CUtLASS 2, an extension of the National Health Service-funded, pragmatic, open, multicenter RCT, compared clozapine against other SGAs and found no statistically significant differences in QLS scores, but did detect a trend (p = 0.08) toward higher scores with clozapine (Lewis et al. 2006a).

Treatment of Different Phases of Schizophrenia

Treatment during the Acute Phase

Route of Administration
Antipsychotic medications may be available as tablets, liquid concentrates, orally-dissolving formulations, short-acting parenteral preparations, or long-acting preparations. In most cases, patients who are cooperative prefer oral to parenteral administration (Marder 1997). Even agitated patients will often accept oral medication. In a survey of 51 psychiatric emergency services, only an estimated 10% of patients required injectable formulations (Currier 2000). In general, oral medication should be offered whenever it is possible to communicate with the patient. Once given,
oral formulations tend to be rapidly and well absorbed from the gastrointestinal tract and reach a peak plasma concentration in 1–10 hours (Burns 2001). The long half-life and active metabolites of most oral antipsychotic drugs allow for once- to twice-daily dosing (Burns 2001, Marder 1997). Among SGAs, quetiapine and ziprasidone have relatively shorter half-lives (Table 102–4) and consequently are usually administered in divided doses. Once- or twice-daily dosing of an oral preparation will typically result in steady-state blood levels in 2–5 days, depending on half-life. One disadvantage to oral administration is that it may be less dependable than parenteral administration (Marder 1997). For example, sometimes patients will appear to accept oral medication but will actually “cheek” or spit the drug, rather than swallow it. Liquid concentrates or orally disintegrating tablets are available for some antipsychotics and may be used to circumvent this problem. A further disadvantage of oral antipsychotic administration is that pharmacokinetic factors such as hepatic disease or slow gastrointestinal absorption may increase the half-life of the drug and the time required to attain steady-state concentration (Marder 1997).

Short-acting IM formulations are particularly useful in the management of acute pathological agitation. Such formulations are commonly used to treat severely disturbed patients who cannot be verbally redirected, who may be violent, and who may require medication over objection. In these situations, many clinicians favor a combination of an antipsychotic and a benzodiazepine, often including an anticholinergic agent if a high-potency neuroleptic is being used (for review, see Miyamoto et al. 2003b). Most short-acting IM antipsychotic preparations reach a peak serum concentration approximately 30–60 minutes after administration. Parenteral administration bypasses first-pass metabolism in the liver and gut, resulting in greater bioavailability of the drug. A single IM injection of a high-potency FGA such as haloperidol or fluphenazine can result in rapid calming. This calming effect is thought to be the result of sedation and the patient’s perception of having his or her needs addressed. True antipsychotic effect was formerly believed to develop only after several days or weeks (American Psychiatric Association 2004). Kapur and colleagues, however, have presented evidence that the onset of antipsychotic action of IM haloperidol may occur within 24 hours of first injection (Kapur et al. 2005). A disadvantage of IM administration is the risk of injury to the patient and to the caregiver, usually by needle stick or accompanying physical

Selection of an Antipsychotic Agent

In addition to route of administration, clinicians selecting an agent for the acute management of agitation associated with psychosis should also consider the patient's clinical symptoms and history of response to individual agents, as well as differences in side effects and half-life of candidate drugs. An ideal medication would be available in parenteral and oral preparations, be well tolerated, and be effective in both acute and long-term settings (Miyamoto et al. 2003a).

First-Generation Antipsychotics

Many clinicians favor oral or IM preparations of high-potency FGAs (e.g., haloperidol) in the acute setting. These agents are felt to be reliable, and possibly safer than older alternatives such as low-potency FGAs and barbiturates (Allen 2000). Droperidol, a butyrophenone antipsychotic closely related to haloperidol, was formerly a popular agent for the control of acute agitation, but the drug received a “black-box” warning from the U.S. FDA in 2001 because of a risk of QTc prolongation, cardiac dysrhythmia, and death. Some authors still consider droperidol to be safe and effective when prescribed in appropriate doses with close monitoring (Marco and Vaughan 2005), but it is no longer routinely recommended for acutely agitated patients (Rund et al. 2006). As mentioned above, an anticholinergic agent is often coadministered when a high-potency antipsychotic is prescribed in the acute setting, in order to reduce the risk of EPS.

Second-Generation Antipsychotics

Many experts now recommend SGAs (except clozapine) as first-line treatment for schizophrenia, including in an acute episode (Kane et al. 2003b). One advantage of SGAs is their lower risk, compared with many FGAs, of akathisia and dystonia, which may worsen agitation. In general, sequential trials of individual SGAs are preferable to combining multiple antipsychotics at once. It is usually possible to safely and rapidly escalate the dose of SGAs in the psychiatric emergency setting. A strategy often used is to combine an oral SGA and a benzodiazepine (Allen et al. 2001). Some experts recommend reducing or discontinuing benzodiazepines once behavioral control is achieved.

A number of studies suggest that certain SGAs may possess antiaggressive properties. Clozapine, for example, appears to reduce aggression in chronically psychotic patients (Volavka et al. 2004), and this effect may be independent of the drug’s antipsychotic and sedative actions (Krakowski et al. 2006). However, rapid dose titration of clozapine for the treatment of aggression is contraindicated because of the potential for serious side effects, including seizure and agranulocytosis. Risperidone and quetiapine have also been found in some studies to specifically reduce hostility during acute psychotic episodes, but other studies have shown no such effect.

The above-mentioned studies notwithstanding, relatively little research has been conducted on the utility of SGAs in the management of acute aggression, and there has been less clinical experience with them than with FGAs. A major challenge in carrying out this research is the difficulty of obtaining informed consent from patients who are, by definition, hostile.

More attention is now being paid to the important clinical issue of SGA efficacy in first-episode schizophrenia. Two studies examined clozapine as an initial treatment (Lieberman et al. 2003a, Woerner et al. 2003), and neither found advantages that would warrant its use as a first-line agent. The European Foundation for Research in Schizophrenia is currently conducting the European First Episode Schizophrenia Treatment Trial (EUFEST), in which patients with first-episode schizophrenia are treated with ziprasidone, olanzapine, quetiapine, amisulpride, or low-dose haloperidol (Fleischhacker et al. 2005). It is hoped that this effort will inform the clinician’s difficult decision of which antipsychotic to initiate early in the course of the illness.

Antipsychotic Dose

The goal of pharmacotherapy is to maximize efficacy and minimize adverse effects with the lowest effective dose (Janicak and Davis 1996). Most current dosing guidelines rely on clinical impressions to achieve this goal. Not surprisingly, doses recommended in these guidelines often differ considerably, sometimes threefold or more (Davis and Chen 2004).

Determination of optimum antipsychotic dose is complicated by the fact that responses may differ from patient to patient and may differ across phases of the illness. For example, first-episode patients generally respond to lower...
antipsychotic doses than do patients with recurrent episodes (Robinson et al. 2005). Poor or partial responders may benefit from somewhat higher doses than robust responders (Davis and Chen 2005), and those in the maintenance phase may be treatable with lower doses than when they were acutely psychotic (Kane et al. 1983). The physiology of this variability is not well understood, but it seems likely that individual variation in pharmacokinetic factors and in brain receptor density and/or sensitivity plays a role.

Rapid Neuroleptization

Rapid neuroleptization was proposed decades ago as a strategy for managing agitation in acutely psychotic patients (for review, see Donlon et al. 1979). This practice involved the use of high doses of IM high-potency FGAs, usually haloperidol, administered repeatedly over a 24-hour period, until the patient demonstrated obvious sedation or other side effects (Donlon et al. 1979). In the years after the introduction of rapid neuroleptization, a number of well-controlled, double-blind studies comparing high-dose strategies with standard-dosage regimens revealed no significant superiority for high dosage in either degree or rapidity of response in acutely psychotic patients (for review, see Miyamoto et al. 2003a). Moreover, very high doses of FGAs produced a significantly greater incidence of EPS, particularly akathisia and akinesia, which can cause significant discomfort and worsen outcome. Thus, rapid neuroleptization has been largely abandoned as a therapeutic strategy.

A modified approach to rapid neuroleptization, called rapid initial dose escalation, was investigated in a randomized, double-blind study (Baker et al. 2003). One hundred forty-eight acutely agitated patients received treatment over 4 days with either 10 mg/day or up to 40 mg/day of olanzapine. Higher doses produced a more rapid and more robust reduction in the PANSS Excited Component, despite the fact that the 10-mg group received almost 20-fold more supplemental lorazepam.

Effective Doses of SGAs

Even after several decades of use, the optimum dose of FGAs, particularly haloperidol, is still debated. The “neuroleptic threshold hypothesis” contends that fine motor phenomena, as opposed to classic EPS, signal the minimum effective dose for many acutely psychotic patients (for review, see Janicak and Davis 1996, McEvoy et al. 1991). The “therapeutic window hypothesis” posits that therapeutic effects are not achieved until a certain dose or serum drug level is reached, and that these effects are lost beyond another, higher dose or drug level (Davis and Chen 2004). Most experts would agree that therapeutic effects do not continue to increase with very high FGA doses, but considerable controversy persists as to whether the efficacy of FGAs actually diminishes at higher doses. Geddes and colleagues argued that doses equivalent to 10–20 mg/day of haloperidol, the average rate and amount of improvement are likely to be no greater than for those assigned to more moderate doses, and may in fact be lower (Marder 1996).

Effective Doses of SGAs

The dosage recommendations for SGAs are summarized in Table 102-4. As with FGAs, optimal dosing of SGAs is a controversial issue. Many clinical trials of SGAs use placebo controls and active comparators, but the active comparator is usually given in one fixed dose or fixed dosage range, whereas the SGA may have more dosing options. This practice has led to much disagreement around the interpretation of such studies.

When risperidone was first released, a dose of 6 mg/day was recommended on the basis of data from large, fixed-dose trials (Marder and Meibach 1994), which found that 6 mg/day was associated with the greatest improvement and with rates of EPS comparable to placebo. A review of clinical trials and market research later concluded that the most effective dose with minimal side effects is 4–6 mg/day (Kasper 1998). Brain imaging studies support the use of lower doses of risperidone. For example, a PET study demonstrated that the mean D₂ occupancy in eight first-episode or drug-free schizophrenic patients who received 6 mg/day of risperidone was 82%, which is probably higher than necessary for achieving optimal clinical effects without EPS (Nyberg et al. 1999). After dose reduction to 3 mg/day, mean D₂ occupancy was 72%, suggesting that 3–4 mg/day may be an optimal dose. On the basis of naturalistic trials, clinical audit, phase IV trials, PET data, and 5 years of practical experience, Williams concurred that the optimal dose of risperidone with respect to efficacy and tolerability is 4 mg/day for most schizophrenic patients (Williams 2001). A randomized study of risperidone ER microspheres found the near-maximal effective dose to be approximately 50 mg/month, with 25 and 75 mg/month producing less improvement (Kane et al. 2003a).

The recommended starting dose of olanzapine is 5–10 mg/day. Ten to 20 mg/day has been shown in clinical trials to be an effective dose for most schizophrenic patients (for review, see Bhana et al. 2001). These findings are consistent with PET studies that demonstrated 71–80% striatal D₂ occupancy in schizophrenic patients treated with 10–20 mg/day of olanzapine (Kapur et al. 1998). Doses above 20 mg/day resulted in greater than 80% D₂ occupancy, EPS, and prolactin elevation. Nonetheless, in some cases, greater efficacy may be achieved at doses above 20 mg/day (Lieberman et al. 2005a, Volavka et al. 2002).

Dosing recommendations for clozapine vary two- to threefold between the U.S. and the Europe (Fleischhacker et al. 1994). This may be due to the fact that in the U.S. clozapine use is restricted to patients with severe treatment resistance, while in Europe the drug is used somewhat more flexibly.
Quetiapine has demonstrated superiority over placebo for the treatment of positive symptoms at dosages of more than 150 mg/day, and for negative symptoms at a dosage of 300 mg/day (Arvanitis et al. 1997). Clinical experience has shown that considerably higher doses of quetiapine may yield further benefit, and some practitioners will prescribe up to 1200 mg/day.

Several trials have found 150–300 mg/day of zotepine to be as effective as some FGAs in improving positive and negative symptoms of schizophrenia (Barnas et al. 1992, Cooper et al. 2000, Petit et al. 1996).

Sertindole in the dose range of 12–24 mg/day may reduce positive symptoms, whereas 20 mg/day may be required to improve negative symptoms (Zimbroff et al. 1997).

Conversely, lower doses of amisulpride (50–300 mg/day) have been found to improve negative symptoms (Boyer et al. 1995, Danion et al. 1999, Paillere-Martinot et al. 1995, Speller et al. 1997), while higher doses (400–800 mg/day) are sometimes necessary to control positive symptoms (Moller et al. 1997, Puech et al. 1998).

A number of short- and long-term double-blind trials have shown aripiprazole to be efficacious against psychotic symptoms in the dose range of 10–30 mg/day (for review, see Lieberman 2004). In these studies, increasing the dose above 15 mg/day did not appear to augment efficacy. Interestingly, in schizophrenic patients with an acute psychotic exacerbation, treatment with 5 mg/day of aripiprazole produced improvements in some outcome measures, including negative symptoms, but not in the PANSS total score (Cutler et al. 2006).

### Maintenance Treatment

#### Therapeutic Goals

The principal goals of treatment during the stable or maintenance phase are to preserve symptom remission, prevent psychotic relapse, implement a plan for rehabilitation, optimize functioning, and improve QOL (American Psychiatric Association 2004, Marder 1999). Antipsychotic medication is central to the achievement of these goals. A review of 24 double-blind studies of maintenance treatment with FGAs found that approximately 70% of patients who were switched to a placebo relapsed during the subsequent year, whereas only about 30% of patients receiving an antipsychotic agent suffered a relapse (Davis 1975, Gilbert et al. 1995).

Due to a paucity of long-term studies, the optimum duration of maintenance antipsychotic pharmacotherapy for schizophrenia has not been rigorously determined. Some guidelines recommend that first-episode patients be treated for 1–2 years; however, 75% of patients will relapse after this treatment is discontinued (Davis et al. 1994, Kissling 1991, Lehman and Steinwachs 1998). Schizophrenic patients who have suffered multiple psychotic episodes should receive at least 5 years of maintenance therapy (Kissling 1991), and in clinical practice many of these patients are treated indefinitely (Davis et al. 1994). Those with severe or dangerous episodes should likewise receive chronic antipsychotic pharmacotherapy.

#### Oral First-Generation Antipsychotics

The risk of FGA-induced long-term side effects, especially TD, inspired a search for strategies to reduce patients’ exposure to these agents while still providing adequate protection against psychotic relapse (Marder 1999). Studies of the dose–response relationship found that lowering the acute treatment dose by approximately 80% may be relatively safe during the maintenance phase, but that relapse rates are excessively high when the dose is reduced further (Marder et al. 1987, Hogarty et al. 1988, Kane et al. 1983). An international consensus conference recommended a gradual reduction in antipsychotic dose of approximately 20% every 6 months until a minimal maintenance dose is reached (Kissling 1991). A minimal maintenance dose was considered to be as low as, for example, 2.5 mg of oral fluphenazine or haloperidol daily, 50 mg of haloperidol decanoate every 4 weeks, or 5 mg of fluphenazine decanoate every 2 weeks (Kissling 1991). If this strategy is employed, patients should be followed closely, as a significant proportion will relapse during dose reduction. As noted previously, targeted or intermittent pharmacotherapy is associated with increased risks of symptom exacerbation, relapse and rehospitalization, and consequently should be avoided (Gaebel 1995).

#### Oral Second-Generation Antipsychotics

The potential of SGAs to delay psychotic relapse in patients with schizophrenia or schizoaffective disorder has been evaluated in a number of studies. Risperidone, olanzapine, and clozapine have each shown superior efficacy, relative to haloperidol or chlorpromazine, in reducing the rate of psychotic relapse. Fewer studies have investigated the effectiveness of other SGAs during the maintenance phase of treatment; however, a limited amount of evidence suggests that aripiprazole, zotepine, ziprasidone, and sertindole are capable of delaying relapse.

Phase I of the CATIE study provided a rare opportunity to compare the long-term effectiveness of multiple SGAs with that of an FGA. In this phase, treatment with olanzapine resulted in the lowest rate of discontinuation, the longest time to discontinuation, and the fewest hospitalizations, as compared with quetiapine, risperidone, ziprasidone, and perphenazine (Lieberman et al. 2005a). Another informative study prospectively followed a cohort of 2,230 patients hospitalized for the first time due to schizophrenia or schizoaffective disorder. Patients treated with perphenazine depot, clozapine, or olanzapine had a lower risk of rehospitalization and of all-cause discontinuation of their first treatment than did those treated with haloperidol (Tiibon et al. 2006). Finally, in a meta-analysis of relapse prevention studies comparing SGAs and FGAs, the rates of relapse and overall treatment failure were found to be modestly but significantly lower with SGAs (Leucht et al. 2003a). Important methodological limitations acknowledged by the authors included the choice of comparator FGAs, doses, relapse criteria, and adherence-monitoring protocols employed in the original studies.

Collectively, the studies described here suggest that some SGAs, such as clozapine and olanzapine, may be associated with a slightly greater reduction in relapse risk, relative to FGAs and other SGAs, during the maintenance phase of treatment.

#### Adherence

Reported rates of antipsychotic nonadherence (i.e., noncompliance) range from 20 to 89% (Dolder et al. 2002).
Consistent with this, a dispiriting 74% of patients in phase I of the CATIE study discontinued their medication before 18 months had elapsed, although these patients knew they were then allowed to be rerandomized to another agent in phase II (Lieberman et al. 2005a).

It is unclear whether FGAs and SGAs differ with respect to adherence rates. Some investigators have found no significant difference in adherence between the two classes of medication (Cabeza et al. 2000). Others have identified differences that approached significance (Olsson et al. 2000), and still others have reported a significant difference favoring SGAs in some measures of adherence (Rosenheck et al. 2000). The variability of these findings may be due to differences in methodology, specific medications evaluated, frequency of assessments, and/or treatment settings (Dolder et al. 2002).

In a first-episode algorithm study involving treatment with FGAs, Parkinsonian side effects increased the likelihood of medication nonadherence, and relatively better executive functioning decreased it (Robinson et al. 2002). This suggests that efforts to minimize side effects and improve cognitive deficits may enhance adherence (Robinson et al. 2005).

Long-Acting Formulations
Long-acting antipsychotics provide continuous medication delivery and reduce plasma drug level fluctuations. Long-acting depot formulations of FGAs, which were introduced in the 1960s, lowered relapse rates by an average of 15% compared to oral neuroleptics in six double-blind, randomized trials (Glazer and Kane 1992). A preparation of risperidone ER microspheres, the first long-acting SGA, demonstrated superior efficacy relative to placebo in a 12-week study (Kane et al. 2003a). The efficacy of long-acting risperidone is further supported by several open-label, flexible-dose studies involving stable patients. Studies comparing the efficacy of long-acting SGAs and long-acting FGAs are needed.

Treatment Resistance
One fifth to one third of all patients with schizophrenia experience significant psychotic symptoms despite adequate trials of pharmacological treatment, and are considered “treatment resistant” (Lieberman 1999b). Additional subsets of patients may be treatment intolerant, treatment noncompliant, or slow to respond (Conley and Kelly 2001). The exact definition of treatment resistance is controversial (for review, see Peuskens 1999). The most widely accepted criteria derive from the work of Kane and collaborators (1988). These criteria are strict and focus particularly on positive symptoms. Some of the more recent definitions of treatment resistance give greater weight to persistent negative symptoms and cognitive impairments, which have an important impact on level of functioning, psychosocial integration, and QOL (Conley and Kelly 2001, Peuskens 1999).

Clozapine
Clozapine is the only medication to consistently display efficacy for psychotic symptoms in well-defined, treatment-refractory patients, and it is the only antipsychotic approved by the U.S. FDA for this indication (Conley and Kelly 2001, Kane et al. 1988). The drug’s singular efficacy in treatment resistance was first conclusively demonstrated in a pivotal study involving 268 patients who were prospectively established to be treatment resistant using narrow criteria (Kane et al. 1988). Thirty percent of patients receiving clozapine responded at 6 weeks, compared to 7% treated with chlorpromazine. A subsequent review and meta-analysis of seven controlled trials comparing clozapine to an FGA in treatment-resistant schizophrenia found clozapine to be superior to FGAs in terms of overall psychopathology reduction, EPS, and compliance, although the magnitude of the drug’s therapeutic effect was not consistently robust (Chakos et al. 2001).

Other Second-Generation Antipsychotics
Investigators have explored the use of other SGAs in treatment-resistant schizophrenia, with largely uninspiring results. A few controlled trials did not detect a difference in efficacy between risperidone and clozapine (Bondolfi et al. 1998), but overall the literature does not provide convincing evidence of equivalence between the two drugs in treatment-resistant schizophrenia (Gilbody et al. 2000). Early clinical reports also suggested a possible role for high-dose olanzapine in the management of treatment-refractory schizophrenia (Dursun et al. 1999); however, a preponderance of evidence from controlled trials has not shown this strategy to be as effective as treatment with clozapine (Conley et al. 1998, Kelly et al. 2003). The CUTFASS 2 trial compared the effectiveness of clozapine with that of other SGAs ( amisulpride, olanzapine, quetiapine, and risperidone) in 136 schizophrenic patients with clinician-defined poor response to two or more antipsychotics (Lewis et al. 2006a, 2006b). Clozapine showed a statistically significant advantage with respect to total PANSS score, but not QOL or associated costs of care over 1 year.

Because of clozapine’s superior efficacy relative to FGAs and other SGAs, monotherapy with this agent represents the “gold standard” for treatment of patients with refractory schizophrenia. Unfortunately, side effects and the need for regular blood monitoring render it unsuitable as a first-line medication. Most experts recommend trials of other SGAs before proceeding to clozapine in almost all patients (Conley and Kelly 2001, Miyamoto et al. 2002). Certain patients may respond preferentially to a single agent of this class and potentially avoid the burden of treatment with clozapine. Clinicians should not, however, routinely withhold clozapine from patients who have failed treatment with multiple other agents.

Adjuvant Treatment
Even with clozapine treatment, a considerable number of patients do not respond or are only partially responsive. One strategy commonly employed in the management of such patients is to augment clozapine with other psychotropic medications. The evidence supporting this practice, however, is very limited. One group investigated the efficacy of clozapine as monotherapy and with sulpiride adjuvant pharmacotherapy, using a double-blind, placebo-controlled design (Shiloh et al. 1997). The clozapine-sulpiride group exhibited significantly greater improvement in positive and negative symptoms. RCTs assessing the augmentation of clozapine with risperidone in treatment-refractory schizophrenia have yielded inconsistent and largely negative findings. Lamotrigine has likewise produced mixed results in
this patient population. Adjuvant treatment with another anticonvulsant agent, topiramate, effectively reduced general psychopathological symptoms in one double-blind RCT involving patients with schizophrenia resistant to treatment with SGAs (Tiihonen et al. 2005).

In sum, no drug has consistently and repeatedly demonstrated efficacy as an adjuvant to clozapine in treatment-resistant schizophrenia. Consequently, antipsychotic polypharmacy should not routinely be employed in this population, as it may worsen side effects without conferring therapeutic advantage. Further controlled studies are needed to clarify the potential of other psychotropic agents to serve as adjuvants in treatment-resistant schizophrenia.

Use of Plasma Levels of Antipsychotic Drugs

The clinical use of plasma antipsychotic levels to guide dose titration remains controversial. Enormous inter-individual variation in plasma drug levels exists among patients treated with the same antipsychotic dose, and for most drugs there is at best a moderate correlation between these levels and clinical effects (Kane and Marder 1993, Van Putten et al. 1991). It is likely that advances in pharmacogenetics (the study of genetic variation that gives rise to differing responses to medication) will be required to elucidate the complex and idiosyncratic relationships among drug dosage, plasma level, therapeutic efficacy, and adverse effects in individual patients.

Nonetheless, it may be useful to monitor the plasma level of antipsychotic medication in certain circumstances. For example, before deciding that an agent is ineffective despite an adequate trial duration at a sufficient dose, it is important to determine whether lack of efficacy may be due to such factors as pharmacokinetic variables (e.g., cytochrome P450 oxidase polymorphisms) or medication nonadherence (Van Putten et al. 1991). A low plasma level (e.g., less than 5 ng/ml of haloperidol) at a normally therapeutic drug dose may prompt the clinician to raise the dose, investigate etiologies of poor absorption or accelerated metabolism, or address medication compliance. A high plasma level (e.g., greater than 15 ng/ml of haloperidol), on the other hand, may suggest lowering the dose, because adverse effects may be overshadowing therapeutic ones. This approach is practicable for the many FGAs for which therapeutic ranges have been established.

With clozapine, the case for routine plasma drug level monitoring is somewhat stronger. Miller and colleagues (1994) reported that plasma clozapine concentrations higher than 350 ng/ml were associated with greater likelihood of response in a small group of patients with treatment-refractory schizophrenia. Similarly, VanderZwaag and colleagues (1996) found that patients randomly assigned to receive treatment with clozapine at a serum level range of 200–450 ng/ml responded better than did patients receiving clozapine at a serum level range of 50–150 ng/ml. Given these and related findings, it is reasonable to monitor plasma drug levels during clozapine treatment, with the goal of titrating the dose to achieve levels between 200 and 400 ng/ml. This typically requires a clozapine dose of 300–400 mg/day (Lehman et al. 2004).

Drug Interactions and Antipsychotic Agents

Most antipsychotics are metabolized by the hepatic cytochrome P450 (CYP) system. The major CYP isoenzymes responsible for the metabolism of SGAs are CYP1A2, CYP2C19, CYP2D6, and CYP3A4. A notable exception is amisulpride, which is excreted relatively unmetabolized in the urine (Spina and de Leon 2007). SGAs have little effect on the elimination of other medications, and this represents an advantage over some FGAs, such as phenothiazines, which can potently inhibit CYP2D6 and other CYP isoenzymes, thereby increasing the levels of medications metabolized by this system (Spina and de Leon 2007). Plasma levels of SGAs are affected by drugs that induce or inhibit CYP isoenzymes, sometimes with consequences for antipsychotic efficacy and adverse effects. These interactions usually involve antidepressant and antiepileptic drugs, with the classic example being an up-to-10-fold increase in clozapine levels following addition of fluvoxamine. Table 102–5 summarizes clinically significant pharmacokinetic drug interactions affecting SGAs. With some FGAs, clearance can be decreased by co-administering certain heterocyclic antidepressants, beta-blockers, antibacterials, antifungals, or cimetidine; cigarette smoking, in contrast, increases clearance of high-potency FGAs (Ereshefsky 1996).

There are other common interactions that will concern clinicians. Via an unclear mechanism, valproic acid increases quetiapine levels by 70–80% (Spina and de Leon 2007). Antipsychotic medications can antagonize the effects of dopamine agonists and levodopa, agents used in the treatment of PD. Antipsychotics may also enhance the effects of central nervous system depressants, such as analgesics, anxiolytics, and hypnotics. Rarely, co-administration of clozapine and benzodiazepines can cause respiratory arrest.

In general, avoidance of unnecessary polypharmacy and readiness to adjust antipsychotic dosage based on clinical response, and possibly plasma drug concentration, will help to minimize adverse drug interactions (Spina and de Leon 2007).

Antipsychotic Medications and Pregnancy

A substantial number of women of childbearing age suffer from schizophrenia and other psychiatric disorders that require treatment with antipsychotic medication, and approximately one third of pregnant women with psychotic symptoms use antipsychotics at least once during pregnancy (Iqbal et al. 2005). Treatment with antipsychotic medication during pregnancy is likely to serve a protective function for women with schizophrenia, as antipsychotic discontinuation often leads to rapid relapse (Baldessarini and Viguera 1995, Gilbert et al. 1995). Such relapse may pose risks to the fetus and mother, including stillbirth, prematurity, small size for gestational age, difficulties with parenting, and, in the majority of cases, loss of custody (Nilsson et al. 2002, Yaeger et al. 2006).

Complicating matters, antipsychotic treatment itself incurs risks for the developing fetus. Most antipsychotics readily cross the placenta and are secreted into breast milk in some degree (Trixler and Tenyi 1997). Metabolite concentrations may be higher in the fetal than in the maternal circulation (Gentile 2004). Animal studies have shown evidence of teratogenic effects with most FGAs and SGAs (Iqbal et al. 2005). In human pregnancies, however, FGAs, particularly high-potency agents, appear to be relatively safe for the fetus (Lehman et al. 2004). For example, a multicenter, prospective, controlled cohort study evaluated the outcomes of 188 haloperidol-, 27 penfluridol-, and 631 non-teratogen-exposed
pregnancies and found that the rate of congenital anomalies did not differ between the antipsychotic-exposed group (3.4%) and the control group (3.8%) (Diav-Citrin et al. 2005).

There are fewer data regarding the safety of SGAs in human pregnancy. All SGAs have been assigned by the U.S. FDA to pregnancy category C (except clozapine, which is a category B agent), but the category C designation is more a reflection of the paucity of studies examining SGAs in pregnancy than of known risk. Most existing information concerning the outcomes of pregnancies during which the mother was treated with an SGA derives from case reports and two manufacturers’ data collections (Gentile 2004), and thus is subject to reporting bias. McKenna and colleagues conducted the first prospective, controlled study examining pregnancy outcomes in 151 women exposed to SGAs, including olanzapine, risperidone, quetiapine, and clozapine, during the first trimester (McKenna et al. 2005). In comparison to healthy control subjects, the exposed group showed no statistical differences in the rates of miscarriage, stillbirth, prematurity, delivery complications, congenital malformations, or perinatal syndromes. Exposed mothers did, however, have a higher body mass index (BMI), and their infants had lower birth weights than in the control group. Although this study did not find higher rates of caesarean section delivery, gestational diabetes, or pregnancy-induced hypertension in antipsychotic-exposed women, these remain concerns, given the association of some SGAs with obesity and diabetes.

Thus, the safety of antipsychotics in pregnancy remains an unresolved issue. More encouraging data exist for FGAs than for SGAs. The risk of antipsychotic treatment during breastfeeding is similarly unknown, and there are not sufficient data to ensure that the benefits of breastfeeding outweigh the risks of drug exposure to the infant. Whenever possible, patients should obtain a prepregnancy consultation to discuss with their clinician(s), partner, and family the known and potential risks and benefits of antipsychotic treatment during pregnancy. In negotiating this difficult decision, emphasis should be placed on optimizing the mother’s health and ability to parent (Yaeger et al. 2006). Social supports should be maximized during pregnancy and in the postpartum. If an antipsychotic agent is used, monotherapy at the lowest effective dose may help to minimize risks to the fetus.

### Adverse Effects

#### Acute Extrapyramidal Symptoms (Dystonia, Parkinsonism, and Akathisia)

Antipsychotic-induced EPS can occur acutely or after chronic treatment, and all antipsychotic medications are capable of producing EPS. In general, this liability is more pronounced with FGAs than with SGAs (see Table 102–6). Among FGAs, agents that possess a high potency with respect to the D2 receptor, such as haloperidol and fluphenazine, carry the highest risk of EPS. Mid- and low-potency FGAs pose less risk. Two recent, large-scale, prospective studies and one meta-analysis suggest that moderately dosed, mid- and low-potency FGAs may, in fact, cause no more EPS than most

Medications Used to Treat Extrapyramidal Side Effects

SGAs (Jones et al. 2006, Leucht et al. 2003b, Lieberman et al. 2005a). Among SGAs, clozapine and quetiapine are exceptional for carrying almost no risk of EPS (Dev and Raninwalla 2000, Kane et al. 1988, Small et al. 1997). In contrast, risperidone may produce dose-dependent EPS as often as some FGAs (American Psychiatric Association 2004, Gasquet et al. 2005), EPS with olanzapine, ziprasidone, and aripiprazole appear to be less common than with risperidone, but more common than with quetiapine or clozapine (American Psychiatric Association 2004).

Commonly occurring acute EPS include Parkinsonism, dystonia, and akathisia. Acute EPS typically develop within hours to weeks of antipsychotic initiation. These movement disorders are dose dependent and almost always reversible, remitting after the offending agent is discontinued (American Psychiatric Association 2004, Casey 1995). It has been estimated that more than 60% of patients who receive acute treatment with FGAs develop some form of clinically significant EPS (American Psychiatric Association 2004), though the evidence for this comes primarily from studies of high-potency agents administered at very high doses. The increasing use of SGAs is believed to have substantially reduced the burden of acute EPS.

Medication-induced Parkinsonism is the most common form of EPS caused by FGAs (American Psychiatric Association 2004). The disorder usually occurs within days to weeks of antipsychotic treatment initiation, and is characterized by rigidity, tremor, and bradykinesia. Care should be taken to distinguish these patients from those with depression, catatonia, or the negative symptoms of schizophrenia (American Psychiatric Association 2004). Medication-induced Parkinsonism occurs most commonly with high-potency antipsychotics, especially when anticholinergic medication is not administered concurrently. Other risk factors include older age, higher dose, a history of Parkinsonism, and underlying basal ganglia damage (Marder 1997).

Dystonia presents as sustained muscular contraction, with contorting, twisting, or abnormal posturing affecting mainly the muscles of the head and neck, but sometimes the trunk or extremities. It tends to be sudden in onset, with 90% of cases occurring in the first 3 days of antipsychotic treatment (American Psychiatric Association 2004). Dystonia is often dramatic in presentation and may be extremely disturbing for patients. Laryngeal dystonia is potentially fatal, as it may compromise the airway. Risk factors for acute dystonias include a history of prior dystonia, young age, male gender, use of high-potency antipsychotic agents, higher dose, and IM administration (American Psychiatric Association 2004).

Akathisia is characterized by both subjective and objective somatic restlessness. Patients with akathisia typically experience an inner sensation of restlessness or an irresistible urge to move various parts of their bodies (American Psychiatric Association 2004). The disorder appears objectively as psychomotor agitation, such as continuous pacing, rocking from foot to foot, or the inability to sit still. Akathisia usually begins within hours to days of antipsychotic administration (Casey 1993) and can occur in as much as 25% of patients treated with FGAs (Braude et al. 1983). It can be extremely distressing for patients and may contribute to medication nonadherence or self-injurious behavior (American Psychiatric Association 2004).

Patients should be monitored for EPS at weekly intervals during antipsychotic initiation and until their medication dose has been stable for at least 2 weeks (Marder et al. 2004). The treatment of acute EPS depends on the specific side effect (see Table 102–7).

The initial treatment of Parkinsonism is to lower the antipsychotic dose, since doses above the EPS threshold are unlikely to yield additional clinical benefit (American Psychiatric Association 2004). If symptoms persist, switching to an antipsychotic associated with fewer EPS should be considered. Alternatively, adding an anticholinergic agent or dopaminergic medication (e.g., amantadine) may be efficacious, though these drugs carry their own risk of adverse effects and so should be used sparingly (American Psychiatric Association 2004).

Acute dystonia responds rapidly to treatment with an anticholinergic (e.g., benztpoline) or an antihistaminergic (e.g., diphenhydramine) agent, especially when administered parenterally. Oral anticholinergic medication should then be continued for a few days to prevent dystonia recurrence.

Initial treatment options for akathisia include lowering the antipsychotic dose, or switching to an antipsychotic agent with a lower risk of akathisia. If symptoms persist, or if psychotic symptoms necessitate a higher antipsychotic dose, individual trials of β-adrenergic antagonists (e.g., 30–90 mg/day of propranolol) or benzodiazepines may be attempted; anticholinergic agents, in contrast, are generally less effective for akathisia (American Psychiatric Association 2004, Casey 1993, Miller and Fleischhaeker 2000).

Because of the frequency with which acute EPS occur, especially with high-potency agents, clinicians may wish to consider the prophylactic use of anticholinergic agents. In a large, double-blind, randomized trial conducted at the U.S. Department of Veterans Affairs, patients taking olanzapine did not experience significantly fewer EPS overall than those taking haloperidol plus benztropine, though less akathisia

TD is a repetitive, involuntary, hyperkinetic movement disorder caused by months to years of exposure to antipsychotic medication. It has been associated with reduced QOL and with increased morbidity and mortality to antipsychotic medication. It has been associated with neuroleptic anticholinergic medication is optimized when the anticholinergic drug is used at the lowest effective dose, with and with those patients at highest risk for EPS, such as those with a history of EPS and those taking a high-potency antipsychotic.

Chronic Extrapyramidal Symptoms (Tardive Dyskinesia and Related Syndromes)

TD is characterized most commonly by orofacial movements, such as lip-smacking, chewing, and tongue protrusion, and also by choreoathetoid movements of the neck, limbs, trunk, and occasionally the diaphragm (American Psychiatric Association 2004, Casey 1999, Glazer 2000). Younger patients with TD tend to exhibit slower, athetoid movements of the trunk, extremities, and neck (Marder 1997). The abnormal movements of TD usually increase with emotional arousal and are absent during sleep (Marder 1997). According to the diagnostic criteria proposed by Schooler and Kane (1982), the movements should be present for at least 4 weeks, and exposure to antipsychotic drugs should be increased at least 3 months. Dyskinetic movements should begin either while the patient is receiving an antipsychotic agent or within a few weeks of discontinuing an antipsychotic.

Less common than the choreoathetoid movements described above are variants of TD known as tardive dystonia and tardive akathisia. These syndromes resemble their acute counterparts, but by definition emerge after longer term antipsychotic treatment. Tardive dystonia and tardive akathisia can be particularly disabling, and often persist despite antipsychotic discontinuation. More than one variant of TD may be present simultaneously.

Determination of the risk of antipsychotic-induced TD is complicated by the observation that spontaneous dyskinesias occur in some never-medicated schizophrenic patients, and thus are part of the natural history of the disease (American Psychiatric Association 2004). Prevalence surveys indicate that mild forms of TD occur in approximately 20% of patients who receive chronic treatment with FGAs (Casey 1995, Kane and Lieberman 1992), and 10% of patients with TD experience moderate or severe symptoms (American Psychiatric Association 2004). A large, prospective study found the cumulative incidence of TD in patients receiving an FGA to be 5% after 1 year, 10% after 2 years, 15% after 3 years, and 19% after 4 years (Kane et al. 1986). Among the predictors of TD are older age, a history of EPS, substance abuse, duration of antipsychotic exposure, and possibly antipsychotic dose (Casey 1999, Miller et al. 2005). Prevalence rates of TD may exceed 50% in high-risk groups, such as the elderly (Casey 1995). The prevalence of tardive dystonia has been estimated to be between 1.5 and 4% (Barnes and McPhillips 1998).

TD has been observed with all antipsychotic drugs (American Psychiatric Association 2004). Given that EPS represent a risk factor for later development of TD, and in light of the relatively lower liability of SGAs to cause EPS, it is reasonable to expect that SGAs should cause less TD than FGAs, at least as compared with high-potency FGAs. The strongest evidence for this hypothesis exists for clozapine (Casey 1999). In addition, a recent review found that SGAs as a class pose less risk of TD than the high-potency FGA haloperidol, but acknowledged that supporting trial data are limited (Correll et al. 2004). The CATIE investigators concluded that patients being treated with an FGA at baseline were more likely to have TD than those not taking an FGA (Miller et al. 2005), but also found that, among patients without a history of TD, treatment with the midpotency FGA perphenazine during the study did not pose more of a risk of abnormal involuntary movements than treatment with an SGA (Lieberman et al. 2005a). Carefully designed, long-term, prospective comparison studies are needed to clarify the relative risks of TD among the available antipsychotic agents.

Management of TD begins with monitoring. Patients should be evaluated for signs of dyskinesia before beginning treatment with an antipsychotic agent, and every 3 months during treatment (American Psychiatric Association 2004). If dyskinetic movements emerge, a neurological evaluation should be considered to rule out other etiologies.

If TD develops in the context of FGA treatment, the clinician may consider reducing the antipsychotic dose, or switching to an SGA. Either of these approaches may paradoxically cause an initial worsening of TD, but in many cases TD will eventually improve or resolve. Switching to an SGA soon after TD develops may be advisable, as the likelihood of TD reversibility declines with sustained exposure to the offending FGA (American Psychiatric Association 2004). While most SGAs have been observed to reverse FGA-induced TD, clozapine is the best supported of these, with reported efficacy against TD and tardive dystonia (Casey 1999).

Although a large number of other agents have been examined for their potential therapeutic effects on TD, there is no known definitive pharmacological treatment. Numerous studies have investigated the potential benefits of benzodiazepines, anticholinergic agents, calcium channel blockers, y-aminobutyric acid agonists, essential fatty acids, estrogen, insulin, and other drugs, without encouraging results (American Psychiatric Association 2004, Casey 1999). Several small trials support a protective function of vitamin E against TD deterioration, but there is no evidence that vitamin E improves TD symptoms (Soares and McGrath 2001). Given the very low incidence of side effects with vitamin E, patients may be prescribed 400–800 IU daily for possible prophylaxis against development or worsening of TD (American Psychiatric Association 2004).

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS) is characterized by the triad of rigidity, hyperthermia (>38°C), and autonomic instability (especially tachycardia and blood pressure lability), occurring in association with the use of antipsychotic medication. NMS is often associated with an elevated serum creatine kinase level, leukocytosis, and...
alteration in level of consciousness. The disorder usually develops during the initial weeks of antipsychotic treatment, and can be sudden in onset. NMS is a psychiatric emergency that should be distinguished from such differential diagnostic considerations as serotonin syndrome, sepsis, endocrinopathy, and heat stroke. If not diagnosed and treated promptly, death can occur in 5–20% of cases (American Psychiatric Association 2004).

NMS is relatively rare, occurring in less than 1% of patients treated with FGAs (Caroff et al. 1998). The relative risk of NMS among SGAs is likely to be even lower, but conclusive data are not yet available. Proposed risk factors include a prior episode of NMS, younger age, male gender, acute agitation, physical illness, dehydration, use of high-potency antipsychotics, rapid dose titration, use of IM preparations, and preexisting neurological disability (American Psychiatric Association 2004).

If NMS is suspected, the offending antipsychotic agent should be discontinued immediately, and the patient should be transferred to a medical setting where supportive treatment can be initiated. Small studies suggest that dantrolene and dopaminergic drugs such as bromocriptine and amantadine may decrease NMS-associated mortality, compared with supportive treatment alone (Caroff et al. 1998). Electroconvulsive therapy has also been reported to be effective in treatment-refractory NMS; however, it should be used with caution given the occurrence of several cases of cardiac arrhythmia (Caroff et al. 1998).

After several weeks of recovery, an antipsychotic agent may be gradually reintroduced. Generally, an SGA or lower potency FGA is selected, and the dose is titrated slowly while observing for signs of NMS recurrence (American Psychiatric Association 2004).

**Endocrine and Sexual Effects**

All FGAs can elevate serum prolactin levels by antagonizing the tonic inhibitory actions of dopamine on lactotrophic cells in the pituitary (American Psychiatric Association 2004). Among SGAs, risperidone and amisulpride can increase serum prolactin levels to an extent comparable to FGAs (Grunder et al. 1999, Haddad and Wieck 2004, Yasui-Furukori et al. 2002). In contrast, quetiapine, clozapine, and aripiprazole do not elevate serum prolactin levels, and olanzapine causes hyperprolactinemia only at high doses (Haddad and Wieck 2004, Turrone et al. 2002, Worrel et al. 2000). Ziprasidone is uncommonly associated with prolactin elevation. Although some patients develop partial tolerance to the pituitary effect of antipsychotics after several weeks, most have chronic serum prolactin elevation so long as antipsychotic treatment is continued (Haddad and Wieck 2004).

Women experience, on average, significantly greater elevation in prolactin than do men during long-term treatment with the same antipsychotic dose (Haddad and Wieck 2004). Hyperprolactinemia may manifest differently in men and women, and there is great individual variation in the prolactin level at which symptoms appear (Haddad and Wieck 2004). In women, prolactin elevation often leads to menstrual disturbances, including anovulatory cycles and infertility, menses with abnormal luteal phases, or frank amenorrhea and hypoestrogenemia. Women may also experience decreased libido, impaired arousal, anorgasmia, and, at least theoretically, increased long-term risk of osteoporosis. Approximately 20% of women develop galactorrhea during treatment with an FGA (Windgassen et al. 1996), and one large, retrospective study found dopamine antagonist use to be associated with a 16% increase in the risk of breast cancer (Wang et al. 2002). The major effects of hyperprolactinemia in men are loss of libido, hypospermatogenesis, erectile or ejaculatory deficits, and occasionally galactorrhea or priapism. Antipsychotic-induced sexual side effects can be particularly bothersome for some patients, while for others sexual dysfunction associated with schizophrenia itself may improve with antipsychotic treatment (Haddad and Wieck 2004). A large, manufacturer-funded, observational study found that patients treated with olanzapine or quetiapine experienced significantly less sexual dysfunction than those treated with risperidone or haloperidol (Dossenbach et al. 2006).

Clinicians should screen for signs and symptoms of hyperprolactinemia prior to and during treatment with prolactin-elevating antipsychotics (Marder et al. 2004). If symptomatic hyperprolactinemia is present, consideration should be given to lowering the antipsychotic dose or to switching to a “prolactin-sparing” agent. If this is impractical or ineffective, a dopaminergic drug, such as bromocriptine, amantadine, or cabergoline, can be considered, though these medications carry a small risk of psychotic relapse (Haddad and Wieck 2004).

**Weight Gain and Obesity**

Obesity can negatively affect self-image, impair social adjustment, and reduce medication compliance (Marder et al. 2004). Furthermore, it can have serious deleterious effects on health and life expectancy via a number of disease processes, including hypertension, coronary artery disease, osteoarthritis, T2DM, stroke, sleep apnea, and certain cancers. Approximately half of all people with schizophrenia meet criteria for obesity, representing a relative risk of nearly two when compared with the general population (Newcomer 2007). Genetic and lifestyle factors may contribute to this phenomenon, but in large measure antipsychotic-induced weight gain is responsible. Up to 40% of patients treated with FGAs gain weight, with low-potency agents posing the greatest risk and high-potency FGAs causing minimal mean weight increases (American Psychiatric Association 2004). Differences have also been discovered among SGAs with respect to weight gain (Table 102–6). One meta-analysis estimated weight change after 10 weeks of treatment at standard antipsychotic doses and found mean increases of 4.45 kg with clozapine, 4.15 kg with olanzapine, 2.10 kg with risperidone, and 0.04 kg with ziprasidone (Allison et al. 1999). Quetiapine appears comparable to risperidone with respect to short-term weight gain, and aripiprazole resembles ziprasidone in being weight neutral (Newcomer and Haupt 2006). Longer-term antipsychotic-induced weight gain follows a similar, hierarchical pattern. Pooled analyses, for example, suggest that aripiprazole and ziprasidone are associated with a gain of about 1 kg over 1 year, amisulpride with a gain of 1.5 kg over the same period, quetiapine and risperidone with a gain of 2–3 kg, and olanzapine with a gain of greater than 6 kg (Newcomer and Haupt 2006). Clozapine appears to cause at least as much long-term weight gain as olanzapine.
The mechanism of action underlying antipsychotic-induced weight gain has been hypothesized to involve changes in appetite and satiety mediated by H1 receptor antagonism (Newcomer 2007). Consistent with this hypothesis, antipsychotics possessing high affinity for H1 receptors, such as clozapine, olanzapine, thioridazine, and chlorpromazine, are associated with considerable weight gain potential. Agents with little H1 affinity, such as aripiprazole, ziprasidone, and haloperidol, tend to be more weight neutral. Antagonism of 5-HT2C receptors may also contribute to antipsychotic-induced weight gain.

Recognizing the considerable potential for obesity to impact negatively on morbidity and mortality, expert consensus guidelines recommend frequent monitoring of BMI, computed by using the formula kg/m2, for every patient with schizophrenia (American Diabetes Association et al. 2004, Marder et al. 2004). As defined by the World Health Organization, a BMI between 18.5 and 25 is “normal,” while 25–30 is “overweight” and ≥30 is “obese” (Newcomer 2007). Waist circumference monitoring is also recommended, as central obesity is a risk factor for diabetes, hypertension, and dyslipidemia, independent of BMI. A waist circumference of >102 cm (>40 in.) in men or >88 cm (>35 in.) in women is indicative of abdominal obesity (Newcomer 2007). Most experts agree that, for patients with a baseline BMI ≥ 25, the relative weight gain potential of the various antipsychotics should be a consideration in medication selection (Marder et al. 2004), and some have advocated avoiding SGAs with the greatest weight gain propensity as first-line treatment (Sernyak 2007). Clinicians should encourage exercise and a healthy diet in all schizophrenic patients to prevent initial weight gain and obesity, since subsequent weight loss is often very difficult. Unless a patient is underweight (BMI < 18.5), an increase of one BMI unit should prompt an intervention, such as engagement in a weight management program, use of an adjunctive agent to reduce weight, or consideration of an antipsychotic with less weight gain potential (Marder et al. 2004). Similarly, a waist circumference ≥35 in. in a woman or ≥40 in. in a man should prompt an intervention. Behavioral therapy programs involving self-monitoring, stimulus control, diet, and exercise have shown efficacy for short-term weight loss and prevention of weight gain in antipsychotic-treated patients, but few long-term studies of behavioral therapy have been undertaken in this population (Ganguli 2007). Although no pharmacological interventions for antipsychotic-induced weight gain have demonstrated proven efficacy, small controlled trials suggest possible benefit with amantadine, topiramate, reboxetine, and sibutramine (Faulkner and Cohn 2006). Metformin was not effective in preventing weight gain in olanzapine-treated adults, but did stabilize weight in a small group of SGA-treated children and adolescents (Klein et al. 2006).

**Diabetes**

The prevalence of T2DM is twice as high among patients with schizophrenia as in the general population (Dixon et al. 2000), placing these patients at increased risk of coronary artery disease, stroke, peripheral vascular disease, retinopathy, nephropathy, neuropathy, and ketoacidosis. Data are rapidly accumulating that indicate that some SGAs increase this burden. Clozapine and olanzapine, for example, are more often associated with T2DM than are FGAs or other SGAs (American Diabetes Association et al. 2004, Newcomer and Haupt 2006). One study found that during 5 years of treatment with clozapine, 37% of patients received a diagnosis of T2DM (Marder et al. 2004). It is unclear whether the risk of T2DM with clozapine and olanzapine is entirely accounted for by the relatively greater increase in adiposity associated with these agents, or whether an additional mechanism is partially responsible, such as a direct effect of the drugs on insulin-sensitive target tissues. Studies investigating the risk of T2DM with quetiapine and risperidone have produced discrepant results, whereas the limited data available for ziprasidone and aripiprazole suggest that these agents do not predispose to T2DM (American Diabetes Association et al. 2004, Newcomer and Haupt 2006).

Expert consensus guidelines recommend measurement of baseline plasma glucose level before starting a new antipsychotic agent; a fasting glucose level is preferred, but a hemoglobin A1c level is acceptable (Marder et al. 2004). Elevation of either of these levels (>100 mg/dl and >6.1%, respectively) should prompt a referral to a primary care provider for management. Fasting plasma glucose or hemoglobin A1c measurement should be repeated 3–4 months after antipsychotic initiation, at least annually thereafter, and whenever a patient endorses symptoms of new-onset diabetes (American Diabetes Association et al. 2004, Marder et al. 2004). Clinicians should inquire and educate patients about the symptoms of new-onset diabetes, which include weight loss, polyuria, polydipsia, and blurry vision. Laboratory or symptomatic evidence of diabetes should lead to a primary care referral.

**Dyslipidemia**

Elevated lipid levels, particularly low-density lipoprotein (LDL) and triglyceride (TG) levels are associated with coronary artery disease and myocardial infarction. Clozapine and olanzapine increase total cholesterol, LDL, and TG levels significantly, as compared with FGAs and other SGAs (American Diabetes Association et al. 2004, Lieberman et al. 2005a, Marder et al. 2004, McEvoy et al. 2006, Newcomer and Haupt 2006). Quetiapine and risperidone appear to raise cholesterol levels modestly, whereas ziprasidone and aripiprazole are cholesterol neutral (American Diabetes Association et al. 2004).

Because patients with schizophrenia are, as a group, at increased risk of coronary artery disease, lipid levels should be monitored more frequently than in the general population. Consensus guidelines recommend that a complete lipid panel be obtained once every 2 years so long as the LDL level is normal (≤130 mg/dl), and every 6 months when the level is greater than 130 mg/dl (Marder et al. 2004). If lipid abnormalities are present, the clinician should refer the patient to a primary care provider. If this is not possible, the clinician should advise the patient to reduce dietary fat intake, and should be prepared to prescribe a lipid-lowering drug in the event that cholesterol levels do not normalize with this intervention (Marder et al. 2004).

**Metabolic Syndrome**

MS is defined by three or more of the following criteria: abdominal obesity (waist circumference ≥35 in. for women or ≥40 in. for men), elevated fasting TGs (≥150 mg/dl), decreased high-density lipoprotein (<40 mg/dl for men or
<50 mg/dl for women), hypertension (≥130/85 mm Hg or on antihypertensive medication), and elevated fasting glucose (≥100 mg/dl or on diabetes medication). Patients with this constellation of conditions may be at even greater risk of cardiovascular disease than those with isolated obesity, T2DM, or dyslipidemia. One study found that a diagnosis of MS was associated with a three-fold increase in risk of both coronary artery disease and stroke over a 7-year period (McEvoy et al. 2005).

As with individual components of MS, the complete syndrome is distressingly common among patients with schizophrenia, especially those that have been treated with antipsychotics. For example, among patients entering the CATIE trial, 53% of women and 36% of men met criteria for MS (McEvoy et al. 2005). Compared to matched controls, women and men were, respectively, 251 and 138% more likely to have MS. Even when controlling for differences in BMI, CATIE subjects were still substantially more likely to have MS than controls. The CATIE investigators concluded that MS is “highly prevalent in U.S. schizophrenia patients and represents an enormous source of cardiovascular risk, especially for women” (McEvoy et al. 2005). Further complicating antipsychotics as contributors to MS risk, a 26-week, randomized, double-blind study found an MS worsening incidence of 19% with olanzapine treatment, 13% with placebo, and 8% with aripiprazole (Newcomer and Haupt 2006).

Unfortunately, metabolic and cardiovascular disorders are often not adequately treated in this population. In CATIE trial subjects at baseline, nontreatment ranged from 30% for diabetes, to 62% for hypertension, to 88% for dyslipidemia (Nasrallah et al. 2006). Given the high prevalence of MS among patients with schizophrenia, and the morbidity and mortality risks conferred by the syndrome, clinicians should vigilantly screen for and promptly treat component disorders of MS in the manner outlined in the preceding sections. When the complete syndrome is present, collaboration with a primary care physician is particularly important.

Cardiovascular Effects
In addition to coronary artery disease, common cardiovascular effects of antipsychotic agents include orthostatic hypotension, sinus tachycardia, and electrocardiogram (ECG) changes.

Orthostatic hypotension occurs most frequently with low-potency FGAs and clozapine, as a result of their high \( \alpha_1 \)-adrenergic affinities, but may be seen with other agents as well. Orthostatic hypotension is most likely to occur early in treatment and with dose titration. Patients should be assessed regularly during these times for vital sign changes consistent with orthostatic hypotension and for symptoms such as dizziness, light-headedness, presyncope, and syncope. Those with pronounced symptoms should be cautioned against rising quickly. Elderly patients are particularly vulnerable to this side effect, which may predispose to falls and related injuries (American Psychiatric Association 2004). Most patients develop tolerance to the orthostatic effects of antipsychotics over a period of weeks. Gradual dose titration often reduces the risk of orthostatic hypotension. Management strategies include reducing or dividing the medication dose, or switching to an antipsychotic with a lower \( \alpha_1 \)-adrenergic affinity. Supportive measures include the use of support stockings, an increase in dietary salt intake, and, in severe cases, administration of the corticosteroid fludrocortisone to augment intravascular volume (American Psychiatric Association 2004).

Sinus tachycardia may result from the anticholinergic effects of antipsychotic medications, or be secondary to orthostatic hypotension. Tachycardia can occur with any antipsychotic agent, but is especially common with clozapine, affecting approximately 25% of patients treated with the drug (Lieberman 1998). While an increase in resting heart rate may be well tolerated in most patients, caution should be exercised when treating elderly patients and those with preexisting heart disease (American Psychiatric Association 2004). If tachycardia is sustained or accompanied by symptoms of cardiac ischemia, an ECG should be obtained and a serum marker of myocardial damage (e.g., troponin or creatine kinase MB) should be considered. In the absence of hypotension, tachycardia due to antipsychotic-associated anticholinergic effects can be managed with low doses of a peripherally acting beta-blocker, such as atenolol (Lieberman 1998).

Abnormalities in cardiac electrophysiology, as reflected in ECG changes, have been observed with most antipsychotic agents (Glassman and Bigger 2001). Prolongation of the QTc interval, especially beyond 500 ms, is of particular concern because it increases the risk of torsades de pointes (TdP), a ventricular tachyarrhythmia that can lead to sudden death. While modest, dose-dependent QTc prolongation has been reported with many antipsychotics, pimozide, sertindole, mesoridazine, haloperidol, and especially thioridazine can increase the QTc interval considerably, and all of these have been associated with fatal or potentially fatal arrhythmias (Glassman and Bigger 2001, Yap and Camm 2000). This association prompted restricted marketing of sertindole in Europe, and a U.S. FDA advisory against using thioridazine in patients responsive to other antipsychotics. Among SGAs available in the U.S., ziprasidone appears to cause the greatest QTc prolongation (20 ms, on average), but TdP has only once been reported in a ziprasidone-treated patient (Heinrich et al. 2006), and this patient had multiple other risks factors for TdP. Expert consensus guidelines recommend that pimozide, mesoridazine, and thioridazine not be prescribed to patients with known heart disease, a personal history of syncope, a family history of sudden death before age 40 years, or congenital long QT syndrome (Marder et al. 2004). A baseline ECG is appropriate prior to treatment with other QTc-prolonging antipsychotics (e.g., ziprasidone) in patients with any of the aforementioned risk factors, in elderly patients, and in those who are taking other drugs known to prolong the QTc interval (Glassman and Bigger 2001, Marder et al. 2004). An ECG is also indicated if the patient presents with syncope or other symptoms associated with a prolonged QTc interval (Marder et al. 2004). The risk of QTc prolongation may be decreased by correcting hypokalemia and hypomagnesemia, and by minimizing concomitant exposure to other QTc-prolonging drugs.

In recent years, evidence has accumulated that clozapine is uncommonly associated with myocarditis and cardiomyopathy. Case series and data-mining studies have estimated the risk of clozapine-induced myocarditis at 0.015–0.188%, though the true risk is likely somewhat higher (Merrill et al. 2005, 2006). Myocarditis typically occurs during the first 2...
months of clozapine treatment and manifests with nonspecific signs and symptoms, including fever, tachycardia, chest pain, dyspnea, flu-like symptoms, eosinophilia, elevated cardiac enzyme levels, and ECG changes. No single finding is pathognomonic, and diagnosis is usually guided by a preponderance of clinical evidence. If untreated, progression to fulminant myocarditis may be rapid, with an attendant mortality rate as high as 50%. If the condition is diagnosed early, however, drug discontinuation and supportive treatment frequently lead to spontaneous recovery. At present, it is unknown whether routine screening for clozapine-induced myocarditis, such as with serial measurements of serum levels of cardiac enzymes during the first months of treatment, would result in earlier detection of the disorder. Clinicians should also be vigilant for the development of clozapine-associated dilated cardiomyopathy, which may develop after months to years of clozapine treatment and may itself be associated with significant morbidity and mortality. Although these adverse cardiac effects may have grave consequences, they should be considered in the context of clozapine’s many salubrious properties, including its distinction as the most efficacious of currently available antipsychotics.

**Gastrointestinal Effects**

The anticholinergic effects of antipsychotic medications include xerostomia (i.e., dry mouth) and constipation. These are relatively commonly encountered with clozapine and low-potency FGAs, and less often with olanzapine and quetiapine (American Psychiatric Association 2004). Because they are frequently dose-related, constipation and xerostomia may improve with antipsychotic dose reduction. Elderly patients are particularly susceptible to anticholinergic effects, owing to reduced cholinergic function.

Patients with xerostomia should be advised to maintain hydration, use sugarless gum or hard candy, and obtain regular dental care. Constipation can usually be treated with stool softeners and laxatives. In rare instances, paralytic ileus occurs in association with clozapine or haloperidol, in which case antipsychotic medication should be discontinued and medical or surgical consultation sought promptly. Paradoxically, clozapine may also cause sialorrhea (excess saliva). This may be treated with a few drops of 1% atropine solution, mixed in a glass of water and administered as a mouthwash on an as-needed basis.

**Hepatic Effects**

Asymptomatic elevations of liver enzyme levels occur with both FGAs and SGAs, usually during the first 3 months of treatment (Barnes and McPhillips 1999, Burns 2001, Casey 1997). These abnormalities may be present in more than 20% of patients treated with some antipsychotics (Selim and Kaplowitz 1999), though the relative liabilities of individual agents to cause liver enzyme elevations have yet to be elucidated.

More severe antipsychotic-induced hepatic effects are rare. Approximately 0.1–0.5% of patients treated with chlorpromazine develop cholestatic jaundice, usually within the first month of treatment, and a proportion of these cases progress to cirrhosis (American Psychiatric Association 2004, Selim and Kaplowitz 1999). Occasionally, symptomatic hepatotoxicity (cholestatic or hepatitic) may be associated with SGAs (Burns 2001). In these cases, the offending medication should be promptly discontinued. Patients taking an antipsychotic medication who develop nausea, abdominal pain, and jaundice should have their liver function evaluated to exclude hepatotoxicity. Since antipsychotic-induced jaundice is infrequent, other etiologies should be ruled out before the cause is judged to be antipsychotic treatment (American Psychiatric Association 2004).

**Hematological Effects**

Antipsychotic medications may cause blood dyscrasias, including leukopenia, neutropenia, agranulocytosis, and eosinophilia. Benign leukopenia, for example, occurs in up to 10% of patients treated with chlorpromazine (American Psychiatric Association 2004). Clozapine-induced agranulocytosis (defined as an absolute neutrophil count less than 500/mm³) is a much less common, but potentially fatal, adverse effect. Early agranulocytosis-related fatalities led to the withdrawal of clozapine in some European countries and severe restrictions on its use in others. With the advent of mandatory, systematic blood count monitoring, the reported rate of clozapine-induced agranulocytosis has fallen below 0.4% in the U.S. (American Psychiatric Association 2004). Less than 2% of these cases now result in mortality, in part because clozapine-induced agranulocytosis is usually reversible if the drug is withdrawn immediately (American Psychiatric Association 2004, Lieberman et al. 1988). If agranulocytosis does occur, the clinician should discontinue clozapine treatment, monitor for signs of infection, and consider bone marrow aspiration; if granulopoiesis is deficient, protective isolation is advisable (American Psychiatric Association 2004). In addition, treatment with granulocyte colony stimulating factor may be considered, as this agent may restore granulopoietic function and reduce recovery time (American Psychiatric Association 2004). Clozapine rechallenge should not be attempted in patients who have experienced agranulocytosis because of the high likelihood of recurrence. FGAs and non-clozapine SGAs pose a lower risk of agranulocytosis, though a number of cases have been reported, some involving patients with a history of this adverse event during previous clozapine exposure (Ruhe et al. 2001).

**Ocular Effects**

Cataracts are ocular lens opacities that can impair vision. The low-potency FGAs chlorpromazine and thioridazine increase the risk of this condition, especially when used at high doses (American Psychiatric Association 2004, Marder et al. 2004). Cataracts have also been found in beagles treated with supratherapeutic doses of quetiapine, but not in other nonhuman animal species, including monkeys. Some case reports exist of lens opacities developing in quetiapine-treated humans; however, most of these patients had known risk factors for cataracts (Marder et al. 2004). Until the risk of cataracts with quetiapine is clarified, clinicians may wish to follow current recommendations of obtaining a slit-lamp eye examination or equivalent shortly after initiation of quetiapine treatment, and every 6 months thereafter while quetiapine is continued. Because patients with schizophrenia often have known risk factors for cataracts (e.g., diabetes, hypertension, and poor nutrition), regular ocular evaluations are advisable even for those not treated with quetiapine. A reasonable frequency for visual monitoring...
in schizophrenic patients not taking quetiapine is yearly for patients over 40 years of age, and every 2 years for younger patients (Marder et al. 2004). Clinicians should also inquire about visual changes and should ask specifically about the quality of distance vision and blurry vision (Marder et al. 2004). If changes are present, referral for ophthalmologic evaluation is warranted.

**Other Side Effects**

Sedation can occur with virtually any antipsychotic, but is particularly common with low-potency FGAs and the SGAs clozapine, olanzapine, quetiapine, and zotepine. This side effect is typically most pronounced during dose titration, as the majority of patients develop some tolerance with continued antipsychotic administration. Significant sedation may persist in some individuals, however, especially in those treated with clozapine. While the sedation that accompanies antipsychotic initiation may be beneficial in agitated patients, persistent sedation can be socially and vocationally disabling. This effect can sometimes be mitigated by lowering the antipsychotic dose, by consolidating divided doses into a single evening dose, or by switching to a less sedating agent. In spite of the high prevalence of antipsychotic-induced sedation, pharmacological treatments have not been well studied. Caffeine is considered a relatively safe option, and the psychostimulant modafinil is sometimes used (American Psychiatric Association 2004). It should be noted, however, that stimulants may aggravate psychosis, and some have been associated with clozapine toxicity (American Psychiatric Association 2004). Caution, therefore, should be exercised when administering stimulants for the treatment of antipsychotic-induced sedation.

Antipsychotic medications, in particular clozapine and low-potency FGAs, can lower the seizure threshold in a dose-dependent fashion (American Psychiatric Association 2004). When used at therapeutic doses, the risk of seizure with FGAs is usually less than 1%. The seizure rate with clozapine is 1% at doses below 300 mg/day, 2.7% at doses between 300 and 600 mg/day, and 4.4% at doses above 600 mg/day (American Psychiatric Association 2004). Because the seizure rate rises with rapid dose increases, clozapine should be titrated gradually.

Finally, medication cost may be regarded as a kind of adverse effect, present in varying degrees with all antipsychotic treatment, and frequently burdening the health care system more than individual patients. Antipsychotic costs can be substantial, especially for SGAs, which may be up to 100-fold more expensive than generic forms of some FGAs (Rosenheck 2006). The preferential use of SGAs since their introduction in the 1990s comes at a cost of over $10 billion annually in the U.S., 75% of which is paid through Medicaid (Rosenheck et al. 2006). Despite the high price of SGAs, several studies have found favorable results for the overall cost-effectiveness of these drugs, though the studies suffered from a variety of threats to validity (Polisky et al. 2006). An analysis of the CATIE study data concluded that treatment with the FGA perphenazine was less expensive than treatment with non-clozapine SGAs, with no significant difference in effectiveness (Rosenheck et al. 2006), but this analysis also had several methodological limitations. A similarly constrained analysis of the CUtLASS trial data showed a trend toward lower costs in those patients receiving FGAs, as compared with those receiving SGAs (Jones et al. 2006). Given the limitations of these studies, clinicians should not select an antipsychotic agent based on cost alone, though consideration of intermediate potency drugs like perphenazine is warranted when a medication change is indicated. Clinicians should also be aware that the cost-effectiveness calculus is likely to evolve over the coming years as a greater number of less expensive, generic versions of SGAs become available.

**Adverse Effects and Antipsychotic Agent Selection**

Readers of this chapter will understand that—despite earlier hopes to the contrary—two recent, large, federally funded effectiveness trials provided strong evidence that SGAs, with the exception of clozapine, are not substantially more effective than FGAs (Jones et al. 2006, Lieberman et al. 2005a, McEvoy et al. 2006). Consequently, when selecting an antipsychotic agent, clinicians should not regard their decision as a choice between FGAs and SGAs. They should instead endeavor to individualize treatment, choosing an agent that is likely to be effective and tolerable for the particular patient in question. Primary considerations include the patient’s past response to antipsychotic medications, available formulations (e.g., oral or IM depot), adverse effect profiles, potential for drug interactions, and the patient’s stated preference. In general, the patient should be included in a discussion of these considerations, and informed consent should precede medication administration. Exceptions to the requirement of informed consent include emergencies, instances in which the patient has waived the right to informed consent or lacks decision-making capacity, and cases in which the process of informing the patient about the treatment might be directly damaging to them (Appelbaum and Gutheil 2006). When considering antipsychotic treatment, the risk of adverse effects, both immediate and delayed, should be weighed against the profound disability that can accompany severe mental illness, and the potential for antipsychotic medication to greatly ameliorate the lives of patients and their families. It is prudent for clinicians to document their reasoning when selecting an antipsychotic medication.

**Future Directions in Antipsychotic Drug Research and Treatment**

Antipsychotic drug research has two primary aims: to increase our understanding of existing medications, and to develop novel agents with greater effectiveness. To date, most antipsychotic drug trials have been funded, conducted, and/or reported by representatives of the pharmaceutical industry. Many of these studies met high methodological standards and improved our knowledge of antipsychotic treatment. However, an exploratory analysis of published head-to-head comparison studies of SGAs found that reported outcomes favored the sponsor’s drug in 90% of cases (Heres et al. 2006). This suggests that a number of sponsored studies with negative findings never reach publication. Those that are published are often of short duration and involve only a selected subset of the larger population of patients with schizophrenia (Lieberman 2006). Several government-funded, long-term, large-scale trials, conducted under “real-world” conditions and involving representative patient samples, have sought to redress the limitations of
industry sponsorship (Jones et al. 2006, Lieberman et al. 2005a, Meltzer et al. 2006, Rosenheck et al. 2006, Stroup et al. 2006). These studies, including CATIE and CUILASS, have advanced our understanding of antipsychotic treatment considerably. Their findings are reliable, generalizable, and have the power to transform contemporary clinical practice. Further studies of this nature are eagerly awaited.

Future research on existing antipsychotic drugs is likely to evaluate outcomes that have received relatively less attention, historically, than has short-term reduction in positive symptoms of schizophrenia. These outcomes include impact on negative and cognitive symptoms, relapse prevention, improvement in social and vocational functioning, suicide prevention, and reduction in family and caregiver burden. Early intervention strategies, targeting first-episode, prodromal and high-risk patients, are also likely to be an area of intensive investigation. While most non-clozapine agents demonstrate approximately equal efficacy for positive symptoms, it is possible that certain agents may have specific utility in other symptom domains, or in particular stages of the illness.

Potential between-drug differences in symptom- and stage-specific efficacy, as well as known differences in side effect profiles, suggest that a priority for future research should be the individualization of antipsychotic treatment. At present, one cannot reliably predict which antipsychotic medication is best suited for any given patient (Crismon et al. 2003). However, it is likely that individual genetic differences are important determining factors in the efficacy and side effect profiles of antipsychotic medication (Basile et al. 2001), and identification of these differences may in the future help to tailor pharmacotherapy to the particular needs of individual patients (Arranz et al. 2000, Shastri 2002). Recent developments in simultaneous profiling of gene transcripts (e.g., gene chips) and proteomics are already helping to clarify the genes and proteins that are affected by antipsychotic medication. In addition, neuroimaging (e.g., structural magnetic resonance imaging, functional magnetic resonance imaging, and magnetic resonance spectroscopy) and electrophysiological (e.g., event-related potentials) studies are becoming increasingly sophisticated, providing more detailed information about brain morphologic changes, pathways, and circuits involved in the pathophysiology of schizophrenia (Rowley et al. 2001). It is hoped that individual differences in these variables may ultimately serve as predictors of treatment response.

The second aim of antipsychotic drug research, to develop agents with greater effectiveness, is being pursued in the NIMH-MATRICS initiative and elsewhere. Several novel antipsychotic compounds, including asenapine, ocaperidone, and lurasidone, which have 5-HT2A and D2 antagonist properties, are currently in phase II or III U.S. FDA clinical trials. As yet, only agents with activity at dopamine D2 receptors have proven to have antipsychotic efficacy. Other systems, however, are being actively investigated. For example, emerging evidence of glutamatergic dysregulation in schizophrenia has led to research on a number of agents with direct or indirect effects on the glutamate system. Glutamate-based drugs in various stages of development include agonists at the glycine site of the NMDA receptor, glycine reuptake inhibitors, glutamate release inhibitors, AMPA agonists and antagonists, and ampakines (for review, see Miyamoto et al. 2005). Some of these agents have already shown promise for the treatment of negative and cognitive symptoms of schizophrenia. Similarly, the central cholinergic system is being investigated for its potential role in the cognitive deficits observed in schizophrenia. Compounds that enhance cholinergic activity have been hypothesized to improve these deficits. Currently available treatments that are potentially suitable for this purpose include acetylcholinesterase inhibitors (e.g., galantamine), muscarinic partial agonists (e.g., xanomeline), nicotinic agonists, and allosteric potentiators of nicotinic receptor function (for review, see Friedman 2004). Other potential cognitive enhancers include modafinil (a wake-promoting agent currently used to treat narcolepsy), talnetant (a neuropekin-3 antagonist), and tolcapone (a catechol-O-methyltransferase inhibitor), all of which are currently in phase II FDA clinical trials. These and other agents merit further investigation and will likely engender a wealth of research in the near future.

Conclusions
CATIE, CUILASS, and other studies have taught us that SGAs are not the therapeutic breakthrough they were once hoped—and briefly believed—to be. Rather, SGAs represent an incremental advance in antipsychotic pharmacotherapy, with pharmacological properties and side effect profiles that are somewhat different than those of FGAs (Lieberman 2006). The one possible exception is clozapine, which has been found to be the most effective antipsychotic drug in virtually every study in which it has been used. However, more than 30 years after its discovery, we still do not know the pharmacological basis of clozapine’s superiority, or even whether it is qualitatively or quantitatively different than other antipsychotic drugs. In the absence of a clearly superior class of medication, clinicians should rely on risk–benefit analysis, clinical judgment, and shared decision making in an effort to pair patients with antipsychotic agents that are likely to be safe and effective for them. Novel compounds with potential efficacy against a variety of symptoms and sequelae of schizophrenia are in development and are eagerly awaited.

Introduction
A highly recurrent and often chronic affective illness such as bipolar disorder produces significant distress and dysfunction, even when correctly diagnosed and treated. The unique clinical challenges posed by this chronic illness include various acute phases of mood instability: depressive, hypomanic, manic, and mixed episodes. In addition, these acute phases can present in a range of patterns and at varying intervals both in the individual patient and across patients carrying the identical diagnosis. Bipolar disorder mandates prescription of lifelong maintenance treatment in an effort to minimize relapse, recurrence, and functional impairment. This wide spectrum of affective pathology requires thoughtful psychopharmacologic strategies that often must be adjusted over time, individually tailoring specific drug therapy in an attempt to meet every unique patient’s changing needs.

In many regards, the pharmacologic treatment of bipolar disorder is still in its infancy. Less than four decades have passed since lithium was first approved by the U.S. Food and Drug Administration (US-FDA). The first approval for treatment of acute bipolar depression did not come until late 2003 with a second following in 2006. The core principles of medication management for bipolar disorder revolve around the use of “mood stabilizers.” However, true to the developing maturity of this field, even this key term—“mood stabilizer”—is not recognized by the US-FDA and a single widely agreed upon definition does not exist.

This chapter reviews the concept of mood stabilizer therapy in the management of bipolar disorder and offers new suggested hierarchical criteria to define “mood stabilizer.” The bulk of this chapter will cover treatments for the acute phases of mania and depression, as well as long-term maintenance. It should be noted that the mood stabilizers effective for mania are generally thought to also be effective for mixed mania and hypomanic states although there is admittedly little data to make definitive conclusions about the veracity of this assumption.

Defining Mood Stabilizers
Varying definitions for a “mood stabilizer” have been increasingly debated over the past decade. Although many believe that the term was first used in relation to lithium, its first appearances in the literature were with regard to the antipsychotic chlorpromazine and the tranquilizer amnophenylpyridone (Laborit et al. 1952, Litchfield 1960).

The ideal mood stabilizer would work in all phases of the illness and in all stages of treatment—from treating acute depression, mania, hypomania, and mixed states to preventing all abnormal elevations or depressions of mood. This ideal mood stabilizer would not aggravate or worsen any feature of the illness, that is, precipitate depression or mania, or lead to rapid cycling or cycle acceleration. In other words, the best “mood stabilizer” would work in all four-treatment roles in bipolar disorder, treating the highs and lows as well as preventing the highs and lows. The picture becomes more complex if we consider the need to treat mixed states and rapid cycling. To date no such ideal mood stabilizer exists, although many would argue that lithium comes closest (Bauer and Mitchner 2004).

A more relaxed definition of mood stabilizer was offered by Sachs (1996). The term mood stabilizer could be applied to any medication that was able to “decrease vulnerability to subsequent episodes of mania or depression” and not exacerbate the current episode or maintenance phase of treatment. Such a definition does not require absolute antidepressant or antimanic efficacy.

The therapeutic benefits of lithium have inspired definitions of a mood stabilizer as any agent that possesses “triple threat” properties (antimanic, antidepressant, prophylactic) in the management of bipolar disorder (Keck and McElroy 2003). The lack of such triple-threat mood stabilizers, as well as criticisms of lithium’s antidepressant powers, led to definitions of mood stabilizers of a uniphasic nature—efficacy in at least one pole of bipolar disorder without exacerbating another phase (Keck and McElroy 2003).

Ketter and Calabrese (2002) suggested a reconceptualization of bipolar disorder that emphasized implications for
treatment that “highlight unmet needs and the importance of differential spectra of efficacy” given the lack of any current medication meeting the most stringent and ideal definition of mood stabilizer. For treatment of aberrant states of mood, behavior, and cognition that deviate above the euthymic baseline, the term “Class A” mood stabilizers was suggested to define agents that (1) stabilize mood from above baseline and (2) possess marked antimanic properties without causing a worsening of depression. For those abnormal conditions where mood deviates below the euthymic baseline, the term “Class B” mood stabilizers has been suggested to define agents that (1) stabilize mood from below baseline and (2) possess marked anti-depressant properties without destabilizing the course of illness by inducing switches into mania or episode acceleration.

Bauer and Mitchner (2004) proposed a “two-by-two” definition by which an agent is considered a mood stabilizer if it has efficacy in treating acute manic and depressive symptoms and in prophylaxis of manic and depressive episodes in bipolar disorder. In an analysis of peer-reviewed; high quality controlled trials, the authors identified lithium as the only agent that can be able to meet the above a priori definition of a mood stabilizer.

Others have sought to define mood stabilizers more pragmatically as agents that demonstrate efficacy more in prophylaxis than in acute episode management (Malhi et al. 2005). In any case, experts in the field continue to discuss the issue of precisely defining mood stabilizers while cautioning against the indiscriminate use of the term. Most importantly, these experts acknowledge that we are still unable to define mood stabilization at a molecular or even physiological level (Goodwin and Malhi 2006). With this caution in mind, we will review medical management of acute and maintenance phases of bipolar disorder with mood stabilizers, acknowledging the imperfections in the use of the term as well as the agents so putatively defined.

**Mood Stabilizers for Acute Mania**

**General Considerations**

The management of mood states that they are pathologically above the healthy euthymic baseline typically focuses on mania although similar treatments could be considered for hypomania, psychotic mania, mixed states and subsyndromal mood elevations. For further details on accurate diagnosis of mania and these related states please refer to other chapters in this book.

Classical manic, hypomanic, and mixed bipolar episodes share distinctive traits of hyperactive behavior and/ or thoughts, a mixture of mood elevations and irritabilities, affinity for impulsivity and lability, and degrees of functional impairment or distress. Hospitalization is most often necessary when attempting to control acute bipolar mania. The first step in choosing initial mood stabilizer therapy for mania should involve assessment of the severity of symptoms, which may guide need for monotherapy versus combination therapy. Patients with hypomanic to mild manic presentations may be candidates for monotherapy, whereas patients with more severe manic or mixed episodes should almost always be treated urgently with combinations of antimanic agents. Other considerations, such as first episode versus break-through episode, rapid cycling or refractory illness, and patient preference and tolerability issues also impact decisions for initial management choices. In addition, some thought should be given to maintenance therapy planning even in acutely manic patients given the recurrent nature of bipolar disorder.

The available evidence suggests that lithium, certain anticonvulsant or antiepileptic drugs (AEDs), and all of the atypical antipsychotic drugs are effective for acute mania and may possess other therapeutic properties that could support calling them “mood stabilizers.”

**Lithium**

Since the introduction of lithium for the treatment of “psychotic excitement” (Cade 1949) and later confirmation of antimanic effect by a team led by Mogens Schou (Schou et al. 1954), this mood stabilizer has been the keystone of bipolar disorder therapy. It received the approval for use in mania by the US FDA in 1970. The short-term efficacy of lithium in the treatment of acute mania is supported by at least five placebo-controlled trials, with more recent studies indicating that about half of acutely manic patients respond well to lithium (Kukopulos et al. 1980, Small et al. 1988, Small et al. 1991). These studies, as well as decades of collective experience, clearly support the use of lithium for acute mania. Cotherapy with other antimanic mood stabilizers or benzodiazepines is frequently necessary for most manic patients.

**Pharmacokinetics**

Lithium is absorbed completely within 8 hr of oral intake with peak plasma levels reached between 1 and 3 hr after ingestion. Absorption is not affected by the presence of food, making it preferable for some patients experiencing gastric
irritation to take lithium right after meals. Distribution of lithium after absorption into the bloodstream is rapid with the majority entering the intracellular space. Its final concentration in blood and tissue is determined by complicated transport mechanisms. On average, the brain concentration of lithium is lower than the plasma concentration while the half-life of lithium in the brain is longer than in blood (Plenge et al. 1994). Renal clearance is the primary route of lithium elimination. Age-related changes necessitate more careful use of lithium in the elderly as elimination may be significantly decreased, lending to greater risk of elevated or toxic levels. It is reabsorbed from the glomerular filtrate in the proximal tubule so clinicians must know that lithium elimination may be substantially increased by certain medications, while certain diuretics that act at the distal tubule may lead to unwanted lithium retention (Table 103–2).

### Mechanism of Action

Lithium’s mechanism of action as an antimanic mood stabilizer may be related to its interaction with various neurotransmitter systems. Little is known about the effects of lithium on noradrenergic neurotransmission in manic individuals although lithium administration has been reported to be associated with the decreased excretion of norepinephrine and its metabolites in manic patients while increasing this excretion in depressed patients (Beckmann et al. 1975; Bowers and Heninger 1977; Greenspan et al. 1976). Lithium may exert antimanic effects via its ability to prevent dopamine receptor supersensitivity. However, just as with its reported effects of increasing acetylcholine synthesis and uptake, these changes in receptor sensitivity have been found to be associated with chronic, but not acute, lithium administration (Jope 1979).

A growing body of research has begun to elucidate the complex effects of lithium on various cellular signal transduction pathways, beginning with initial direct targets of lithium, its second messenger roles, and ultimate effects on gene expression and cellular resilience. An established mechanism of lithium’s antimanic properties has yet to be determined although compound effects at different levels and pathways seem most likely. Again, most studies on the effects of lithium on signal transduction mechanisms have explored chronic lithium administration and resultant changes.

Lithium has significant inhibitory effects on the cyclic adenosine monophosphate (cAMP)-generating system, induced by various neurotransmitters and hormones (Forn and Valdecasas 1977; Marmol et al. 1992) while increasing basal cAMP in several regions of the brain with chronic administration (Mork et al. 1992). Signal transduction may thus be stabilized by lithium via a balancing effect of increasing basal activity while inhibiting stimulated activity.

Studies have suggested that the untreated manic patients may have raised myo-inositol and phosphomonoester (PME) concentrations and that lithium may be clinically effective due to its normalizing actions on the phosphoinositol second messenger system (Silverstone et al. 2002). Lithium has demonstrated effects on the arachidonic acid cascade, glycogen synthase-kinase-3, protein kinase activities and protein phosphorylation, and G-proteins (van Calker 2006). These varied effects ultimately are believed to alter gene expression and cellular resilience in patients with bipolar disorder treated with lithium.

### Clinical Application

While lithium is effective for mania, clinical improvement is relatively slow, with an initial onset of therapeutic response generally occurring no sooner than 7–14 days after it is started. Additionally, lithium has a significant adverse effect profile that complicates long-term management (Table 103–3). These effects may be less apparent during acute treatment with lithium than during maintenance treatment.

Pretreatment procedures and testing are recommended before beginning therapy with lithium: general medical history, physical exam and weight, BUN and creatinine determination, thyroid function studies, and pregnancy testing for women of child-bearing age. Lithium carries a teratogenicity category D warning. Electrocardiography and complete blood count measurement should be obtained for patients over the age of 40. Some experts recommend more detailed screening to include fasting glucose determination and dehydration test with vasopressin to determine renal concentrating capacity. Calculation of an estimated creatinine clearance may be more practical and serves to provide a baseline reference value for monitoring of potential renal problems on lithium (Table 103–4) (Cockcroft and Gault 1976).

For treatment of acute mania, lithium should be dosed to achieve therapeutic plasma concentrations (sampled 12 hr after the last dose) between 0.8 and 1.2 mEq/L, avoiding toxic effects more commonly seen with levels at or above 1.5 mEq/L. A routine initial dosing regimen is the administration of lithium carbonate 300 mg four times daily with a gradual titration to achieve therapeutic plasma concentrations (sampled 12 hr after the last dose) between 0.8 and 1.2 mEq/L, avoiding toxic effects more commonly seen with levels at or above 1.5 mEq/L.
blood levels (0.6–0.8 mEq/L) may sufficiently stabilize mood over a period of several weeks to months. Lower doses and levels of lithium may be sufficient when combination pharmacotherapy strategies, such as lithium plus an anticonvulsant or antipsychotic, are used. These lower doses may greatly reduce the frequency of troublesome side effects during early treatment and thus enhance adherence.

The most common side effects of lithium are nausea, vomiting, tremor, diarrhea, or more frequent stools, polydipsia, and polyuria. During acute treatment, gastrointestinal disturbances and tremor can be mitigated by slower dosing strategies. These adverse effects typically subside within 1–2 weeks, although on occasion they can persist. Worsening of any of these adverse effects, as well as the development of bradycardia, syncope, confusion, or ataxic gait should prompt the clinician to immediately measure lithium blood levels and consider changes in dosing or treatment alternatives. Psoriasis, acne, and other skin/hair reactions have also been described in association with lithium therapy.

Lithium toxicity may be heralded by emergence or aggravation of any of the above adverse effects, progressing to include one or more other symptoms such as coarsening tremor, sluggishness, slurred speech, parkinsonism, hyperreflexia, myoclonic twitches, and mental status changes. Early recognition of toxicity is critical as is investigation of cause (Table 103–5). The possibility of drug interactions with lithium must always be considered, particularly with thiazide (and possibly loop) diuretics, angiotensin converting enzyme (ACE) inhibitors, nonsteroidal antiinflammatory drugs, and other psychotropics.

### Antipsychotics

Antipsychotic drugs are presented in greater detail elsewhere in this book, including distinctions between “typical” or conventional, older antipsychotics and the newer “atypical” or second generation antipsychotics. The chemistry, pharmacology, adverse effects, and precautions associated with the use of these drugs for schizophrenia apply as well to bipolar disorder. Particular attention should be paid to the metabolic risks associated with the atypical antipsychotics described in Chapter 97 of this book, along with monitoring and safety requirements.

Although typical antipsychotics can be used effectively to treat mania, there is very little evidence to suggest that they meet any definition of a mood stabilizer. Here we will focus only on the use of newer atypical antipsychotics to treat acutely manic patients with bipolar disorder, as growing evidence suggests that one or more of these medications may be considered mood stabilizers by some definitions.
Atypical Antipsychotics
Randomized, placebo-controlled trials have demonstrated the efficacy of all five second-generation atypical antipsychotics (olanzapine, risperidone, quetiapine, ziprasidone, aripiprazole) and led to their US FDA approval for the management of acute bipolar mania with or without psychotic features. With the exception of quetiapine, they are all approved for mixed states in bipolar disorder. A recent meta-analysis of randomized controlled trials of these five atypical antipsychotics in the treatment of acute mania, as monotherapy or adjunctively, concluded that differences in efficacy between these agents are likely to be small (Perlis et al. 2006).

Olanzapine for Bipolar Mania
Olanzapine became the first atypical antipsychotic, and the first antipsychotic since chlorpromazine, indicated for the treatment of mania associated with bipolar disorder when it received approval by the US FDA in 2000 based on data from two large placebo-controlled trials (Tohen et al. 2000, Tohen et al. 1999). Response rates to olanzapine monotherapy in these trials ranged from 49–65%. Olanzapine has been reported to bring about symptomatic remission from mania significantly earlier than divalproex (Tohen et al. 2003a). A recent Cochrane Database System Review substantiates some superior efficacy for olanzapine over divalproex for acute mania, but notes the increased risk of weight gain for olanzapine compared to divalproex (Rendell et al. 2003).

In manic patients only partially responsive to either lithium or divalproex, the use of adjunctive olanzapine led to significantly faster antimanic response and a greater reduction in symptom severity than placebo augmentation (Tohen et al. 2002). Coexisting depressive or mixed symptoms also improved substantially. Olanzapine has been reported to be efficacious for treatment of the acute manic and depressive symptoms associated with dysphoric mania and a rapid cycling course (Gonzalez-Pinto et al. 2002, Sanger et al. 2003).

Olanzapine is also available in an intramuscular (IM) formulation approved for use in the treatment of agitation associated with schizophrenia or bipolar I mania. The IM use of olanzapine is of particular utility in the hospitalized manic patient with severe agitation and can be administered as an initial 10 mg dose and repeated if needed in 2 hr and again 4 hr later up to a maximum daily IM dose of 30 mg. This maximal dosing may lead to substantial orthostasis and so must be employed with much caution. Concomitant administration of IM lorazepam should be avoided as this combination may lead to a pronounced sedation and a respiratory depression.

Olanzapine has structural and pharmacologic similarities to clozapine. Olanzapine binds with high affinity to dopaminergic, serotonergic, adrenergic, and muscarinic and histaminergic receptors. Like clozapine it has a low risk for causing extrapyramidal side effects or raising prolactin.

Although its exact mechanism of action as an antimanic agent remains unknown, the broad and unique binding properties of this drug provide multiple potential therapeutic means which may account for its efficacy in bipolar disorder (Bymaster et al. 1996).

Risperidone for Bipolar Mania
Substantial evidence supports the efficacy of risperidone in acute mania. An initial 1998 study compared risperidone with haloperidol and lithium and demonstrated that all three agents significantly reduced manic symptoms by study endpoint of 4 weeks (Segal et al. 1998). Two subsequent multicenter, double-blind, placebo-controlled monotherapy studies of risperidone for acute mania found response rates at 3 weeks of 43–73% compared with only 24–36% in placebo-treated subjects (Hirschfeld et al. 2004, Khanna et al. 2005). A third international trial conducted by Smulevich et al. (2005) included extension to 12 weeks and demonstrated ongoing reductions in mania with risperidone; this study allowed a slightly slower initial dosing schedule for risperidone, reaching a maximum of 6 mg/day by Day 5.

Two trials of risperidone added to mood stabilizers (lithium, valproate, or carbamazepine) for 3 weeks have shown an advantage of risperidone over placebo in acutely manic bipolar patients, with or without psychotic features (Sachs et al. 2002, Yatham et al. 2003). In the Yatham et al. (2003) study, risperidone was able to separate from placebo add-on despite allowing carbamazepine as one of the mood stabilizers (which was associated with a 40% reduction in serum risperidone levels). The risperidone data is consistent with observations made from the olanzapine studies—combined atypical antipsychotic and traditional mood stabilizer therapy leads to greater improvement in mania than monotherapy.

The mean modal antimanic doses for risperidone as monotherapy or add-on therapy ranged from 4–6 mg/day, with the lower end of the range used when combined with another mood stabilizer. Again, clinical practice and individual patient needs may demand doses that are above or below this dose range.

Risperidone is presently the only atypical antipsychotic with a long acting intramuscular injection form that employs encapsulation of the active drug in microspheres of a biodegradable polymer (glycolic acid-lactate, also used for sutures). Slow release of risperidone occurs with gradual hydrolysis of the polymer beginning about 3 weeks after initial injection. It is estimated that the 50 mg injectable dose given every two weeks is roughly equivalent to up to 4 mg of oral risperidone given daily. For individual patients with mania prone to frequent relapse or recurrence due to poor oral medication adherence, the long acting injection of risperidone holds much promise.

Risperidone is a potent 5HT-2A and D 2  antagonist similar to clozapine but has less affinity for D 3  and D 4  receptors. It also blocks H 1 , alpha-1, and alpha-2, but not acetylcholine receptors. Doses of risperidone above 6 mg/day are known to produce greater than 80% blockade of D 2  receptors in the basal ganglia, resulting in an increased likelihood of extrapyramidal side effects. As with olanzapine, its exact mechanism of therapeutic action in bipolar disorder is not known although antipsychotics in general may exert antimanic actions, at least in part, via D 2  receptor.
antagonism. Central dopaminergic hyperactivity has been postulated as the pathophysiology of mania (Gerner et al. 1976).

**Quetiapine for Bipolar Mania**

Unlike other acute mania trials, quetiapine mania studies excluded mixed states. Accordingly, quetiapine is FDA approved only for the treatment of acute manic episodes associated with bipolar disorder. McIntyre et al. (2005) reported a 12-week randomized trial with quetiapine therapy in which quetiapine treatment produced a response rate of 43.6% as compared with a 35.0% placebo response rate at Day 21. By Day 84, the response rate with quetiapine treatment grew to 61.4% as compared with 39.0% in the placebo group. In a second 12-week study of identical design, the response rate in quetiapine-treated subjects was 53.3% versus 27.4% with placebo; at Day 84, quetiapine response rate was 72.0% versus 41.1% for placebo (Bowden et al. 2005). In a combined analysis of these two studies, the quetiapine monotherapy response rate for mania was 48% with only 31% placebo response at Day 21 (Vieta et al. 2005).

Quetiapine combined with lithium or divalproex in a 3 week, multicenter, randomized controlled trial resulted in a 54% response rate compared with a 33% response rate in those receiving mood stabilizer plus placebo (Sachs et al. 2004). In both monotherapy and adjunctive therapy indications for bipolar I mania, the recommended dose for quetiapine is 600 mg/day, following a bid titration schedule over 5 days after starting with 50 mg bid.

There are more than 20 metabolites of quetiapine, and almost all of them are inactive. Quetiapine is metabolized by 4 routes, including hydroxylation, sulfoxidation, oxidation, and dealkylation. The latter generates the primary active metabolite of the parent compound, norquetiapine, and is hypothesized to act by inhibiting the norepinephrine transporter. Therefore, quetiapine is now believed to interact with three principal neurotransmitter systems, including dopamine, serotonin, and norepinephrine.

Quetiapine is an antagonist at multiple neurotransmitter receptor sites in the brain, including 5HT2A, 5HT2C, D1, D2, histamine H1, alpha-1 and alpha-2. It has an appreciable affinity at cholinergic muscarinic and benzodiazepine receptors. Its dopamine antagonism may be responsible for its antimanic effects. Rapid dissociation from the D2 receptor is thought to contribute to quetiapine’s minimal propensity for inducing extrapyramidal side effects or prolactin elevation. Antagonism of H1 receptors may explain somnolence observed with quetiapine use.

**Ziprasidone for Bipolar Mania**

Ziprasidone monotherapy has also demonstrated rapid onset of antimanic activity leading to significantly greater symptomatic reduction and response rates compared to placebo in two double-blind, randomized controlled trials (response rates for ziprasidone 46–50%, for placebo 29–35%) (Keck et al. 2003a). US FDA regulatory approval was given in 2004 for acute manic or mixed episodes associated with bipolar disorder, with or without psychotic features.

Similar to the other atypicals, ziprasidone has high affinity for dopamine, serotonin, and alpha-adrenergic receptors with only a moderate affinity for histaminic receptors. Although its clinical significance can be debated, ziprasidone is unique among the atypicals in that it does display some inhibition of synaptic reuptake of serotonin and norepinephrine.

Ziprasidone may be started at 40 mg twice a day (given with meals to enhance absorption) and increased up to 160 mg/day within the first week, with an average dose of around 120 mg/day in study responders. Ziprasidone is available in an IM form that can help to rapidly control associated agitation with 10 mg IM every 2 hr (or 20 mg every 4 hr) as needed up to 40 mg/day.

**Aripiprazole for Bipolar Mania**

This newest atypical antipsychotic has been investigated in two randomized placebo controlled trials of acute bipolar mania, which led to US FDA approval in 2004 for monotherapy treatment of acute manic or mixed episodes associated with bipolar disorder. In the first 3-week placebo-controlled monotherapy trial, aripiprazole produced significant reduction in manic symptoms compared to placebo-treated patients by day 4 of the study and this statistically-significant difference was maintained throughout the trial (Keck et al. 2003b). These results were confirmed by a second placebo-controlled study by Sachs et al. (2006).

Compared to the other approved atypical antipsychotics aripiprazole possesses a novel mechanism of action, appearing to mediate its primary therapeutic effects through partial agonism at the D2 receptor. Partial agonism is also seen at the 5HT1A receptor, while like other atypicals aripiprazole displays antagonism at the 5HT2A receptor. Aripiprazole has moderate affinity for histamine and alpha-adrenergic receptors, and no appreciable affinity for cholinergic muscarinic receptors.

Treatment of manic or mixed episodes in bipolar disorder with aripiprazole may commence with 15–30 mg/day, with responders requiring an average daily dose near 30 mg/day. An IM formulation of aripiprazole has recently received approval to treat agitation associated with schizophrenia or bipolar mania. The recommended dose is 9.75 mg IM and can be repeated every 2 hr up to a maximum of 30 mg/day.

Table 103–6 provides dosing information for the use of atypical antipsychotics for the management of acute bipolar mania.

**Tolerability and Safety Issues with Atypicals**

Atypical antipsychotics generally have superior tolerability when compared with typical antipsychotics in the management of bipolar disorder. Side-effect profiles vary among the different atypical agents, while monitoring needs
remain the same. Of principal concern with longer-term use is the risk for metabolic derangements, notably weight gain, type-2 diabetes, and lipid elevations. Prior to initiating therapy for mania with any atypical antipsychotic, baseline determination of fasting glucose, weight, waist circumference, and lipid profile is recommended (refer to Chapter 97 in this book.).

**Anticonvulsants/AEDs**

Reports of the beneficial behavioral effects associated with the use of AEDs in patients with bipolar disorder, particularly for mania, date back to the 1960s. Discussions regarding the potential for some shared etiologic process between epilepsy and bipolar disorder, such as kindling, were common in the literature of the time. Theoretically, as in epilepsy where repeated subthreshold neuronal stimulation can generate an action potential that triggers a seizure, kindling in a patient with bipolar disorder could produce activation of or switching to disordered mood states—mania, depression, mixed states. The proposed reduction of kindling by AEDs such as carbamazepine along with observations of positive “mood stabilizing” effects led to widespread investigation of virtually every developed AED in bipolar disorder (Post et al. 1982).

It does not appear that a distinct class effect for AEDs in the management of bipolar disorder exists since not all anticonvulsants have been able to demonstrate efficacy for this mood disorder. The likely explanation for this variability for AEDs in bipolar disorder relates to the complex differences in the mechanisms of action for these drugs (Muzina et al. 2005). Multiple mechanisms of action have been proposed for AEDs as anticonvulsants, including glutamate receptor blockade, enhanced effects of gamma-aminobutyric-acid (GABA), sodium and/or calcium channel blockade, activation of potassium conductance, carbonic anhydrase inhibition, and synaptic vesicle protein modulation. Despite assumed primary modes of anticonvulsant action for any individual AED, each has a dissimilar profile in terms of possessing multiple distinct mechanisms that may confer anticonvulsant properties. These mixed effects may also potentially explain the differential effects among AEDs in terms of treating disordered mood states and why not all AEDs can effectively treat mania.

Future exploration of pathophysiologic causes beyond simple catecholamine “imbalance” will better inform our understanding of how AEDs affect mood and direct focused AED drug development that may impact other proposed causes for mood disorders, such as defective G-proteins, altered second-messenger systems, mitochondrial disorders, and excessive methylation of DNA-histone proteins (Muzina et al. 2006).

Here, we will consider AEDs that may provide antimanic mood stabilization based on randomized, double-blind, placebo-controlled studies with adequate sample size. Other than divalproex and carbamazepine, other AEDs have not demonstrated strong enough evidence to qualify for inclusion here.

**Divalproex Sodium/Valproate**

Divalproex sodium became the first anticonvulsant approved as a treatment for bipolar mania by the US FDA in 1995, after a large-scale, randomized, double-blind parallel-group study found divalproex equivalent to lithium in superiority over placebo for the management of acute mania (Bowden et al. 1994). In this study, efficacy of divalproex appeared independent of prior responsiveness to lithium. Both active treatments demonstrated a nearly 50% response rate with monotherapy, while placebo response was only 25%. A new extended release (ER) preparation of divalproex recently received approval for acute manic or mixed episodes of bipolar disorder, with or without psychotic features, demonstrating a similar response rate of nearly 50% although placebo response was numerically higher in this study, 34% (Bowden et al. 2006).

Divalproex is recommended as a first-line acute treatment option for mania in most evidence-based practice-guidelines, either as monotherapy or in combination with antipsychotics for more severe manic episodes. Table 103–7 lists factors associated with an acute response to divalproex compared to lithium and/or carbamazepine.

| Table 103–7 Factors Associated with Acute Response to Divalproex/Valproate |
|-------------------------------------------------|-------------------------------------------------|
| - History of prior poor response to lithium     | - Higher number of lifetime episodes of mania or depression |
| - 8 or more total lifetime episodes             | - More than 2 prior major depressive episodes    |
| - Mania with depressive features                | - Presence of irritability                        |
| - Atypical manic states                         | - Later age of illness onset                      |
| - Comorbid substance abuse                      | - Mania associated with neurological or medical illness |

**Pharmacokinetics**

Following oral administration of divalproex, its absolute bioavailability quickly approaches 100%; the ER preparation bioavailability is closer to 90%. This suggests that a slightly higher dose of the ER form is needed in order to reach bioequivalence with the immediate release preparation (8–20% higher dose for ER). Peak plasma concentrations are achieved within 3–5 hr although up to 17 hr may be needed to reach peak concentration for the ER form. Mean terminal half-life is about 12–16 hr for either preparation, with steady state conditions usually being achieved within 3–4 days.

This AED is metabolized almost entirely by liver via the cytochrome P450 2D6 system. Mitochondrial beta-oxidation is the other major metabolic pathway. It does not induce its own metabolism. It inhibits drug oxidation and may increase serum levels of other oxidatively metabolized drugs, such as phenytoin, phenobarbital, and tricyclic antidepressants. Coadministration with other microsomal enzyme-inducing drugs, such as carbamazepine, will decrease plasma valproic acid levels. Inhibitors of the P450 system, such as selective serotonin reuptake inhibitors, can increase levels of valproic acid in the plasma. Toxicity can also be induced when divalproex is given along with other drugs that may be highly protein bound.

**Mechanism of Action**

As discussed above regarding AEDs in general, the exact mechanism of antimanic or “mood stabilizing” action for
divalproex is not known. Presumably this AED is able to treat mania via increasing levels or activity of the primary inhibitory neurotransmitter, gamma-aminobutyric acid (GABA). Alternatively, divalproex may mimic or enhance GABAs’ effects at postsynaptic receptor sites.

Clinical Application
Before initiating acute treatment of mania with divalproex, a general medical history with special attention to any past problems of hepatic or hematological nature should be obtained, as well as baseline liver profile, and complete blood cell count. Pregnancy screening should be conducted before starting divalproex, particularly given its FDA black-box warning of teratogenicity category D.

Divalproex can be dosed with either an oral-loading or standard-titration strategy. For acute management of severely ill manic patients, divalproex oral-loading with a therapeutic starting dose of 20–30 mg/kg per day is suggested over standard, gradual titration schedules. Oral-loading typically achieves serum concentrations of valproic acid greater than 50 mg/L by Day 2, which represents the low end of the therapeutic range of serum concentrations for this agent of 50–125 mg/L. Similar results can be obtained by using the ER preparation. This oral-loading strategy for divalproex has been demonstrated to lead to a more rapid antimanic effect when compared with standard-titration divalproex, lithium, or placebo; it is also better tolerated than olanzapine and as well tolerated as lithium or standard-titration divalproex (Hirschfeld et al. 2003). Lower, divided doses are initially recommended (250 mg tid or 500 mg bid) for patients with less severe mania or in elderly patients.

Adverse effects seen during initial therapy with divalproex are usually mild, transient, and easily managed. Gastrointestinal distress and sedation are the most commonly seen side effects during acute treatment, although other dose-related effects including tremor and benign hepatic transaminase elevations are occasionally encountered. Reduced dosage or slower upwards titration can be helpful, in addition to use of divalproex sodium formulation or ER divalproex instead of valproic acid may also lessen these side effects. Tremor may be minimized through dose reduction or concomitant beta-blocker medication. During acute treatment with divalproex, clinicians should consider the possibility of rare but potentially serious adverse effects such as irreversible hepatic failure, hemorrhagic pancreatitis, or hyperammonemic encephalopathy when patients experience severe abdominal distress, confusion or delirium.

Divalproex commonly displaces otherwise highly protein-bound drugs from their protein binding sites, requiring greater awareness of clinically significant drug interactions. Divalproex can also inhibit the metabolism of other drugs cleared by the liver. Most notably, it inhibits lamotrigine metabolism by 50% resulting in the critical need to initiate lamotrigine at 50% lower doses when coadministered with divalproex.

Carbamazepine
There were approximately 20 double-blind studies examining the efficacy of carbamazepine and its 10-keto analog oxcarbazepine in the treatment of mania prior to the completion of the first large, randomized, double-blind, placebo-controlled parallel trial of carbamazepine monotherapy using a beaded, extended-release formulation (Muzina et al. 2004; Weisler et al. 2004). Prior to this (Weisler et al. 2004) study, earlier double-blind studies of carbamazepine in the treatment of acute mania were confounded by effects of other allowed psychotropic medication such as lithium or antipsychotics. The response rate using this formulation of carbamazepine to treat acute mania over three weeks was 41.5%, significantly greater than response of 22.7% with placebo treatment although separation from placebo was not noted until Week 2. A post-hoc analysis found benefit for patients with mixed states as well.

Pharmacokinetics
Carbamazepine is 80% bioavailable after oral administration, with immediate and beaded release formulations bioequivalent. Nearly 80% is protein bound with the primary route of hepatic metabolism via the cytochrome 3A4 system to its active epoxide form. With initial administration of the ER form, half-life averages between 35–40 hr, but with repeated administration this falls to 12–17 hr due to auto-induction. Inhibitors of the P450 system will increase carbamazepine levels while inducers can decrease levels.

Clinical Application
Before treatment with carbamazepine, a general history and physical exam should be performed, including screening for any history of liver disease or blood dyscrasias. Routine laboratories including complete blood count, liver profile, and electrolytes with creatinine should be obtained. More frequent monitoring is indicated in the elderly or in any individual on carbamazepine who develops fever, easy bruising or bleeding, weakness, or infection.

There is no clear target serum level of carbamazepine for acute mania. Immediate release carbamazepine therapy may be started at a total divided daily dose of 200–600 mg, with incremental increases of 200–1000 mg/day followed by careful monitoring of blood levels, side effects, and clinical efficacy. The beaded, ER form may be started at 400 mg/day and increased as tolerated up to 1600 mg/day. Many factors can affect carbamazepine blood levels beyond direct dosing, including auto-induction of metabolism and significant drug interactions.

During acute treatment with carbamazepine, the most commonly observed side effects are nausea, fatigue, blurred vision, and ataxia. More gradual initial titration of the dose may minimize these effects. Infrequently, liver transaminase elevations, rash, hyponatremia, and blood dyscrasias may complicate acute treatment.

Summary: Mood Stabilizers for Acute Mania
There has been a surge in the number of medications effective to treat mania acutely in the past decade, mostly due to the emergence of atypical antipsychotics and their demonstration of efficacy for bipolar mania and mixed states. All of the atypicals, lithium, carbamazepine, and divalproex have had large positive studies supporting their role as antimanic agents. Table 103–8 summarizes the positive monotherapy studies that have produced evidence from large randomized, double-blind, placebo-controlled studies (Sachs 2007). Analyses of these studies find that these agents produce fairly robust clinical effects, with the numbers-needed-to-treat (NNT) ranging from 2.7–6.7 and...
Acute bipolar depression presents diagnostic and treatment challenges for many clinicians more commonly than other major mental disorders. A detailed exploration regarding diagnosis of bipolar depression can be found elsewhere in this book. The clinical approach to managing bipolar depression, once recognized, has been guided for many years by extrapolations and assumptions based on evidence from unipolar major depression studies. The use of agents deemed “antidepressants” based on efficacy in treatment trials for unipolar major depression has not been well studied for bipolar depression. From 1968 to 2001, there were only 12 randomized, placebo-controlled trials of traditional antidepressants in the treatment of bipolar depression (Ghaemi and Thase 2002). Only five of these studies reported the antidepressant studied to be more effective than placebo.

In addition, there remains much uncertainty and debate about the potential danger of cycle acceleration or “switching” associated with the use of antidepressants for patients with bipolar depression. While the phenomenon has not been thoroughly investigated, there is a growing consensus among US psychiatrists that traditional antidepressants should be avoided in the treatment of acute bipolar depression, particularly if their use is not counter-acted or “protected” by coadministration of known antimanic mood stabilizers. Although some may posit that a traditional antidepressant medication is able to acutely treat bipolar depression and is also effective in terms of prophylaxis against depressive recurrence may represent a “mood stabilizer,” the use of this term has not included antidepressants. Indeed, a recent effectiveness trial of adjunctive antidepressant treatment for bipolar depression found no efficacy for the use of the agents even when the common clinical practice of adding the antidepressant to a mood stabilizer was employed (Sachs et al. 2007).

### Effectiveness of Adjunctive Antidepressants

Both common clinical practice and various treatment guidelines have recommended the addition of an antidepressant medication to a mood stabilizer in the treatment of acute bipolar depression. Many have believed that doing so would provide efficacy for the treatment of depression while protecting against manic switches or cycling. The recent publication of an effectiveness trial designed to investigate this issue raises significant doubts about the utility of this common practice (Sachs et al. 2007).

The Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) is a collaboration sponsored by the National Institute of Mental Health created to assess the effectiveness of treatments for bipolar disorder. The design of this large, naturalistic treatment study seeks to provide results that are generalizable to routine clinical practice. In this multicenter, double-blind, placebo-controlled, parallel-group study of standard antidepressants prescribed adjunctively with mood stabilizers for acute bipolar depression, 366 depressed patients with bipolar disorder were randomized to active adjunctive treatment (bupropion or paroxetine in addition to mood stabilizer) or to placebo (mood stabilizer alone) and followed for 26 weeks. The population studied included bipolar I or II disorder, with or without rapid cycling, and were allowed treatment for ongoing co-existing substance use disorders, anxiety disorders, or psychotic symptoms. Baseline depression was in the moderate range (mean Montgomery Asberg Depression Scale score ∼24) in both groups.

The a priori primary outcome for this study was durable recovery, defined as euthymia for at least 8 consecutive weeks. Results demonstrated no significant differences between the use of adjunctive antidepressant or adjunctive placebo in

### Mood Stabilizers for Acute Bipolar Depression

#### General Considerations

Acute bipolar depression presents diagnostic and treatment challenges for many clinicians more commonly than other major mental disorders. A detailed exploration regarding diagnosis of bipolar depression can be found elsewhere in this book. The clinical approach to managing bipolar depression, once recognized, has been guided for many years by extrapolations and assumptions based on evidence from unipolar major depression studies. The use of agents deemed “antidepressants” based on efficacy in treatment trials for unipolar major depression has not been well studied for bipolar depression. From 1968 to 2001, there were only 12 randomized, placebo-controlled trials of traditional antidepressants in the treatment of bipolar depression (Ghaemi and Thase 2002). Only
also briefly review evidence related to lithium and the AEDs olanzapine–fluoxetine combination, and quetiapine. We will to regulatory approval in the US of only two medications: studied for use in acute bipolar depression which has led evidence from large, randomized controlled trials of agents L-dopa and amphetamine, have long been known to elevate dopamine transmission and dopaminergic agonists, such as with antidepressant medications is known to potentiate CSF HVA is increased in manic patients. Chronic treatment with antidepressant medications is known to potentiate dopamine transmission and dopaminergic agonists, such as L-dopa and amphetamine, have long been known to elevate mood. Recent reports of efficacy in bipolar depression using the D2/D3 receptor agonist pramipexole adjunctive to mood stabilizer therapy further add to the speculation that enhancing dopamine can treat depression (Goldberg et al. 2004).

Atypical antipsychotics may address depression through blockade of both D2 and 5HT2A receptors. Blockade of the 5HT2A receptors by atypical antipsychotic drugs on presynaptic dopamine neurons leads to an increase in the release of dopamine. Rapid dissociation from the D2 receptor, as with quetiapine, may explain why less dysphoria is observed with this agent compared with other more potent D2 blockers. It has been postulated that the D2 antagonism of atypicals such as quetiapine and olanzapine in combination with 5HT2A antagonism accounts for the mood stabilizing properties of these agents (Brugue and Vieta 2007). Since an excess of dopamine may lead to mania, the simultaneous blockade of D2 receptors in the mesolimbic system may help to prevent manic switches by producing a regionally selective balance between dopamine and serotonin circuits thereby stabilizing mood from below baseline as well as from above (Yatham et al. 2005). Other mechanisms of potential antidepressant action by atypicals may include positive induction of neurotrophic changes, including those involving brain derived neurotrophic factor (BDNF) and glial fibrillary acidic protein (Qing et al. 2003, Xu et al. 2002). These and other findings suggest complex mechanisms beyond simple alterations in levels of serotonin, dopamine, and norepinephrine, in explaining the antidepressant activity of atypical antipsychotics.

Discussion here will focus on the very limited evidence from large, randomized controlled trials of agents studied for use in acute bipolar depression which has led to regulatory approval in the US of only two medications: olanzapine–fluoxetine combination, and quetiapine. We will also briefly review evidence related to lithium and the AEDs for bipolar depression.

Atypical Antipsychotics for Acute Bipolar Depression

It is interesting to note that the first antipsychotic drug, chlorpromazine, came to attention due to its positive effects on mood. Its calming effects led to study in psychotic states launching the birth of psychopharmacology. Attempts to develop better antipsychotics after chlorpromazine’s discovery by creating similar structural analogues paved the way for the discovery of imipramine. Over the years, the use of antipsychotics to treat affective states such as depression gradually grew out of favor due mostly to concerns about neurological side effects. The emergence of atypical antipsychotics has placed these drugs on the frontline in treating bipolar depression.

Mechanism of Action

Although research has focused on serotonin and norepinephrine in depression there are lines of evidence suggesting that dopamine may play a major role in the pathophysiology of depression. This is important to explore if we hope to better understand how atypical antipsychotics may effectively treat bipolar depression.

Innervation of the nucleus accumbens, amygdala, ventral hippocampus and prefrontal cortex by mesocorticolimbic circuits is believed to support behavioral functions related to reward and motivation. Alterations in this circuitry may be responsible for many of the core features of depression, with a deficiency in dopamine as a leading candidate cause (Willner 1983). Several studies have found reduced levels of the dopamine metabolite homovanillic acid (HVA) in the cerebrospinal fluid of patients with bipolar depression, while CSF HVA is increased in manic patients. Chronic treatment with antidepressant medications is known to potentiate dopamine transmission and dopaminergic agonists, such as L-dopa and amphetamine, have long been known to elevate

Olanzapine–Fluoxetine Combination (OFC) and Olanzapine for Bipolar Depression

The first controlled study of an atypical antipsychotic for the treatment of bipolar depression was completed by Tohen et al. (2003b). This 8-week, placebo-controlled, parallel-group trial randomized patients with bipolar I disorder to olanzapine, OFC, or placebo. Bipolar II patients were not included. Subjects were required to be at least moderately depressed and could not meet criteria for mania to be enrolled. Treatment with olanzapine was initiated at 5mg/day and could be increased to 20 mg/day in 5 mg increments. OFC was initiated at 6 and 25 mg/day (olanzapine 6 mg with fluoxetine 25 mg) but could be increased to 6 and 30 or 12 and 50 mg/day after at least 1 day at each dose.

Both olanzapine and OFC demonstrated significantly greater and sustained mean symptomatic improvements over placebo. The response rate was significantly higher in the OFC-treated group (56.1%) compared to the olanzapine-treated group (39%), both of which were higher than the 30.4% rate of response for patients taking placebo. When examining rates of remission, OFC was found to result in a remission rate of 48.8%, significantly higher than either olanzapine monotherapy (32.8%) or placebo (24.5%).

Further analysis of individual depression symptoms showed that olanzapine and OFC significantly improved inner tension, sleep, and appetite compared with placebo. However, only OFC significantly improved core mood items such as apparent sadness, reported sadness, lassitude, inability to feel, and pessimistic thoughts. Olanzapine monotherapy and OFC did not separate from placebo in reducing suicidal thoughts.
Quetiapine for Bipolar Depression

Completion of two large, multicenter double-blind, placebo-controlled, parallel-group 8 week studies of quetiapine monotherapy has led to its approval as the second pharmacologic agent for acute bipolar depression (Calabrese et al. 2005a, Thase et al. 2006). These studies included subjects experiencing either bipolar I or II depression and did not exclude rapid cycling. After meeting enrollment criteria similar to the aforementioned OFC trial, subjects were randomized to quetiapine 300 mg/day, quetiapine 600 mg/day, or placebo. Quetiapine was initiated at 50 mg/day and titrated to achieve a target dose of 300 mg/day by Day 4 or 600 mg/day by Week 1.

Both studies confirmed significant antidepressant benefits associated with quetiapine over placebo, regardless of bipolar I or II status or the presence of rapid cycling.

Overall, the response rate with quetiapine treatment was 60% and the placebo response rate was 40%. There was no added benefit with the higher 600 mg dose of quetiapine. More than half of all quetiapine-treated patients experienced remission by 8 weeks compared to 33% remission rate with placebo. Significant improvements in anxiety, sleep, and quality of life were also observed in quetiapine-treated subjects.

Furthermore, at the final assessment, quetiapine was associated with significant reductions in suicidal thoughts as compared with placebo.

Other Atypical Antipsychotics

Limited data is available regarding the use of other atypical antipsychotics other than olanzapine and quetiapine in the treatment of bipolar depression. One small open-label study reported benefit in 7 of 10 subjects in the treatment of bipolar depression. Risperidone has been noted to improve depressive symptoms in patients with bipolar I or II depression and did not exclude rapid cycling. After meeting enrollment criteria similar to the aforementioned OFC trial, subjects were randomized to quetiapine 300 mg/day, quetiapine 600 mg/day, or placebo. Quetiapine was initiated at 50 mg/day and titrated to achieve a target dose of 300 mg/day by Day 4 or 600 mg/day by Week 1.

Both studies confirmed significant antidepressant benefits associated with quetiapine over placebo, regardless of bipolar I or II status or the presence of rapid cycling.

Overall, the response rate with quetiapine treatment was 60% and the placebo response rate was 40%. There was no added benefit with the higher 600 mg dose of quetiapine. More than half of all quetiapine-treated patients experienced remission by 8 weeks compared to 33% remission rate with placebo. Significant improvements in anxiety, sleep, and quality of life were also observed in quetiapine-treated subjects.

Furthermore, at the final assessment, quetiapine was associated with significant reductions in suicidal thoughts as compared with placebo.

A double-blind adjunctive trial of risperidone given singly or in combination with paroxetine in a small sample of BD (I or II) patients (n = 30) who were receiving a stable dose of mood stabilizer demonstrated that risperidone, risperidone plus paroxetine, and paroxetine were all modestly effective in improving depressive symptoms in patients with bipolar or schizoaffective disorder and reported response in nearly 70% of risperidone-treated subjects (Vieta et al. 2001). However, risperidone has also been compared to quetiapine in a small, 4-month, open-label study of psychotic patients with depressive symptoms. Quetiapine produced a greater improvement in depression scores than did risperidone in patients with a primary mood disorder including bipolar disorder (Sajatovic et al. 2002).

As noted earlier, the AEDs are a heterogeneous group of medications that have demonstrated variable effects in the treatment of acute bipolar depression. No statistically significant differences in response rates were found for lamotrigine (24%), inositol (17%), or risperidone (5%). Despite the lack of significance in the primary efficacy measure, post hoc analysis of data revealed greater improvements in depressive symptoms, overall severity, and functioning in the lamotrigine-treated patients at study conclusion (Nierenberg et al. 2006). These results suggest that only a limited number of patients with treatment-resistant bipolar depression would completely recover with the addition of risperidone.

In a retrospective chart review of 12 patients receiving aripiprazole for treatment-refractory bipolar depression only three of 12 patients were found to be much improved or very much improved on Clinical Global Impression of Improvement (CGI-I) scores (Kemp et al. 2007). Another small open-label study reported benefit in 7 of 10 subjects with bipolar I depression prescribed adjunctive aripiprazole (Sokolski 2007). Larger, placebo-controlled trials are needed to further investigate aripiprazole’s role in the management of bipolar depression.

Anticonvulsants/AEDs for Acute Bipolar Depression

As noted earlier, the AEDs are a heterogeneous group of medications that have demonstrated variable effects in the treatment of acute bipolar depression. The antidepressant effects of AEDs in bipolar disorder are less well-studied and there is very limited supportive evidence for their use in acute bipolar depression although clinical practice often includes these agents in utilitarian fashion (Muzina et al. 2005, Muzina et al. 2006). Most of the attention to date has centered on divalproex/valproate and lamotrigine with very little controlled data regarding the use of other AEDs in acute bipolar depression.

Divalproex/Valproate

Large-scale, consistent efficacy in the treatment of acute bipolar depression has not been demonstrated to date by this AED despite initial open-label data that suggested that divalproex may have benefit in the treatment of nonrefractory bipolar I or II depression (Sachs 1996). A later unpublished report, presented in poster format only, examined antidepressant effects in 45 subjects with bipolar I or II depression randomized to receive either divalproex (mean dose ~ 1.4 g/day) or placebo (Sachs et al. 2001). The results of this 8-week trial were negative, with changes in depression scores not reaching a statistically significant difference between the two groups. On the other hand, a twelve-week open trial of single daily dosing of divalproex by Winsberg et al. (2001) in medication-naïve and mood-stabilizer-naïve bipolar II depression found that divalproex was well tolerated and that 63% of subjects responded to treatment favorably. There was a trend towards a higher rate of antidepressant response to divalproex in medication-naïve patients (82%) compared to mood stabilizer naïve patients (38%). The authors speculated that the medication-naïve group responded at a higher rate due to a milder form or earlier phase of illness, lack of prior medication failures, or that they were less likely to have the course of their illness worsened by exposure to previous antidepressants.

In an 8-week, double-blind, placebo-controlled, randomized clinical trial of 25 mostly male outpatients with acute bipolar I depression, divalproex was significantly more likely to reduce symptoms of both depression and anxiety (Davis et al. 2005). The mean serum divalproex level was 81 mcg/ml at week 8. The extended-release preparation of divalproex has also been evaluated in a small sample (N = 18) of patients with bipolar I, II, or Not Otherwise Specified (NOS) depression. After 6 weeks of double-blind treatment, divalproex significantly improved depressive symptoms with associated reductions in apparent sadness and pessimistic thoughts (Dunn et al. 2006).

Lamotrigine

The results from the first double-blinded, placebo-controlled study of lamotrigine in the acute treatment of bipolar
depression contributed to its common off-label use while awaiting confirmation from subsequent trials (Calabrese et al. 1999). However, to date, replication of these findings has not occurred as seen in recently published reports of 4 additional separate failed trials in acute bipolar depression (Calabrese et al. in Press).

In the first study, Calabrese et al. (1999) randomly assigned 195 subjects with acute bipolar I depression to receive lamotrigine 50 mg/day, 200 mg/day or placebo in the first study of 7 weeks’ duration. Patients in the lamotrigine 200-mg/day group had significant improvement in their depressive symptomatology as compared to placebo. Improvement was seen as early as Week 3 in both the active treatment groups compared to placebo and more than half of the patients treated with lamotrigine 200 mg/day experienced an antidepressant response by study end. The efficacy of the 50 mg/day dose of lamotrigine was similar to placebo on several measures, supporting the higher 200-mg/day dose.

Subsequent lamotrigine monotherapy trials for acute bipolar depression did not confirm this first study (Calabrese et al. in Press). No significant differences were found between groups treated with lamotrigine or placebo over an 8–10-week study period on primary endpoints. Table 103–9 briefly summarizes the results from the five lamotrigine monotherapy trials for acute bipolar depression. A high placebo response rate in these four studies may explain the failure of lamotrigine to separate from placebo, although it would appear that given the large numbers of subjects studied, robust antidepressant effects with lamotrigine as a monotherapy for acute bipolar depression should not be expected for the majority of patients. Other reports point towards a more adjunctive antidepressant role for lamotrigine in acute depressive disorders, including treatment refractory cases (Nierenberg et al. 2006).

**Lithium for Acute Bipolar Depression**

Lithium continues to hold position as a first-line treatment for acute bipolar depression, either as monotherapy or in combination with an antidepressant, in many practice guidelines despite very limited evidence to support it in this phase of bipolar disorder. There have only been eight small placebo controlled trials comprising a total of 116 bipolar patients and none have been completed since 1978. All employed crossover designs with seven of eight trials reporting lithium superior to placebo with moderate to marked antidepressant response in 79% of bipolar patients. A 1991 meta-analysis by Souza and Goodwin confirmed efficacy of lithium in the acute treatment of depression of unipolar variety (Souza and Goodwin 1991).

Although not well studied, most recommendations for the use of lithium to acutely manage depression associated with bipolar disorder are to dose to a minimum serum lithium level of 0.8 mEq/L. There is scant evidence available by which to compare the efficacy of lithium relative to standard antidepressants. In a double-blind, placebo-controlled study of bipolar depressed patients on lithium, the addition of either paroxetine or imipramine was not effective in alleviating depressive symptoms in patients with serum lithium levels greater than 0.8 mEq/L (Nemeroff et al. 2001). However, this post hoc analysis result likely minimizes the antidepressant efficacy of lithium since this study enrolled subjects who had already demonstrated nonresponse to lithium prior to intake and subsequent addition of an antidepressant.

**Summary: Mood Stabilizers for Acute Bipolar Depression**

Bipolar depression remains an area of unmet need in terms of therapeutics. As we have reviewed here, compared to acute mania there is relatively limited data to provide a strong evidence base to treat bipolar depression with the exception of OFC and quetiapine. Table 103–10 summarizes the positive studies of acute treatment for bipolar depression based on evidence from large randomized, double-blind, placebo-controlled studies (Sachs 2007). This table includes the one positive trial for lamotrigine. OFC and quetiapine have demonstrated efficacy with NNT’s ranging from 3.9–7.4, comparable to effective treatments for mania. As noted already here, although lamotrigine was able to demonstrate efficacy for acute bipolar depression in one trial (NNT 4.5–8.3), these results have not been replicated.

emerging, most recently the eugeroic stimulant modafinil
(see sidebar or shaded paragraphs below) (Frye 2005). These
and other novel compounds will require further investigation
in all phases of bipolar disorder management to explore
their potential inclusion as mood stabilizers.

The Use of Modafinil for Bipolar Depression
Modafinil, a stimulant medication in the eugeroic
class, is most commonly used to treat narcolepsy.
This wakefulness-promoting agent has less abuse
potential than other psychostimulants and has been
studied in a placebo-controlled trial for acute bipolar
depression (Frye 2005).

Patients with bipolar I or II disorder were eligible
for inclusion into this study if experiencing an
active depression of at least mild severity based on
Clinical Global Impression score or an Inventory
of Depressive Symptomatology – Clinician Rating
30-item (IDS-C30, score >16) and having an
inadequate response to therapeutic dose or blood
level of a mood stabilizer, with or without an
antidepressant. A total of 85 patients were enrolled
and randomized in double-blind fashion to receive
either adjunctive modafinil or adjunctive placebo.
Modafinil was dosed at 100 mg/day for the first week
of the study and then increased to 200 mg/day for
the remaining 5 weeks.

Significantly greater improvement in depressive
symptoms on the IDS-C30 was observed in the
group receiving adjunctive modafinil compared
with placebo (P < 0.05). Response rates were also
significantly better with modafinil than with placebo
(44% versus 22%, respectively). The results suggest
that modafinil may help address acute depressive
symptomatology in patients with bipolar disorder
who have not adequately responded to traditional
mood stabilizer alone or in combination with
standard antidepressant medication.

Mood Stabilizers for Maintenance Treatment
of Bipolar Disorder

General Considerations
Prevention of acute bipolar episodes through effective
maintenance treatment is critical in order to improve the poor
long-term outcomes that exist for individuals with bipolar
disorder. Mood stabilizers have emerged as the cornerstone
of prophylactic treatment in bipolar disorder, with lithium
being the first known effective agent, supported by first-
generation maintenance studies conducted and published
during the 1960s and 1970s.

The need for alternatives to lithium for maintenance
treatment of bipolar disorder is clear since not all patients
respond to and/or tolerate it. AEDs and atypical antipsy-
chotics have been studied and offer alternatives to lithium
for long-term treatment of bipolar disorder.

Prevention of acute bipolar manic episodes through
maintenance treatment is critical in order to minimize the
deleterious and far-reaching consequences associated with
mania. There remains significant debate as to the most
appropriate treatments for prevention of future manic
episodes. The most common practice in the Unites States is
the continuation of the medication(s) that resolved an acute
manic episode. More commonly in Europe, acute manic
episodes are treated with typical or atypical antipsychotic
medication that is later discontinued and replaced with
lithium or another mood stabilizer choice for maintenance.
Despite these differences, most experts agree that some form
of maintenance pharmacotherapy should be prescribed fol-
lowing acute manic episodes or other frequently recurrent
disruptive states such as hypomania.

Given its highly recurrent nature and propensity for
illness relapses and recurrences to be depressive, the abil-
ity to prevent depression could have a profound impact
on ameliorating the burden of bipolar disorder. The 2003
FDA approval of lamotrigine for the prevention of mood
episodes associated with bipolar disorder, with specific
mention of preferential prophylaxis of depressive episodes,
was a milestone event in the therapeutics of bipolar disor-
der. The approved availability of a treatment option other
than lithium for this phase of preventative therapy is criti-
cal given the large unmet need in the treatment of bipolar
depression and the relatively high rate of depressive relapse
despite lithium maintenance.

Of concern in the management of this depressive risk
is the potential for any medication prescribed to precipitate
a manic switch or to destabilize the course of bipolar dis-
order. Significant debate exists over the long-term use of
antidepressants in bipolar disorder, where controlled data is
lacking to support efficacy but there are data to suggest an
unacceptably high rate of manic relapse during long-term
follow-up of patients treated with antidepressants for main-
tenance (Prien et al. 1984).

Pertinent to our earlier discussion of mood stabilizer
definitions and limitations is the recognition that the avail-
able medications appear to have some differential spectra
of efficacy in their prevention of mania versus depression.
It should be noted that the studies that established efficacy
for the medications discussed below all included randomly
assigned subjects who had experienced remission from an
acute episode during treatment with the study medication
before randomization. This methodological issue means that
the evidence supports the use of these maintenance
medications only when they are initiated as part of a suc-
cessful acute treatment regimen. Switching to or starting
maintenance therapy after an acute episode is resolved is
not supported by these data.

Lithium
In a review of maintenance therapies it was noted that
early studies consistently reported lithium to be more effec-
tive than placebo for bipolar prophylaxis (Muzina and
Calabrese 2005). Examination of eight early controlled
bipolar I prophylaxis studies that allowed for cumulative
analyses of relapse rates supports the superiority of lithium
over placebo for maintenance treatment as 31% of lithium-
treated patients experienced a relapse during a 5–24 month
period of maintenance compared to 76% of placebo-treated
patients. Placebo-treated patients had an almost three-
fold increased rate of manic relapses compared to lithium
maintained patients (59% placebo vs. 22% lithium). The
combined data from these early controlled studies demonstrate a twofold reduction in depressive relapses in lithium-treated patients compared to those on placebo (16% lithium vs. 33% placebo).

A larger and more heterogeneous analysis of 28 studies of various designs demonstrated similar positive results for lithium prophylaxis (Baldessarini et al. 2002). Yielding 2,985 different subjects, their analyses posited an overall crude ratio of 3.2-fold lower recurrence risk with lithium. Lithium-treated patients were less likely to be hospitalized, experienced fewer days ill per year, and when recurrences occurred their average duration was decreased. Long-term lithium treatment was found to reduce morbidity in patients with bipolar I or II disorder. Frequency of episodes decreased by 47% in bipolar I disorder and by 65% in bipolar II disorder. Depression was also prevented by lithium, more successfully for bipolar II patients who experienced 54% fewer episodes of depression per year than the 35% reduction seen in bipolar I disorder.

However, many of these early studies pre-1975 used discontinuation study designs that involved patients with a known positive response to lithium being abruptly discontinued from lithium if randomly assigned to the nontreatment or placebo group of the maintenance phase of the study. This design may have inflated the preventative effect of lithium due to the known effect of rapid lithium discontinuation, which can increase early relapse into depression or mania. Additionally, early lithium studies may have lacked specification of diagnostic criteria, not differentiated unipolar from bipolar depressed patients, and reported response rates as a percentage of only those patients completing the study while failing to report reasons for premature discontinuations. In 1999, Davis et al. (1999) analyzed data from 19 blinded, randomized, controlled trials of prophylaxis in 865 patients and controlled for the possible effects of abrupt lithium withdrawal inflating efficacy as mentioned above. They reported lithium significantly reduced relapse by 50% in bipolar disorder.

A study conducted by Bowden et al. (2000) provided randomized, blinded and placebo-controlled data that supported both divalproex and lithium as effective maintenance therapies in patients with bipolar I disorder. This study was the original maintenance study to employ modern methods, including enrollment of patients during an index manic phase and tapering lithium over two weeks instead of rapid discontinuation. Although the primary outcome measures in this study did not discriminate between the two “active” compounds and placebo and neither active treatment separated from placebo in terms of the primary outcome measure there were secondary measures of note. Lithium extended the time until relapse by 55% compared to placebo. However, divalproex was more successful than lithium in extending the duration of prophylaxis as well as preventing depressive symptoms.

The efficacy of lithium as maintenance therapy in bipolar I patients over an 18-month period has also been investigated using modern methods as an active arm in the lamotrigine maintenance trials (Bowden et al. 2003, Calabrese et al. 2003). In a pooled analysis of the data from these two lamotrigine bipolar trials, lithium was more effective than placebo in preventing relapse in patients with bipolar disorder, with significant efficacy against manic relapse but with a less substantial effect against depressive relapse (Goodwin et al. 2004).

Standard dosing to achieve blood levels of lithium between 0.8 and 1.0 mmol/L or higher is generally recommended over “low” dosing to levels between 0.4 and 0.6 mmol per liter. Maintenance at lithium levels in this low range has been associated with a 2.6 greater risk of relapse compared to standard dosing into the higher range (Keller et al. 1992). Furthermore, patients maintained in the higher range are less likely to experience subsyndromal episodes. Lithium side effects are more frequent when standard dosing is employed. However, these results may have been affected by study design that called for an abrupt reduction of lithium by 50% for those patients randomized into the “low” dosing group who had lithium on board in the standard range. These patients accounted for nearly all of the relapses in the “low” dose group.

**AEDs for Maintenance Therapy**

**Lamotrigine**

The Bowden and Calabrese 18-month maintenance trials noted above provide further support for the use of lamotrigine as a mood stabilizer, perhaps complementary to the effects of lithium (Bowden et al. 2003, Calabrese et al. 2003). Their results led to approval by the US FDA in June 2003 as a maintenance treatment for bipolar I disorder. In recently manic or hypomanic patients with bipolar I disorder, both lithium and lamotrigine were superior to placebo at delaying the time until additional pharmacotherapy was required for treatment of a mood episode. Lamotrigine demonstrated significantly greater efficacy for prolonging time to a depressive episode compared with lithium. In recently depressed patients with bipolar I disorder, both lamotrigine and lithium were significantly superior to placebo at delaying time to intervention for any mood episode. Lamotrigine and lithium were superior to placebo on the analysis of overall survival in the study, while lamotrigine, but not lithium, was superior to placebo in terms of delaying time to intervention for depressive episodes. These studies established that lamotrigine was significantly more effective than placebo in preventing relapse in patients with bipolar disorder while demonstrating primary effectiveness against depression.

These complementary studies enrolled patients in a double-blind phase of maintenance therapy after a recent depressed, hypomanic, or manic episode remitted with open-label stabilization during which lamotrigine was initiated as adjunctive or monotherapy and other psychotropics were discontinued. In both studies, 50% of patients achieved stabilization criteria allowing for progression into double-blind maintenance therapy with lamotrigine (50–400 mg/day), lithium (0.8–1.1 mEq/L), or placebo. The primary efficacy endpoint used was time to intervention for any mood episode.

In both of these studies, lamotrigine and lithium demonstrated effective prophylaxis against any emerging mood episode compared with placebo. There were statistically fewer relapsing mood episodes and longer median survival in lamotrigine and lithium treated patients compared with placebo. Median survival before intervention for any mood episode for lamotrigine-treated patients ranged from...
118–256 days, significantly better than placebo (only 85–93 days). Lithium also beat placebo with a median survival of 170–292 days. However, there were important differences in the spectra of maintenance efficacy.

In both studies, lithium, but not lamotrigine was superior to placebo at delaying the time to intervention for a manic or hypomanic episode. In total for both studies 123 hypomanic/manic events emerged during maintenance, with 25% of placebo treated patients experiencing a hypomanic, manic, or mixed episode (47 of 188; 21%) of the lamotrigine group relapsed (58 of 273), but only 11% of patients in the lithium-treatment arm had breakthrough mania or hypomania (18 of 164). Lithium was clearly more effective than placebo and lamotrigine in preventing manic and hypomanic relapse in recently symptomatic bipolar I patients.

In contrast, lamotrigine appears to be more effective than lithium in the prevention of depressive relapse in bipolar I patients. Lamotrigine but not lithium, was significantly better than placebo at prolonging time to intervention for a depressive mood episode in both studies. There were 209 depressive relapses in the patients observed in the two studies, with a higher rate of relapse in the placebo (68 of 188, or 36%) and lithium treatment groups (56 of 164, or 34%); lamotrigine was better at preventing recurrence of depression with a 31% rate of depressive relapse and a longer median survival before treatment of depression was necessary. The difference was particularly evident in the treatment of recently manic or hypomanic patients in whom only 14% of those receiving lamotrigine (8 of 58) needed intervention for emergent depression compared with 23% of patients receiving lithium (10 of 44) and 30% receiving placebo (21 of 69).

**Clinical Application of Lamotrigine**

No pretreatment laboratories are required before initiating lamotrigine, although routine physical examination, basic baseline chemistries, and pregnancy testing are advisable.

A history of hypersensitivity to lamotrigine is the only contraindication to use. The risk of rash must be discussed before initiating therapy with lamotrigine and may be better informed by data from multicenter trials of lamotrigine in mood disorders. Calabrese et al. (2002) reviewed data on 3,153 patients treated with lamotrigine in mood disorder trials and compared rash rates to the 1,056 placebo-treated patients and found rates of benign rash were 8.3% and 6.4% in lamotrigine- and placebo-treated patients, respectively. Rates of serious rash were 0% with lamotrigine and 0.1% with placebo. In the open-label setting, the overall rate of rash for lamotrigine was 13.1% and of serious rash, 0.1%. One mild case of Stevens-Johnson syndrome was reported in a patient treated with lamotrigine and there were no cases of toxic epidermal necrolysis. Any lamotrigine-treated patient developing any rash that cannot readily be explained by a known other cause, i.e. contact dermatitis, should immediately discontinue lamotrigine and notify their treating physician prior to resuming therapy. In unclear or difficult cases, dermatologic consultation should be obtained before restarting or rechallenging with lamotrigine.

Following a careful and gradual dosage titration schedule reduces the risk of rash. Lamotrigine should be initiated at 25 mg/day with the first dosage increase to 50 mg/day 2 weeks later. Lamotrigine may be increased to 100 mg/day in Week 5 and to 200 mg/day in Week 6. The presence of enzyme-inducing drugs, such as carbamazepine, can lead to doubling of the lamotrigine dose while concomitant administration with divalproex dictates a 50% reduction in lamotrigine dosing. Concomitant prescription of estrogen-containing oral contraceptives may lead to enzyme-induction and increased metabolism of lamotrigine, which may necessitate an increase in lamotrigine dose during the maintenance phase in some patients based on clinical circumstances.

The most common side effects observed with lamotrigine are dizziness, ataxia, somnolence, headache, diplopia, blurred vision, nausea, and vomiting. These side effects are typically mild and rarely lead to treatment discontinuation. Decreasing the dose or slowing the rate of dose escalation may alleviate these bothersome side effects.

**Divalproex/Valproate for Maintenance**

This AED is commonly used as both antimanic and maintenance therapy for bipolar disorder although it does not carry labeled indication for maintenance in the US. Early studies suggested comparable efficacy with lithium for maintenance with better tolerability.

Bowden et al. (2000) conducted the first double-blind, randomized controlled maintenance study in bipolar I disorder which followed patients from an index manic episode through a subsequent 52-week maintenance phase. Subjects who met recovery criteria after initial open-label antimanic treatments were randomized into the placebo-controlled, double-blind, parallel-group maintenance study and placed into divalproex, lithium, or placebo groups. Patients that were randomized off of their divalproex or lithium and onto the other agent or placebo had the drug gradually tapered off during the first 2 weeks of maintenance treatment. Study drugs were administered three times per day and dosed to serum trough concentrations of between 71 and 126 μg/mL for valproate and 0.8 to 1.2 mmol/L for lithium.

No significant difference was found in time to recurrence of any mood episode during maintenance therapy between these 3 groups. Specifically examining the time to either a manic episode or a depressive relapse for the three treatment groups favored divalproex compared to lithium on several secondary outcome measures, including less deterioration in depressive symptoms. Early termination for intolerance or noncompliance during the study also favored divalproex over lithium.

The Cochrane Database of Systematic Reviews reviewed the available evidence to clarify the justification of the increasing use of valproate, especially in the United States, for bipolar disorder prophylaxis (Macritchie et al. 2001). Of 19 trials detected by their search criteria, the above Bowden et al. 2000 study was the only one that met their inclusion criteria for a randomized, controlled trial comparing valproate with placebo or other mood stabilizers for specific use in maintenance therapy. This review concluded that there was little data available to robustly support valproate in the maintenance treatment of bipolar disorder.

In a comparator study of olanzapine versus divalproex over a 47-week period of initial acute treatment of mania or mixed state followed by maintenance treatment of 251 patients with bipolar disorder, the mean improvement in mania rating scale scores was significantly greater in the olanzapine-treated group (Tohen et al. 2003a). However,
there were no significant overall differences between the two treatments in the rates of symptomatic remission or subsequent relapse over the entire 47-week period, suggesting comparable maintenance efficacy for the two agents.

**Carbamazepine for Maintenance**
A meta-analysis on mood stabilizers in the prevention of recurrent affective disorders that included 10 double-blind, randomized studies comparing carbamazepine to lithium found no significant difference in relapse rates over a 1–3 year maintenance period (55% versus 60%, respectively) (Davis et al. 1999). However, studies regarding maintenance with carbamazepine monotherapy have produced variable results and consensus based on available data and expert opinion is that carbamazepine is inferior to lithium in the maintenance treatment of bipolar disorder (Muzina et al. 2002). There is stronger evidence supporting its use in combination with other mood stabilizers for maintenance, particularly with lithium.

**Atypical Antipsychotics for Maintenance Therapy**
At the time of this chapter’s creation, only two atypical antipsychotics have published long-term maintenance studies of monotherapy that were of sufficient rigor to warrant regulatory approval for maintenance in the US—olanzapine and aripiprazole. Data regarding the use of the other atypical antipsychotics for maintenance therapy in bipolar disorder is pending.

It should be noted that no published long-term maintenance study of atypical antipsychotic agents has enrolled patients presenting recently depressed. The olanzapine and aripiprazole maintenance trials began by enrolling recently manic or mixed bipolar I patients into an initial stabilization phase followed by the randomized and blinded phase of the study with active monotherapy or placebo. This study design has important implications related to attempts to investigate full mood stabilizing efficacies of these and other medications since it has been demonstrated that the polarity of the index episode tends to predict the polarity of relapse into a subsequent episode in a ratio of about 2:1 to 3:1 (Calabrese et al. 2004). The impact of this “like breeds like” phenomenon on maintenance studies is that in order to fully assess prophylactic efficacy for any agent these trials must include and stratify for both recently depressed and recently manic episodes. Interpreting the results of the atypical antipsychotic maintenance studies described below should take this issue into consideration when attempting to best understand the maintenance mood stabilizing effects of these agents.

**Olanzapine**
An 18-month placebo-controlled study evaluating the preventive efficacy of olanzapine added to either lithium or valproate found that among patients who experienced syndromic remission from an acute manic episode following the addition of olanzapine to lithium or valproate, those remaining on the combination therapy sustained symptomatic remission longer than those on lithium or valproate monotherapy (Tohen et al. 2004). There was no reported difference in duration of syndromic remission. In a head-to-head comparison olanzapine monotherapy was significantly more effective than lithium in preventing manic and mixed episode relapse/recurrence in patients acutely stabilized with olanzapine and lithium cotreatment (Tohen et al. 2005). Olanzapine and lithium were comparable in preventing relapse or recurrence of depression.

In the first placebo-controlled, double-blind study to examine the efficacy of olanzapine monotherapy in relapse prevention in bipolar I disorder the median time to symptomatic relapse into any mood episode after open-label stabilization of acute mania with olanzapine was significantly longer among patients continuing to receive olanzapine than in placebo-treated patients (174 days versus 22 days, respectively). This study suggests that olanzapine prevents bipolar I relapse into any mood state for significantly longer periods of time than placebo. Olanzapine monotherapy is FDA approved as a maintenance therapy in bipolar I disorder.

**Aripiprazole**
An international randomized, double-blind, parallel-group, placebo-controlled study of aripiprazole monotherapy in patients with recent bipolar I mania or mixed episode provided 26 weeks’ of maintenance data supporting the mood stabilizing effect of this atypical antipsychotic (Keck et al. 2006a). Recently manic or mixed bipolar patients who had been stabilized during an open-label phase with aripiprazole 15 or 30 mg/day over 6–18 weeks were randomized to receive either aripiprazole monotherapy or placebo for the 26-week, double-blind maintenance phase. Aripiprazole was superior to placebo in delaying the time to relapse, although this effect was found for manic prophylaxis and not for depression. Aripiprazole-treated patients had significantly fewer relapses (25%) than placebo patients during this 26-week study (25% versus 43%, respectively).

This 26-week aripiprazole relapse prevention study was designed a priori with a prospective, 74-week, double-blind, placebo-controlled extension phase (Keck et al. 2006b). Patients who completed the initial 26-week stabilization continued on into the 74-week extension phase on double-blinded aripiprazole or placebo. The results of this extended maintenance study of aripiprazole monotherapy demonstrated that time to relapse into any mood episode was significantly longer for patients who received active treatment than placebo. Only 33% of aripiprazole-treated patients experienced any relapse by Week 100 of the study, whereas 51% of patients in the placebo group relapsed by then. Notably, when looking at phase-specific relapse aripiprazole was able to demonstrate prophylactic efficacy against mania but not depression. Aripiprazole was well-tolerated over this extended period with on average less than 1 lb (0.4 kg) of weight gain.

**Other Atypical Antipsychotics**
Limited evidence from case reports or small open-label studies exists to support the use of risperidone, quetiapine, or ziprasidone as maintenance therapy in bipolar disorder. Based on the known acute antimanic effects of these atypical antipsychotics and the results from the olanzapine and aripiprazole maintenance studies, it might be assumed that these agents will have similar prophylactic profiles with a tendency for better efficacy against manic relapse than depressive relapse. The antidepressant efficacy of quetiapine acutely plus its antimanic properties raises the possibility...
that it or one of these atypical antipsychotics may eventually demonstrate mood stabilization that is closer to the elusive “ideal” definition of a mood stabilizer.

**Summary: Mood Stabilizers for Maintenance**

Clinical management of maintenance needs in bipolar disorder is benefited by a growing number of treatment options, each with its own particular profile of advantages and disadvantages (see Table 103–11). Five agents (lithium, divalproex, lamotrigine, olanzapine, and aripiprazole) have been able to demonstrate efficacy in maintenance treatment of bipolar disorder based on evidence from large randomized, double-blind, placebo-controlled studies, although divalproex did so only on secondary outcome measures and lithium was able to effectively prophylax against manic relapses/recurrences. Table 103–12 provides a summary of these results, where the NNT for the effective maintenance mood stabilizers ranged from 3.0−6.7.

**Mood Stabilizers for Rapid Cycling Bipolar Disorder (RCBD)**

The demanding treatment issues posed by RCBD have been identified for decades now, dating to early reports that patients did not respond adequately when treated with lithium (Dunner and Fieve 1974, Kukopulos et al. 1980). Frequently recurring and refractory depressive episodes appear to be a “hallmark” of RCBD and may be exacerbated (cycle induction or acceleration) by antidepressant use (Calabrese et al. 2001a). It was initially suggested that divalproex was more effective in this patient population, particularly for the prophylaxis of hypomanic or manic phases of the illness (Calabrese and Deluca 1990). However, a more recent double-blind comparator study did not find divalproex superior to lithium in the long-term management of RCBD (Calabrese et al. 2005b). In this 20-month study, recently hypomanic/manic patients who had experienced a persistent bimodal response to combined treatment with lithium and divalproex were randomly assigned to either lithium or divalproex monotherapy. It should be noted that of the 254 patients enrolled in the open-label acute stabilization phase, only 60 experienced a sufficient persistent bimodal response and subsequent randomization into the double-blind

maintenance phase. The preponderance of nonresponse to combined lithium and divalproex was refractory depression versus manic (3:1). Of those patients assigned to double-blind maintenance monotherapy, more than half relapsed with no significant differences in time to relapse between lithium and divalproex treatment. Depressive relapse was more common than hypomanic/manic relapse. Lithium-treated patients were more likely to experience side effects leading to premature discontinuation than those receiving divalproex (4:1). This study confirms earlier observations suggesting highly recurrent refractory depression as the hallmark of RCBD.

Lamotrigine monotherapy has been reported to be effective for some patients with RCBD based on data from a study using open-label lamotrigine added to ongoing pharmacotherapy followed by double-blind, placebo controlled maintenance monotherapy in responders after concomitant psychotropics were tapered off (Calabrese et al. 2000). Forty-one percent of lamotrigine patients versus 26% of placebo patients were stable without relapse over the 6 months of study.

Atypical antipsychotics may provide additional utility in the treatment of RCBD although limitations such as study design and sample size may hamper generalizability of the available data. Clozapine has demonstrated prophylactic efficacy in RCBD (Calabrese et al. 1991) and risperidone also has some data to suggest efficacy for rapid cyclers (Vieta et al. 1998, Cocconi et al. 2002). Similarly, there have been reports of efficacy using olanzapine for RCBD when acutely manic as either adjunctive therapy (Demopoulos et al. 2000) or as monotherapy (Sanger et al. 2003) or for dysphoric mania (Gonzalez-Pinto et al. 2002). More recently, the atypical antipsychotics quetiapine and aripiprazole have also been studied in patients with RCBD with favorable results.

Quetiapine monotherapy has also been associated with benefits for patients with RCBD. In a recent post-hoc analysis of the acute bipolar depression quetiapine monotherapy trials, quetiapine was found to be clinically effective and well tolerated in the short-term treatment of depressive episodes in patients with bipolar I or II disorder that have a rapid cycling course (Vieta et al. 2007). This sub-analysis included 108 subjects with RCBD in the acutely depressed phase randomized to double-blind, placebo-controlled treatment over 8 weeks. Effect sizes for quetiapine treatment were >1.0 and were similar in bipolar I and II disorder.

Although small in sample size, data regarding aripiprazole use in patients with RCBD from the aripiprazole maintenance study (totaling 100 weeks) has been analyzed (Muzina et al. 2007). Subjects with bipolar I disorder received aripiprazole or placebo as part of this double-blind maintained study, with 28 of the 161 patients who met stabilization criteria for 6 consecutive weeks diagnosed with rapid cycling. The time to relapse was significantly longer with aripiprazole treatment compared with placebo at 26 weeks and 100 weeks, with an overall 81% reduction of relapse risk associated with aripiprazole maintenance in RCBD.

Management of RCBD requires careful investigation and elimination of any potential mood destabilizing forces as well as consideration of the best regimen mood stabilizer(s) pharmacotherapy. Traditional antidepressants, often avoided or used with caution in bipolar disorder, should be viewed even more suspiciously in RCBD given the lack of supportive evidence for their use and concerns for cycle acceleration. Lithium, divalproex, lamotrigine, and the atypical antipsychotics are the current mainstays of treatment although given the tendency of RCBD to be refractory to treatment, combination strategies are most often necessary. Thyroid hormone augmentation may also be of great benefit for some patients with RCBD and should be considered particularly when refractoriness to mood stabilizers is observed (Post et al. 1997, Kilzieh and Akiskal 1999, Calabrese et al. 2001b).

Redefining Mood Stabilizers

In their provocative paper entitled “What is a mood stabilizer?” Goodwin and Malhi (2006) effectively dissect the limitations of various definitions and the inherent weakness of “terminologic exactitude” in pharmacology. Despite the intrinsic flaws of the term ‘mood stabilizer’ the discussions surrounding it have prompted clinicians to attend to both poles of the illness and in all phases of treatment. They conclude that by using the strictest definition proposed by Bauer and Mitchner (2004)—a mood stabilizer should treat both poles of bipolar disorder acutely and prevent recurrence—that only lithium just barely qualifies. They go on to suggest that the term should be reserved only for agents that have been compared to lithium and have performed adequately in such a comparison. This suggestion has much merit, although as we have covered here, lithium itself does not clearly rise to these high criteria given the limited evidence for its efficacy in treating bipolar depression acutely and preventing depressive recurrence.

We propose reserving the term mood stabilizer for use in general discussions about the search for an ideal agent that is effective in all poles of illness and as such recognize that no complete mood stabilizer has been discovered. Perhaps such an agent may become reality once we uncover the underlying pathophysiology of bipolar disorder and begin to develop drugs with targeted molecular actions that restore normal mood stabilizing controls.

In clinical practice we must acknowledge that current psychotropic agents are partial mood stabilizers at best. A very minimal requirement should be the lack of evidence for causing switches to mania or depression or cycle acceleration. Lack of mood destabilizing effects plus efficacy in at least one area of bipolar disorder management should allow for use of the term “partial mood stabilizer.” Partial mood stabilizers may be further categorized based on level of evidence for specific directional efficacy, either unidirectional, bidirectional, intermediate, or mixed. Table 103–13 seeks to define these proposed terms and to include the reviewed putative mood stabilizers into these new categories.

Conclusion

The evidence base for and theoretical concepts of pharmacological treatments of bipolar disorder have undergone remarkable growth and evolution over the past decade. Increasing study of medications in all poles of the disorder and in maintenance has challenged the common usage of the term “mood stabilizer.” Simply defining this type of medication has not been easy and continues to spark debate. The search for a perfect and complete mood stabilizer continues, while in clinical practice we must employ evidence-based
strategies using partial mood stabilizers as well as other off-label, less well-studied drug therapies.

The management of mania has become simpler, if only due to having a wider variety of medication options—either in monotherapy or in combination—to employ in stabilizing mood from above the normal baseline. Bipolar depression remains a therapeutic challenge, although the emergence of better-studied and approved medications to stabilize mood from the depressive pole is encouraging. Maintenance therapy is a lifelong necessity in bipolar disorder and should be considered and reviewed at every encounter with the patient, during acute episodes as well as during periods of euthymia that might be threatened by recurrence or tolerability issues.

Beyond the scope of this chapter, nonpharmacological treatments should also be considered for their potential “mood stabilizing” properties. These treatments range from electroconvulsive therapy through cognitive-behavioral therapy and into family-based and other supportive psychotherapies. Individually tailoring a “mood stabilizer” treatment plan for each and every patient with bipolar disorder is a dynamic process and must include all of these considerations.

Introduction

There has been an exponential increase in the number of medications demonstrated to be effective for the treatment of anxiety and anxiety disorders (Table 104–1). This chapter will provide a brief review of the history and evolution of these treatment strategies, followed by descriptions of each class of medication. Then the efficacy and adverse effects data from clinical trials with different disorders will be presented so that the reader can compare and contrast the advantages and disadvantages of different classes of medications for the treatment of each anxiety disorder described in the *Diagnoses and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR).

Beginning in the late 19th century, there was a progression from alcohol, bromides, and opiates to barbiturates developed in the early 20th century. Barbiturates were effective in decreasing anxiety, but they were addictive and lethal in overdose. There was continued advancement in the development of anxiolytics like meprobamate (effective but again addictive and lethal in overdose) and the antihistamine hydroxyzine, which was less effective than meprobamate and barbiturates and very sedating. The next major advance in anxiolytic therapy was the work pioneered by Klein and Fink (1962) demonstrating that some tricyclic antidepressants (TCAs) were useful in the treatment of panic disorder. This was rapidly followed by studies reporting that monoamine oxidase inhibitors (MAOIs) could be used to treat certain patients with anxiety disorders. However, the major advancement in the field of anxiolytics in the 1960s was the development and approval of benzodiazepines. These agents were much safer than the barbiturates and meprobamate, had a rapid onset of action (so patients felt better quickly), and had a broad spectrum of efficacy extending from situational anxiety to pathological anxiety disorders. Many different benzodiazepines, with different absorption times and half-lives, were developed and have been valuable not only for treating anxiety and anxiety disorders but for treating seizure disorders and alcohol withdrawal. Unfortunately, with widespread usage some individuals did develop craving and dependence on benzodiazepines as well as significant problems with withdrawal when abruptly discontinued. The next major class of agents approved was the azopyrones, of which buspirone is the most well known. This agent was found to be effective in generalized anxiety disorder but was not effective for the treatment of most other anxiety disorders or situational anxiety.

There was a cascade of anxiolytic research in the 1990s. The selective serotonin reuptake inhibitors (SSRIs) as a class were demonstrated to be efficacious treatments for most of the anxiety disorders described in the DSM-IV-TR. Although these agents have a delayed onset when contrasted with the benzodiazepines, they have a broader spectrum of action, no problems with dependence, and much less of a problem with withdrawal symptoms. The 1990s also saw the approval of venlafaxine as a treatment for generalized anxiety disorder. One of the most intriguing transitions in anxiolytic development has been the ongoing research investigating the use of anticonvulsant medications for the treatment of anxiety disorders.

A General Approach to Using Medication with Anxious Patients

Patients may present physicians with many different concerns related to anxiety. However, one need that all patients who seek help for symptoms of anxiety have is the need for reassurance that they are not alone, that their physicians truly hear their concerns, and that their physicians will attempt to help them. One important step in building rapport and reassuring a patient is taking a complete history. This is not only essential for making an appropriate diagnostic formulation, but also demonstrates an interest in the patient's situation.
intervention. The diagnosis dictates the class of medication to be used and the length of pharmacotherapy. Potential differential diagnoses for patients with anxiety disorders include the following: adjustment disorders secondary to life stressors, anxiety disorders secondary to a medical condition, symptoms of anxiety secondary to a medical condition, anxiety secondary to alcohol or substance abuse or dependence, generalized anxiety disorder (GAD), panic disorder (PD), social anxiety disorder (SAD), specific phobia, posttraumatic stress disorder (PTSD) and obsessive–compulsive disorder (OCD). Since patients with either symptoms of anxiety or an anxiety disorder are in distress and usually feel vulnerable, sharing the diagnostic formulation with the patient is an important intervention that facilitates the patient’s commitment to the treatment plan. Formulating this therapeutic alliance is crucial since anxious patients may be reticent to take medication. When they do take medications, they commonly ruminate about medication side effects. As discussed in other chapters in this text, patients with anxiety disorders or anxiety as a symptom are more likely to have somatic preoccupations and heightened somatic sensitivity. A collaborative approach where physicians and patients form a “team” to monitor both the potential benefits and the liabilities of any medication intervention frequently enfranchises the patient and enhances adherence. An important rule in general is “to start low and go slow” when initiating pharmacological treatment for patients with anxiety disorders. Interestingly, although treating patients with anxiety disorders frequently requires a more gradual initial titration schedule, patients usually attain maintenance dosages of antidepressant medications that are greater than the dosage commonly used to treat major depressive disorder.

### Antidepressant Medication

Since the reports by Klein and Fink in the early 1960s, medications initially identified because of their antidepressant properties have been successful at treating anxiety disorders. The basic action of the majority of the antidepressants is to increase the availability of neurotransmitters in the synaptic cleft. As is demonstrated in Table 104–2, antidepressants work by a variety of mechanisms of action. The most widely used antidepressants that also have anxiolytic properties are the SSRIs. These agents have the broadest spectrum of activity that spans the entire spectrum of anxiety disorders detailed in the DSM-IV-TR. Although all of the SSRIs have a slightly different site of action, their basic mechanism of action is the inhibition of the serotonin reuptake pump. This facilitates an increase in levels of serotonin throughout the body. Table 104–3 presents the inhibition constants for the SSRIs, some TCAs, and several other antidepressant agents.
As illustrated in Table 104–4, a variety of serotonin receptor subtypes have been implicated in the modulation of anxiety disorders, depressive disorders, migraine, pain, and neuropsychiatric disorders. The stimulation of those receptors also accounts for the commonly observed side effects of SSRIs (Table 104–5). The pharmacokinetic properties of the SSRIs are presented in Table 104–6.

The mechanism of action of the TCAs also involves the inhibition of reuptake sites thereby increasing the amount of the neurotransmitter present throughout the body and in the synaptic cleft. The disadvantage of the TCAs includes their side effect profile and their potential lethality in overdose (Table 104–5). Other antidepressants have a variety of different mechanisms of action. The MAOIs inhibit the enzyme monoamine oxidase, a crucial intracellular enzyme for the catabolism of serotonin, norepinephrine, dopamine, and phenethylamine. The first-generation MAOIs irreversibly bind to monoamine oxidase. After cessation of MAOI treatment, it takes approximately 2 weeks for restoration of monoamine oxidase functioning through the generation of new enzyme. The other major mechanisms of action for antidepressants that also have anxiolytic effects include the inhibition of both serotonin and norepinephrine transporter sites, as is seen with venlafaxine and clomipramine. However, venlafaxine does not begin to exhibit this effect until one gets to a minimum of 150 mg per day. Mirtazapine works primarily through antagonism of the presynaptic alpha-2-adrenergic receptors. This increases serotonin, norepinephrine, and possibly dopamine levels in the synapse. The primary mechanism of action of nefazodone is the antagonism of postsynaptic serotonin type-2 receptors. While the precise mechanism of action of bupropion is not fully appreciated, it is thought to increase norepinephrine levels. The pharmacokinetic properties of the antidepressants are illustrated in Table 104–6. The relative differences in terms of major pharmacokinetic and pharmacodynamic properties are outlined in Table 104–7.

### Benzoazepine Medication

The benzodiazepines as a class work by increasing the relative efficiency of the gamma-aminobutyric acid (GABA) receptor when stimulated by GABA. The benzodiazepines bind to a site located adjacent to the GABA receptor and cause an allosteric change to the receptor that facilitates the increased passage of the chloride ions intracellularly when GABA interacts with the receptor complex. This leads to a relative hyperpolarization of the neuronal membrane and inhibition of activity in the brain. The benzodiazepines as a group have different affinities for GABA receptors; in fact some agents bind to only one of the two types of GABA receptors. For example, both clonazepam and alprazolam work only on the central GABA_A receptor, while diazepam binds to both GABA_A and GABA_B receptors. The pharmacokinetic properties of the benzodiazepines are outlined in Table 104–6. The relative pharmacodynamic and pharmacokinetic properties of the benzodiazepines are further outlined in comparison to the other medications in Table 104–7. As a class, benzodiazepines are efficacious for the treatment of PD, SAD, GAD, alcohol withdrawal, and situational anxiety. Although OCD falls within the taxonomy of anxiety disorders, benzodiazepines do not seem to be particularly effective in treating these patients.

### Buspirone

Buspirone is a member of the group of agents called azaspirodecanediones. It is believed to exert its anxiolytic effect by acting as a partial agonist at the 5-HT_A autoreceptor. Stimulation of the 5-HT_A autoreceptor causes a decreased release of serotonin into the synaptic cleft. However, buspirone also exerts another effect through its active metabolite 1-phenyl-piperazine (1-PP) that acts on

It usually takes approximately 4 weeks for the benefit of buspirone therapy to be noticed in patients with GAD. One major advantage of buspirone is that it does not cross-react with benzodiazepines. The most common side effects associated with buspirone include dizziness, gastrointestinal distress, headache, numbness, and tingling. The pharmacokinetics and average daily dosage are described in Table 104–6. The most common pharmacokinetic and pharmacodynamic actions of buspirone are described in Table 104–7.

**Beta-Blocker Medication**

Beta-adrenergic blockers competitively antagonize norepinephrine and epinephrine at the beta-adrenergic receptor (Table 104–7). It is thought that the majority of positive effects of beta-blockers are due to their peripheral actions. Beta-blockers can decrease many of the peripheral manifestations of anxiety such as tachycardia, diaphoresis, trembling, and blushing. The advent of more selective beta-blockers that only block the beta 2 -adrenergic receptor has been beneficial since blockade of beta 1 -adrenergic receptors can be associated with bronchospasm. Beta-blockers may be useful for individuals who have situational anxiety or performance anxiety. They generally have not been effective in treating anxiety disorders such as generalized SAD, PD, or OCD.

**Anticonvulsant Medication**

One of the areas of greatest investigation has been the use of anticonvulsant medication to treat anxiety disorders. Mono-therapy and augmentation trials with anticonvulsants have been performed in GAD, SAD, PD, and OCD. Despite a rather sizable investment on the part of the pharmaceutical industry and investigators, at this time there are no FDA-approved convulsant agents for the treatment of anxiety disorders. Please see Tables 104–6 and 104–7 for a review of some of the more salient pharmacological properties of anticonvulsants.

**Antipsychotic Medication**

The conventional or typical antipsychotic medication, whose mechanism of action is primarily to block dopamine type-2 alpha-2-adrenergic receptors to increase the firing rate of the locus coeruleus. Some not yet well-characterized combination of these effects may be responsible for anxiolytic effect of buspirone.

receptors, has been used as adjuvant medication for the treatment of anxiety disorders for years. However, because of problems with extrapyramidal side effects and the risk of developing tardive dyskinesia, these agents had fallen out of favor. The newer class of atypical antipsychotic medications have a markedly decreased risk of both extrapyramidal side effects and tardive dyskinesia, and so those antipsychotic medications are beginning to be used again as adjuvants in patients with treatment-resistant anxiety disorders. This simultaneous blockade of both neurotransmitter systems seems to decrease extrapyramidal side effects and the risk of developing tardive dyskinesia. Although the different atypical antipsychotic medications have different affinities for dopamine type-2 and serotonin type-2 receptors, this is the common mechanism of action of these agents. The atypical antipsychotic medications also differ dramatically in terms of their pharmacodynamic properties. As described below, there are very few published studies investigating atypical antipsychotic medication augmentation for the treatment of anxiety disorders. Please review the pharmacokinetic and side effect data for the antipsychotic medications that have been used to treat anxiety disorders in Tables 104–6 and 104–7.

Generalized Anxiety Disorder

Selective Serotonin Reuptake Inhibitors

Pollack et al. (2001) published an 8-week randomized, double-blind, placebo-controlled, flexible-dosage trial investigating the efficacy of paroxetine in 326 adult outpatients with GAD. Inclusion criteria both at screen and baseline were a Hamilton Anxiety Rating Scale (HAM-A) total score ≥ 20 and a score ≥ 2 on HAM-A items 1 (anxious mood) and 2 (tension). Eligible patients underwent a 1-week, single-blind placebo run-in, and then were randomized to paroxetine or placebo. Patients assigned to paroxetine started treatment at 10 mg/day for the first week and were titrated to 20 mg/day by week 2. After the second week, patients tolerating the medication could have their medication increased every 7 days by 10 mg/day to a maximum 50 mg/day. The primary efficacy measure in this study was the mean change in total HAM-A score from baseline to week 8. Response to treatment was defined by a score of (1) “very much improved” or (2) “much improved” on the CGI. Remission was defined by a HAM-A total score of 7 or less. The trial was completed by 78.9% of paroxetine patients and 81.6% of placebo patients. Seventy-four percent of paroxetine patients met response criteria versus 55.6% of placebo-treated patients. Forty-three percent of paroxetine-treated patients met remission criteria compared to 26.3% of placebo-treated patients. The mean daily dose of paroxetine was 26.8 ± 7.5 mg/day. Rickels et al. (2003) published an 8-week randomized, double-blind, placebo-controlled trial using two fixed doses of paroxetine to treat GAD. Five hundred sixty-six outpatients with DSM-IV-TR diagnosis of GAD and a score of ≥ 20 on the HAM-A were randomized to receive either 20 or 40 mg/day of paroxetine or placebo. The primary outcome measure was the change from baseline in total score on the HAM-A. Response was defined as a rating of “very much improved” or “much improved” on the CGI. Remission was defined as a HAM-A total score of ≤ 7. Both the 20 mg and 40 mg paroxetine-treated groups demonstrated statistically significant reductions in HAM-A total scores when compared with the placebo group. Response rates were 62% and 68%, respectively, for the 20 and 40 mg/day paroxetine-treated groups, compared with 46% response rate for the placebo group. Remission rates were 30% and 36% of patients in the 20 and 40 mg paroxetine groups, respectively, compared with 20% given placebo. Stocchi et al. (2003) published a 24-week double-blind GAD study contrasting paroxetine and placebo. Six hundred fifty-two adult outpatients with DSM-IV-TR GAD and a CGI-S score of ≥ 4 received paroxetine (20–50 mg/day) or placebo for 8 weeks. Patients whose CGI-S scores decreased by at least 2 points to ≤ 3 at week 8 were randomly assigned to double-blind treatment with paroxetine (n = 278) or placebo (n = 288) for an additional 24 weeks. The primary efficacy measure was the proportion of the patients relapsing (an increase in CGI-S score of at least 2 points to a score of ≥ 4 or withdrawal due to lack of efficacy) during double-blind treatment. Significantly fewer paroxetine relapsed during the 24-week double-blind phase (10.9% vs. 39.9%, p < 0.001). Subjects randomized to placebo discontinuation were almost five times more likely to relapse than those continuously on double-blind paroxetine (estimated hazard ratio = 0.213 [95% CI = 0.1 to 0.3]; p < 0.001). Therefore, studies demonstrate that paroxetine is an effective short-term and continuous treatment for patients with GAD.

Escitalopram also has been extensively studied as a treatment for GAD. Davidson et al. (2004) conducted an 8-week randomized, double-blind, placebo-controlled, multicenter, flexible-dose study of escitalopram (10 mg/day for the first 4 weeks and then flexibly dosed from 10–20 mg/day) of 315 US outpatients that met DSM-IV-TR

criteria for GAD. Mean change from baseline to week 8 in the HAM-A was used as the primary efficacy variable. The escitalopram group \( (n = 158) \) demonstrated statistically significant and clinically relevant, greater improvement \( (n = 157) \) on all efficacy parameters in this study. Mean changes from baseline to week 8 on the HAM-A total score using a last-observation-carried-forward approach were \( -11.3 \) for escitalopram and \( -7.4 \) for placebo. Response rates at week 8 were \( 68\% \) for escitalopram and \( 41\% \) for placebo among completers, and \( 58\% \) for escitalopram and \( 38\% \) for placebo looking at the last-observation-carried-forward values. There was no statistical difference in reported adverse events in the escitalopram-treated group \( (8.9\%) \) compared to the placebo-treated group \( (5.1\%) \). Davidson et al. \( (2005) \) also examined the safety and efficacy of long-term, open-label treatment of GAD with escitalopram. Three 8-week, double-blind, placebo-controlled trials of nearly identical design were conducted with escitalopram in GAD (DSM-IV-TR criteria). Patients completing these trials were given the option of entering a 24-week, open-label, flexible-dose trial of escitalopram \( (10–20 \text{ mg/day}) \). Two hundred ninety-nine \( (56.8\%) \) of 526 patients completed 24 weeks of open-label treatment. The HAM-A score at baseline of open-label treatment was 13.1. Long-term escitalopram treatment led to continued improvement in anxiety and quality-of-life measures. Of those completing 24 weeks of treatment, \( 92.0\% \) were responders \( (\text{CGI} \leq 2) \). The mean HAM-A score in the completer analysis was 6.9, and the mean HAM-A score in LOCF analysis was 9.2 at endpoint. Insufficient therapeutic response and adverse events led to withdrawal of 4.2% and 9.9% of patients, respectively. Mean increase in weight from baseline was 3.0 lb. Although uncontrolled, these data mirror the type of improvement observed in double-blind continuation studies with other SSRIs.

Allgulander et al. \( (2004) \) performed the first large, global multicenter, placebo-controlled, flexible-dose study of sertraline \( (50–150 \text{ mg/day}) \) compared to placebo in GAD outpatients. After a 1-week single-blind placebo lead-in, patients were randomly assigned to 12 weeks of double-blind treatment with placebo \( (n = 188) \) or flexible doses of sertraline \( (n = 182) \). The primary outcome measure was the change from baseline to endpoint in the HAM-A total scores. Sertraline-treated subjects had significantly greater improvement \( (\text{mean} = 11.7) \) over placebo patients \( (\text{mean} = 8.0) \) on the HAM-A at week 4. Brawman-Mintzer et al. \( (2006) \) performed a similar study comparing sertraline \( (50–200 \text{ mg/day}) \) to placebo in outpatients with GAD for 10 weeks. The primary efficacy measure was change from baseline in HAM-A total score. Response was defined as \( \geq 50\% \) decrease in HAM-A total score at endpoint. Sertraline produced statistically significant reduction in anxiety symptoms, as measured by the HAM-A total changes scores \( (p = 0.032) \). Response rates were 59.2% for the sertraline group compared to 48.2% for the placebo group. Ball et al. \( (2005) \) conducted an 8-week, randomized, double-blind, flexible-dose study investigating paroxetine \( (10–40 \text{ mg/day}) \) versus sertraline \( (25–100 \text{ mg/day}) \) in 53 outpatients meeting DSM-IV-TR criteria for GAD. Both paroxetine and sertraline were associated with significant decreases in mean HAM-A scores \( (\text{paroxetine} = 57\% \pm 28\%; \text{sertraline} = 56\% \pm 28\%) \). There were no significant differences between the two groups in either remission rates, as defined by a CGI-S score of 1, \( (\text{paroxetine} = 40\%, 10/25; \text{sertraline} = 46\%, 13/28) \) or response rates, defined as at least a 50% reduction in score from baseline to posttreatment \( (\text{paroxetine} = 68\%, 17/25; \text{sertraline} = 61\%, 17/28) \). Thus in this small study the two SSRIs were comparable to one another on all efficacy assessments.

### Special Populations
The efficacy and safety of sertraline treatment for children with GAD was investigated in a 9-week, double-blind, placebo-controlled study by Rynn et al. \( (2001) \). Twenty-two children and adolescents, ages 5–17 years, who met DSM-IV-TR criteria for GAD and had a HAM-A rating \( \geq 16 \) participated in this study. All patients underwent a 2- to 3-week preevaluation period, followed by a 9-week double-blind treatment phase. Sertraline was initiated at 25 mg/day for the first week then titrated to 50 mg/day for weeks 2–9. Primary outcome measures were the HAM-A total score, HAM-A psychic and somatic scores as well as the CGI-Severity and Improvement Scale scores. Mean HAM-A scores for the sertraline group reduced from 20.6 ± 3.6 at baseline to 7.8 ± 5.7 at week 9, while those receiving placebo decreased from 23.3 ± 4.0 at baseline to 21.0 ± 7.8 at week 9. Mean CGI-Severity scores significantly improved for the sertraline-treated group \( (4.0 \text{ baseline to 2.4 weeks}) \) while the placebo-treated group remained unchanged \( (4.0 \text{ baseline to 3.9 weeks}) \). Importantly, no statistically significant differences were found in adverse events between the two groups. Only two patients in the placebo-treated group and one patient in the sertraline group dropped out prior to study completion.

These data suggest that low doses of sertraline may be effective and well tolerated for children with GAD.

Lense et al. (2005) examined efficacy and tolerability of citalopram in 30 subjects with anxiety disorders aged 60 or older (30 subjects meeting DSM-IV-TR criteria for GAD). Subjects were randomly assigned to treatment with citalopram or placebo for 8 weeks. Response was defined as a score of 1 (very much improved) or a 2 (much improved) on the CGI-I scale or a 50% reduction in the HAM-A scale score. Ten (67%) of the 15 citalopram-treated subjects diagnosed with GAD met response criteria versus 4 (27%) of the 15 placebo-treated subjects with GAD.

In summary, data from randomized, placebo-controlled treatment trials suggest that SSRIs may be useful in the treatment of adults, children, and elderly patients with GAD. The medication dosages used to treat individuals with GAD are similar to the dosages used to treat major depressive disorder.

Serotonin–Norepinephrine Reuptake Inhibitors—Venlafaxine and Reboxetine

There have been several placebo-controlled multicentered studies demonstrating that venlafaxine XR is an effective treatment of GAD. Davidson et al. (1999) performed an 8-week placebo-controlled trial of 75 and 150 mg/day of venlafaxine XR contrasted with 30 mg/day of buspirone. Venlafaxine XR reduced HAM-A scores significantly more than either placebo or 30 mg/day of buspirone. In an additional study by Rickels et al. (2000b), patients with GAD were randomized to three doses of venlafaxine XR, namely 75, 150, or 225 mg/day; all three doses were more effective in decreasing HAM-A scores than placebo. Results from a 6-month, fixed-dose study of venlafaxine XR (37.5, 75, or 150 mg/day) versus placebo suggests that patients treated with venlafaxine did significantly better than patients treated with placebo. Secondary analysis from this study suggests that the two higher doses of venlafaxine were also associated with significant improvement in social functioning (Haskins et al. 1999). Gelenberg et al. (2000) compared the 6-month efficacy and safety of flexible doses of venlafaxine XR in adult outpatients with GAD. Two hundred and fifty-one adults who met DSM-IV-TR criteria for GAD without comorbid major depressive disorder met the following criteria: (1) a screen and baseline score of at least an 18 on the HAM-A, (2) at least 2 on items 1 and 2 of the HAM-A, (3) a total score of at least 9 on the Raskin Depression Scale at screen and baseline, and (4) a Covi Anxiety Scale score greater than the total score on the Raskin. Patients were started on venlafaxine XR at 75 mg/day or placebo during week 1. After week 8, the dose could be increased to 150 mg/day of venlafaxine XR or placebo. At day 15, increases were again allowed to the maximum 225 mg/day or placebo. Primary efficacy measures included the HAM-A total score, the HAM-A psychic anxiety factor score, and the CGI-S Severity and Global Improvement Scale scores. Response to treatment in this study was defined as a 40% decrease from baseline on HAM-A total score or a CGI-G100 Improvement Scale score of (1) “very much improved” or (2) “much improved.” By week 2, 42% of patients in the venlafaxine XR group were categorized as responders compared to 21% of placebo patients. During weeks 6–8, response rates were 69% for venlafaxine XR and 42–46% for placebo. Adverse events led to treatment discontinuation for 17% of the placebo-treated subjects and 26% venlafaxine-treated subjects.

Doses as low as 37.5 mg/day and as high as 225 mg/day are effective in decreasing symptoms of anxiety for patients with GAD. Studies indicate that venlafaxine XR is an effective short-term and long-term treatment for GAD. Side effects appeared to be mild and tended to decrease in number and intensity over the course of the studies. Nausea, dry mouth, and somnolence were the most commonly reported side effects.

Tricyclic Antidepressant Medication and Monoamine Oxidase Inhibitors

A variety of TCAs have been demonstrated to be effective treatments for GAD (Hoehn-Saric et al. 1993, Liebowitz et al. 1988). However, the side effects and difficulty to titrate the dosage of these medications have made their use uncommon. Many patients discontinued the imipramine-treatment group because of side effects.

Other Antidepressant Medication (Bupropion, Mirtazapine, Nefazodone, Trazodone)

There are some older studies that suggest that trazodone is an effective treatment for GAD (Rickels et al. 1993). There has been one open-label study suggesting that nefazodone may be efficacious for patients with GAD (Hedges et al. 1996).

Benzodiazepine Medication

There have been hundreds of studies demonstrating that benzodiazepines as a class are more effective than a placebo in the treatment of both symptoms of anxiety and GAD (Greenblatt et al. 1983). In general, the response rate from these benzodiazepine studies is between the 60 and 80% range (Rickels et al. 1983, Uhlenhuth et al. 1998). Unfortunately, benzodiazepine treatment of GAD is controversial. Despite evidence that the anxiolytic effect does not tend to diminish over time and that the majority of patients do not abuse benzodiazepines, most physicians are reticent to initiate long-term treatment for GAD (Bowden and Fisher 1980, Ciraulo et al. 1988).

There have been a variety of studies with abecarnil. In general abecarnil has not been demonstrated to be more effective than either buspirone or a traditional benzodiazepine (Pollack et al. 1997, Rickels et al. 2000a).

Rapaport et al. (2006) investigated combination therapy with alprazolam ODT and SSRI/SNRI compared with SSRI/SNRI monotherapy. One hundred twenty-nine subjects with a primary diagnosis of GAD were randomized 1:1 to 8 weeks of open-label treatment with alprazolam or no augmentation. The primary efficacy measure was time to response, defined as a ≥50% decrease from baseline in HAM-A total score. There was no statistically significant difference between treatment groups in time to response. Results did reveal that at weeks 2 and 4 CGI-I scores demonstrated that combination therapy (SSRI/SNRI + alprazolam) was associated with earlier improvement in response than SSRI/SNRI monotherapy (week 2, 42.9% vs. 21.1%, p < 0.05; week 4, 63.3% vs. 41.3%, p < 0.05). Similarly, subject-rated measures of global improvement (PGI) suggested combination therapy ameliorated symptoms earlier than monotherapy (week 2, 41.9% vs. 20.4%, p < 0.05; week 3, 50.8% vs. 30.2%, p < 0.05; week 6, 70.0% vs. 42.8%, p < 0.01). Of concern,
approximately one third of patients in this trial could not be tapered off alprazolam ODT during the specified taper phase. This requires more investigation.

In summary, the short-acting benzodiazepines, longer acting benzodiazepines, and even the low potency benzodiazepines have all been demonstrated to be effective monotherapies or adjunctive treatments for GAD. The choice of an agent should take into account the age, medical health, and comorbid diagnosis of the patient.

**Buspirone**

Buspirone has been shown to be more effective than placebo in decreasing HAM-A scores in a large number of placebo-controlled trials (Laakmann et al. 1998, Rickels et al. 1982, 1988). It is thought that buspirone may be particularly effective against psychological symptoms such as worry, tension, irritability, and apprehension, but less effective in ameliorating somatic symptoms because of its activation of locus coeruleus (Riblet et al. 1982, Rickels et al. 1982).

Data from placebo-controlled and comparative studies against benzodiazepines suggest that the onset of action of buspirone usually takes at least 2 weeks (Connor and Davidson 1998, Laakmann et al. 1998). However, clinical experience suggests that buspirone treatment may take 3–4 weeks before one sees a truly beneficial effect in patients with GAD. Buspirone also requires multiple daily administration to be effective. Although a recent meta-analysis suggests that buspirone may be given twice a day for the treatment of anxiety and GAD, the majority of studies and the current labeling for buspirone suggests that it should be administered three times a day (Sramek et al. 1999). Discontinuation of buspirone has not been associated with development of withdrawal symptoms; however, over time patients discontinued from pharmacotherapy tend to relapse (Rickels et al. 1988).

In a placebo-controlled comparative study of hydroxyzine versus buspirone, both agents were found to be more effective than placebo treatment (Lader and Scotto 1998).

In summary, although there are considerable data suggesting that buspirone is an effective treatment for GAD, most of these data are from acute trials. It is clear that buspirone’s time to onset is delayed in contrast to the benzodiazepines and that it may not be as useful as benzodiazepines for the treatment of GAD patients with primarily somatic symptoms.

**Anticonvulsant Medication**

Two different anticonvulsants have been studied for the treatment of GAD: pregabalin and tiagabine. There are four large multicenter placebo-controlled studies investigating the efficacy of pregabalin in patients with GAD. Pande et al. (2003) published a 6-week, double-blind, four-armed placebo-controlled comparison of pregabalin (150 mg/day and 600 mg/day) and lorazepam (6 mg/day). This study, as was the case with most other pregabalin studies, had three phases: a 1-week placebo lead-in phase, a 4-week double-blind treatment phase, and a 1-week taper phase. The primary efficacy measure in this study was the change in HAM-A tools scores over 4 weeks. In this study, both pregabalin groups and the lorazepam groups significantly differentiated from placebo in terms of decreases in HAM-A total scores. However, pregabalin was well tolerated and had a lower drop-out rate than lorazepam in this study. Feltner et al. (2003) performed an identical study in a 600 mg/day pregabalin group and a 6 mg/day lorazepam group separated from placebo on the HAM-A, but the 150 mg/day pregabalin group did not. Rickels et al. (2005) published a five-arm, double-blind, placebo-controlled study in outpatients with GAD. In this 6-week study, three doses of pregabalin (300 mg/day, 450 mg/day, and 600 mg/day) were contrasted with alprazolam 1.5 mg/day and placebo. All three pregabalin groups and the alprazolam group caused statistically significantly greater change in HAM-A total scores than placebo. In this study, all three pregabalin groups as well as alprazolam caused statistically significant decreases in the HAM-A psychic anxiety subscale when compared to placebo. Two of the three pregabalin groups also statistically separated from placebo on the HAM-A somatic anxiety subscale. However, it was the middle 450 mg/day group that did not separate from placebo on this measure, making it difficult to interpret these results. Montgomery et al. (2006) published a 421-patient study investigating the efficacy of two doses of pregabalin versus venlafaxine and placebo for the treatment of moderate to severe GAD (HAM-A ≥ 20). Primary outcome measure was the change in HAM-A mean total score. In three active treatment groups, pregabalin (400 mg/day and 600 mg/day) and venlafaxine (75 mg/day) resulted in significantly greater decreases in HAM-A total scores than placebo. The active groups did not differentiate in other measures. The discontinuation rates were slightly higher for the venlafaxine group; 20.4% versus 6.2% for 400 mg/day pregabalin, 13.6% for pregabalin 600 mg/day, and 9.9% for placebo. In summary, there are four positive studies demonstrating that pregabalin, in a dose range from 150 mg/day through 600 mg/day, was effective in the treatment of GAD. Despite this rather impressive array of data, pregabalin is not approved by the FDA for this indication at this time.

There has been one large double-blind, placebo-controlled trial of tiagabine as a treatment for patients with GAD. Pollack et al. (2005) published a large 8-week randomized, double-blind, flexible-dose, placebo-controlled study investigating tiagabine (4–16 mg/day) versus placebo. Tiagabine did not differentiate from placebo in the last-observation-carried-forward analyses of the HAM-A, but it did differentiate from placebo when a mixed models’ repeated measures analysis was performed. It was well tolerated and was not associated with problems with sexual functioning, weight or sleep-related side effects.

**Antipsychotic Medication**

At this time, there are two published augmentation trials evaluating the efficacy of atypical antipsychotic medication for patients with treatment-resistant GAD. Pollack et al. (2006) openly treated individuals with fluoxetine. Those who did not respond to fluoxetine entered into a double-blind phase where they were randomized to receive either olanzapine (20 mg/day) or placebo. In this small study, olanzapine augmentation significantly improved CGI-I scores and caused a significant reduction in HAM-A total scores. The rates of both response and remission were much greater in the olanzapine-treated group than in the placebo-treated group. However, olanzapine was associated with significant increase in weight. Brawman-Mintzer et al. (2005) investigated the efficacy of risperidone augmentation for treatment-resistant GAD. In this trial, individuals who
continued to have a HAM-A score of ≥18 or a CGI-S score of moderate or greater after 4 weeks of anxiolytic treatment were randomized to receive flexible-dose risperidone (0.5–1.5 mg/day). Risperidone augmentation caused a statistically significant decrease in HAM-A total scores.

**Treatment Conclusions**

People with GAD suffer from a combination of both physical symptoms as well as psychic anxiety. There has been a wealth of clinical trials that demonstrate that a myriad of classes of agents are effective in the short-term treatment of GAD. These include the TCAs, trazodone, buspirone, benzodiazepines, SSRIs, and SNRIs like venlafaxine XR. Several of the SSRIs and venlafaxine XR have received FDA approval as a short-term treatment for GAD. The longer term maintenance studies clearly suggest that patients continue to improve and are more likely to achieve remission from their symptoms of GAD if they are continued at full dose of their treatment over a period of at least one year. There also are data suggesting that discontinuation of pharmacotherapy is associated with the recurrence of illness. At this time, a clinician could choose any of the existing SSRIs or SNRIs as a first-line treatment and anticipate that the majority of patients would realize significant relief of symptoms over 8–12 weeks.

On many occasions, individuals have difficulty with the initial upward taper of traditional antidepressant medications, so it is not unreasonable to consider adding, for a short period of time, a benzodiazepine. Unfortunately, it is also apparent that there is a subgroup of individuals with GAD who have a more refractory course. There are limited data available to suggest the most appropriate augmentation or switch therapies for patients with GAD. However, there is an emerging body of literature suggesting that acute augmentation with low doses of atypical antipsychotic medications may be beneficial in relieving residual symptoms of GAD. Such patients’ medications should be selected based on the types of persistent target symptoms that are present.

**Social Anxiety Disorder**

**Selective Serotonin Reuptake Inhibitors**

SSRIs have emerged as first-line treatment for SAD. Most of the efficacy data are derived from multicenter, double-blind trials of paroxetine, sertraline, and fluvoxamine. The first study to demonstrate that an SSRI was efficacious in treating SAD was a 12-week trial of 183 patients randomized to either paroxetine (20–50 mg/day) or placebo. Fifty-five percent of patients randomized to paroxetine improved significantly, versus 24% of those randomized to placebo (Stein et al. 1998). These results have been replicated in a second, large multicenter study for SAD (Baldwin et al. 1999).

Multiple large-scale studies of escitalopram for acute treatment and relapse prevention of SAD have been published (Kasper et al. 2005, Montgomery et al. 2005, Lader et al. 2004). Kasper et al. (2005) recruited 358 adult outpatients for their 12-week, multisite, randomized, placebo-controlled, flexible-dosage study. Two hundred and ninety (81%) participants completed the study, with 145 patients enrolled in each treatment group at the study’s endpoint. Although escitalopram was significantly better than placebo on all primary and secondary efficacy measures, it also had a higher incidence of headache, nausea, and sexual side effects than placebo, which should be taken into consideration. Among completers, escitalopram was significantly better than placebo on all efficacy measures, even with an extremely high placebo response rate of 39%. Lader et al. (2004) enrolled 837 participants in a 24-week, multisite, randomized study where patients received placebo (n = 166), 5 mg escitalopram (n = 167), 10 mg escitalopram (n = 167), 20 mg escitalopram (n = 170), or 20 mg paroxetine (n = 169). Twenty milligrams escitalopram was significantly more effective than placebo or 20 mg paroxetine on 5 of 6 symptom dimensions of the Liebowitz Social Anxiety Scale (LSAS).

Liebowitz et al. (2003) conducted a study enrolling 415 outpatients with severe generalized social anxiety in a 12-week, double-blind study of flexible-dose sertraline (50–200 mg/day) versus placebo. Among completers, sertraline was significantly more effective than placebo in causing improvement on a wide array of measures including the LSAS, CGI-I, Q-LES-Q, and the SDS. In a subgroup analysis, 87 subjects were identified as having Quality of Life Enjoyment and Satisfaction Questionnaire (Q-LES-Q) scores more than two standard deviations below mean normative community values. Thirty-seven percent of these subjects randomized to sertraline treatment had restoration of Q-LES-Q scores back to the normal range versus 11% of placebo-treated subjects. These data further support the findings of previous studies, strengthening the use of sertraline as treatment for patients with SAD.

In a study of fluvoxamine treatment for 82 patients with SAD, 42% of patients randomized to fluvoxamine responded to treatment (mean dose 202 mg/day), as compared to 24% of patients who received placebo (Stein et al. 1999). There are also smaller trials demonstrating that other SSRIs, including fluoxetine and citalopram, also seem to be effective in the treatment of SAD (Bouwer and Stein 1998, Van Ameringen et al. 1993). (For more on social anxiety, please see Chapter 70.) In another large double-blind study, Westenberg et al. (2004) enrolled 300 patients in a 12-week, multicenter study comparing 100–300 mg/day fluvoxamine controlled release (CR) with placebo. Fluvoxamine CR caused greater improvement on the primary outcome measures when compared with placebo. Ratings of sexual functioning were performed and were not statistically significant between the groups.

In a longer maintenance study, Montgomery et al. (2005) examined the effects of 12 weeks of open-label treatment with flexible doses of 10–20 mg escitalopram, where all responders were then randomly assigned to 24 weeks of fixed-dose, double-blind treatment with escitalopram or placebo. Four hundred and thirty six patients completed the open-label phase and 198 completed the double-blind extension phase.

The use of sertraline for the longer term treatment of SAD was investigated in a two-part study where subjects entered a 20-week, double-blind, placebo-controlled study that was followed by a 24-week double-blind extension for first phase treatment responders (Van Ameringen et al. 2001). This study was conducted at 10 outpatient clinics in Canada. Two hundred and four adult outpatients with SAD were randomly assigned 2:1 to sertraline or placebo. Following a 1-week placebo run-in period, patients received an initial dose of 50 mg/day of sertraline or placebo. After 4 weeks,
the dose could be increased 50 mg/day every 3 weeks up to a maximum of 200 mg/day. In the event of intolerable side effects, doses could be reduced to a minimum of 50 mg/day.

Primary efficacy measures included the CGI-Improvement Scale, the patient-rated Marks Fear Questionnaire (FQ), and the physician-rated Brief Social Anxiety Disorder Scale. At study endpoint, 53% of sertraline patients compared to 29% of placebo patients were (2) “much improved” or (1) “very much improved” as measured by the CGI-Improvement Scale. The mean score on the FQ decreased from 23.07 at baseline to 15.54 at endpoint for the sertraline-treated group, while the placebo-treated group decreased from 21.72 at baseline to 19.38 at endpoint. The mean score on the Brief Social Anxiety Disorder Scale for the sertraline-treated group decreased from 47.48 at baseline to 31.18 at endpoint, versus 45.72 to 37.23 at endpoint for the placebo-treated group. The mean dose of sertraline was 146.7 mg/day. Fifty sertraline responders and 15 placebo responders entered the double-blind, placebo-controlled relapse-prevention phase of the study. Patients who were randomly assigned to continue sertraline treatment received a mean daily dose of 148.0 mg/day. Eighty-eight percent of sertraline-treated patients, 40% of placebo-switched patients, and 40% of the initial placebo-responder patients completed the study. Four percent of the subjects who received sertraline maintenance relapsed as compared to 36% of the placebo-switch group. These findings agree with work by Kauppinen et al. (1995) and a general practice trial by Blomhoff et al. (2001).

In summary, SSRIs are a useful first-line medication for patients seeking treatment for SAD, especially those patients presenting with comorbid depression. Maintenance therapy trials with escitalopram and sertraline confirm the continued benefit shown by maintenance pharmacotherapy.

Serotonin–Norepinephrine Reuptake Inhibitors—Venlafaxine and Reboxetine

The first case reports and open-label studies investigating the efficacy of venlafaxine in SAD were published in the mid-1990s (Kelsey 1995). Recently, multiple double-blind studies examining the efficacy of venlafaxine ER in SAD have been published (Allgulander et al. 2004, Rickels et al. 2004, Liebowitz 2005). Rickels et al. (2004) conducted a 12-week, double-blind, placebo-controlled study of venlafaxine extended release (ER) in 272 outpatients with generalized SAD. Among 172 completers, venlafaxine ER was significantly more effective than placebo, as demonstrated by LSAS, CGI-I, and CGI-S scores. These results were supported by the double-blind, placebo-controlled, flexible-dose trial by Liebowitz et al. (2005), which examined the effects of venlafaxine ER (75–225 mg/day) in 440 patients with SAD. The study’s primary efficacy measure was the LSAS total score, with CGI-I, CGI-S, Social Phobia Inventory (SPIN), and LSAS subscales serving as secondary measures. Venlafaxine ER treatment caused significant improvement over placebo on the LSAS, with response rates being 44% in venlafaxine-treated patients versus 30% in placebo-treated patients, where response was defined as a CGI-I score of 1 or 2. In addition, remission rates were significantly greater in the venlafaxine ER group than in the placebo group (20% vs. 7%, where remission was an LSAS score ≤ 30). Allgulander et al. (2004) conducted a similarly designed study, examining the efficacy of 75–225 mg/day venlafaxine ER, 20–50 mg/day paroxetine, or placebo for 12 weeks. Treatment with venlafaxine ER demonstrated a significant improvement over placebo on all efficacy variables, although no significant differences were observed between the venlafaxine ER and paroxetine groups. Even so, both active treatments led to remission in less than half of patients, suggesting that short-term, 12-week studies may not be long enough to attain the medications’ full therapeutic effects with a chronic illness like SAD. The aforementioned placebo-controlled trials confirm the benefit of venlafaxine in the acute treatment of social phobia patients, thus calling for the examination of the medication’s long-term effects.

Tricyclic Antidepressant Medication and Monoamine Oxidase Inhibitors

In general, TCAs have not been found to be effective for the treatment of SAD. A recent open-label study of nine patients diagnosed with SAD found no difference between imipramine and placebo. However, six patients dropped out early because of side effects (Simpson et al. 1998a).

MAOIs have been shown to be superior to placebo treatment for SAD (Gelernter et al. 1991, Versiani et al. 1992). The mean daily dose of the drug in these trials ranged between 60 and 90 mg/day. Although surpassed by the SSRIs as first-line agents, there is no doubt that first-generation MAOIs are effective. Unfortunately, the risk of hypertensive crisis and the need for patients to follow a tyramine-free diet makes this class of drugs unappealing for the majority of patients. Selegiline (L-Deprenyl) is of clinical interest because at low doses it is selective for MAO-B and has fewer side effects. Simpson et al. (1998b) conducted a 6-week open trial of selegiline in 16 patients with SAD. The dose of selegiline was fixed at 5 mg twice a day, and patients were instructed to follow a standard MAOI diet. Responders were defined by a score of 1 or 2 on the CGI at the last observation. Nine subjects completed the trial; three were considered responders. Of completers, mean LSAS scores decreased from 85.9 ± 25.4 at baseline to 58.0 ± 25.4 at endpoint, and mean Liebowitz Social Phobic Disorders Scale—Overall Severity (LSPD) scores decreased from 5.0 ± 0.9 at baseline to 4.4 ± 1.2 at endpoint. These data suggest that low dose selegiline may have a modest effect in SAD.

The promising results derived from efficacy studies of first-generation MAOIs spawned the study of reversible monoamine oxidase inhibitors (RIMAs) for this indication. RIMAs have significantly less risk of hypertensive crisis and subsequently no need for a tyramine restricted diet. They also have a more tolerable side effect profile. Brofaromine and moclobemide are the two most studied RIMAs. However, there is conflicting evidence about their efficacy for the treatment of SAD. Of four published placebo-controlled multicenter moclobemide studies, three have been positive (Stein et al. 2002b, International Multicenter Clinical Trial Group 1997, Blanco and Liebowitz 1998, Noyes et al. 1997, Schneider et al. 1998). Two controlled studies of brofaromine in SAD showed superior efficacy to placebo (Fahlen et al. 1995, Van Vliet et al. 1993). However, brofaromine is no longer under development in the US, and moclobemide is not available in the US.
Other Antidepressant Medication (Bupropion, Mirtazapine, Nefazodone, Trazodone)

Emmanuel et al. (1991, 2000) have published two papers investigating bupropion treatment for SAD. In the most recent work, a small 12-week open-label flexible-dose study, the efficacy of bupropion SR in the treatment of SAD was evaluated (Emmanuel et al. 2000). Eighteen subjects with DSM-IV-TR diagnosed SAD were seen weekly for the first 4 weeks, then biweekly for the next 8 weeks. Bupropion SR was initiated at 100 mg/day and titrated to a maximum of 200 mg twice a day, depending on response to treatment. Ten subjects completed the 12-week treatment period; 5 of the 10 were responders. The mean dose of bupropion SR was 366 ± 68 mg/day. The mean CGI-I scores changed from 4.3 ± 0.7 at baseline to 2.5 ± 0.9 at week 12, and the mean Brief Social Phobia Scale (BSPS) scores decreased from 42.2 ± 13 at baseline to 21.0 ± 11 at week 12.

Muehlbacher et al. (2005) conducted a double-blind, placebo-controlled trial of mirtazapine treatment for SAD patients. Sixty-six women enrolled in the 10-week, fixed-dose study of 30 mg/day mirtazapine or placebo. After 10 weeks of treatment, significant differences were noted between mirtazapine and placebo on the SPIN and the LSAS. Large-scale studies examining the efficacy of mirtazapine in SAD are warranted.

Benzodiazepine Medication

The benzodiazepines, clonazepam and alprazolam, have been shown to be efficacious in treating SAD (Dubuff et al. 1995; Gelernter et al. 1991, Nardi and Perna 2006). The limitations of these drugs are the same as when used in any indication. Due to the potential for abuse and drug withdrawal, their use must be monitored carefully. This is a particularly problematic issue in SAD because of the high rate of comorbid substance abuse. Benzodiazepines may be best suited for patients with situational and performance anxiety on an as-needed basis.

Buspirone

Buspirone showed promise during open-label studies of SAD but did not differentiate from placebo in controlled trials (Van Vliet et al. 1997). Data from open-label trials also suggest that buspirone may be used as an adjuvant with SSRIs when patients exhibit only partial response to monotherapy (Van Ameringen et al. 1996).

Beta-Blocker Medication

Stein et al. (2001) conducted a double-blind, placebo-controlled crossover study of pindolol potentiation of paroxetine for the treatment of SAD. Pindolol was selected as an adjunct to SSRIs because it is a 5-HT1A autoreceptor antagonist besides being a beta-adrenergic receptor blocker. It is postulated that antagonism of the 5-HT1A autoreceptor would stimulate presynaptic release of serotonin. In fact, pindolol has been shown to accelerate the antidepressant response of SSRIs in some studies (Perez et al. 1997, Zanardi et al. 1997). Fourteen patients who were less than “very much improved” on CGI-I ratings after 10 weeks of maximally tolerated dose of paroxetine were randomized to receive 5 mg of pindolol t.i.d. or placebo for 4 weeks. After 4 weeks, subjects were tapered and crossed over to receive the other agent (pindolol or placebo) for another 4-week period. Pindolol augmentation was not more effective than placebo augmentation in this study.

Anticonvulsant Medication

There are three double-blind, placebo-controlled studies evaluating the efficacy of anticonvulsant therapy for patients with SAD. Two of these studies were performed with either gabapentin or pregabalin. A third study was performed using levetiracetam. Pande et al. (1999) published a study where 69 patients with SAD were randomized for 14 weeks to receive either gabapentin (900–3600 mg/day) or placebo. In this study, 32% of patients randomized to flexible-dose gabapentin were considered responders versus 14% of patients receiving placebo. Pande et al. (2004) published a 10-week, double-blind, placebo-controlled trial of two fixed doses of pregabalin (150 mg/day or 600 mg/day). The 600 mg/day dose of pregabalin significantly reduced total scores on the LSAS when contrasted with placebo. The 600 mg/day dose was associated with a significant reduction in total fear, total avoidance, social fear, and social avoidance as measured on the brief social phobia scores. Zhang et al. (2005) published the results of a small, double-blind, placebo-controlled trial of levetiracetam for the treatment of SAD. Eighteen patients were randomized to receive a flexible dose of levetiracetam (500–3000 mg/day) or placebo for seven weeks. In this small study, the two groups did not significantly differ on response rates, BSPS scores or CGI-I scores. The authors did indicate that there were significant reductions in both the BSPS and CGI-I scores, but they felt the study was underpowered to demonstrate statistical significance. Further studies, especially maintenance studies, are still called for in order to determine the potential benefits of anticonvulsant therapy for patients with SAD.

Treatment Conclusions

SSRIs, MAOIs, benzodiazepines, and venlafaxine XR have all been demonstrated to be effective pharmacotherapies for patients with SAD. Since all of the antidepressants can cause activation, it is important to start the initial titration at a very low dose and to taper the patient up over a period of weeks to months. There is some evidence to suggest that starting a benzodiazepine with a stimulating antidepressant may allow patients to tolerate the antidepressant more easily and may facilitate a more rapid titration of the antidepressant. Although these data are limited, this approach is widely practiced in many clinical settings.

SAD frequently requires not only pharmacotherapy, but also some form of adjunctive cognitive behavioral therapy in order to facilitate decreasing anxious behaviors. For individuals who cannot tolerate traditional antidepressants and who are fearful of benzodiazepines, there are some data supporting the use of anticonvulsants. Although none of the anticonvulsants are currently approved for treatment of SAD, gabapentin, pregabalin, and levetiracetam have all been reported to be efficacious for patients with SAD. As we have previously discussed with GAD, some individuals are not fully responsive to a first or second treatment intervention. There is a paucity of evidence-based data to guide further intervention, although many patients do seem to respond best to either combination therapy.
Panic Disorder

Selective Serotonin Reuptake Inhibitors

SSRIs are generally accepted as a first-line treatment for PD. The major advantage of these agents is their tolerability and thus longer term acceptance by patients. As of now there is evidence that fluoxetine, sertraline, paroxetine, fluvoxamine, and citalopram are effective in the acute treatment of PD.

There are two published large multicenter double-blind, placebo-controlled studies investigating the efficacy of fluoxetine versus placebo. Michelson et al. (1998) conducted a large multicenter double-blind, placebo-controlled trial investigating the efficacy of 10 or 20 mg/day fluoxetine versus placebo. Results suggested that fluoxetine reduced panic attack frequency, global distress, and agoraphobic distress. Patients with a CGI-Improvement score of (1) “very much improved” or (2) “much improved” at the end of the randomized, placebo-controlled trial were entered into a 24-week continuation study (Michelson et al. 1998). During this study patients either continued on active treatment or received placebo. Patients randomized to fluoxetine continued to improve during the course of 24 weeks while patients who were randomized to placebo demonstrated a marked exacerbation in symptoms and were more likely to meet criteria for a recurrence of PD (Michelson et al. 1999). A more recent study by Michelson et al. (2001) was a 12-week, randomized, placebo-controlled trial of fluoxetine (10–60 mg/day) conducted at nine sites in Europe. One hundred and eighty adult patients who met DSM-IV-TR criteria for PD and had a minimum of four full panic attacks in the month preceding entry into the study, and two full panic attacks during the 2-week baseline evaluation period, were randomized to treatment. Patients also had to have at least moderate symptom severity, as measured with the Panic Disorder Severity Scale (PDSS), and a CGI-Severity rating of 4 or greater. Fluoxetine was initiated at 10 mg/day for week 1 and increased to 20 mg/day until week 6. Patients who had not achieved a CGI-Severity score of 2 or less were, at week 6, increased to 40 mg/day. Fluoxetine could be further increased to 60 mg/day. Fluoxetine was statistically superior to placebo at both the 6-week point and at study endpoint. Fluoxetine-treated patients also had statistically significant improvement on the Sheehan Disability Scale (SDS). The final mean daily dose of fluoxetine was only 29.6 mg/day. Reports of adverse events among the placebo and fluoxetine groups were similar and low.

Four large multicenter trials investigating the efficacy of sertraline in the treatment of PD have been published. Two studies were placebo-controlled, fixed-dose trials and two studies were placebo-controlled, flexible-dose studies. In the flexible-dose sertraline trials, patients were started on 25 mg/day for the first week and then the dose was escalated to 50 mg/day of sertraline. Sertraline-treated patients experienced significant reductions in panic attack frequency, CGI-Improvement and Severity Scales, the PDSS, the Patient Global Evaluation (PGE) Rating Scale, and the Q-LES-Q (Londborg et al. 1998, Pollack et al. 1998, Rapaport et al. 1998). Sertraline was also found to be efficacious in fixed dose with the 150 mg/day dose seeming to be the most effective dose in these studies (Dubuff et al. 1995). There is one large multicenter long-term trial by Rapaport et al. (2001) where individuals who initially entered 10-week treatment trials were then offered 1 year of open-label treatment of sertraline and responders were then entered into a double-blind, 26-week placebo discontinuation trial. Frequency of panic attacks was recorded by patients in panic attack diaries. Clinically significant deterioration was examined over the course of the double-blind phase; deterioration was specified as (1) relapse, (2) discontinuation due to insufficient clinical response, and (3) exacerbation of panic symptomology. At the end of 26 weeks of double-blind treatment, patients randomized to placebo were twice as likely to discontinue due to lack of efficacy than patients treated with sertraline. Similarly, 13% of sertraline patients experienced acute exacerbation of panic symptoms versus 30% of placebo patients. These data demonstrated that maintenance treatment with sertraline was associated with continued improvement and protected patients from recurrence (Rapaport et al. 2001). The mean daily dose of sertraline was 112.1 mg/day. A head-to-head comparison trial was conducted by Bandelow et al. (2004), comparing paroxetine to sertraline. Two hundred twenty-five patients with PD were randomly assigned in a double-blind study to paroxetine 40–60 mg/day or sertraline 50–150 mg/day. Patients were assessed with the Panic and Agoraphobia Scale (PAS) scores, CGI-I (responders defined as those with a score ≤ 2), and panic attack frequency. At endpoint, paroxetine and sertraline were associated with equivalent levels of improvement on the PAS total score, as well as all secondary measures. Seventy-eight percent of patients taking paroxetine and 82% of patients taking sertraline were CGI-I responders. Paroxetine and sertraline had equivalent efficacy in the acute treatment of PD, but sertraline treatment had less weight gain and less clinical worsening during taper phase.

There have been a number of double-blind, placebo-controlled multicenter studies demonstrating the efficacy of paroxetine for the treatment of PD. Ballenger et al. (1998) reported that 40 mg/day of paroxetine was more effective than placebo in reducing panic attacks and the symptoms of PD. In one large multicenter European trial, paroxetine (20–60 mg/day) was contrasted with clomipramine (50–150 mg/day) and placebo. Both active treatments were more effective than placebo in reducing the number of panic attacks. The paroxetine group also seemed to have a more rapid onset of action and reported fewer side effects (Lecrubier et al. 1997). Patients who completed the study were entered into a 9-month extension study; subjects treated with paroxetine and clomipramine demonstrated continued improvement over time (Lecrubier and Judge 1997). A head-to-head comparison trial of paroxetine and citalopram was conducted by Perna et al. (2001). Fifty-eight patients with PD were randomly assigned to one of the two active treatments (both 10–50 mg/day) in a single-blind design. Patients were assessed by the PASS, the SDS, and the FQ at baseline, day 7, and day 60. Responders were defined by a reduction of at least 50% from baseline on both PASS and SDS global scores at day 60. At endpoint, 84% of patients receiving paroxetine and 86% of patients receiving citalopram responded. PASS total scores decreased from 9.3 ± 4.9 at baseline to 3.5 ± 4.6 at day 60 for the paroxetine-treated group, and from 8.7 ± 3.7 at baseline to 3.1 ± 3.0 at day 60 for the citalopram group. Only one patient from each group dropped out because of side effects. Sheehan et al. (2005) published a pooled analysis that combined three identical trials investigating the efficacy of paroxetine versus placebo.
Several smaller placebo-controlled trials and one large multicenter placebo-controlled acute trial have been published demonstrating that citalopram is an effective treatment of PD. In the large multicenter study of citalopram, placebo, and clomipramine, 475 patients were randomized to 8 weeks of treatment. The patients received three flexible doses of citalopram and one of clomipramine. All three doses of citalopram (10–60 mg/day) and clomipramine (60–90 mg/day) were more effective than placebo in decreasing panic attacks to zero and decreasing phobic symptoms. The 20–30 mg/day dose of citalopram seems to be the most effective of the doses (Wade et al. 1997). Patients, who in the physician’s judgment were responders in the acute trial, were offered continued double-blind treatment for 10 months. In this double-blind continuation study, citalopram was demonstrated to be more effective than placebo in decreasing phobic avoidance and interpersonal sensitivity (Leinonen et al. 1999). A number of studies report that fluvoxamine is more effective than placebo for the treatment of PD (Boshuisen et al. 2001, Hoehn-Saric et al. 1993). Asnis et al. (2001) performed an 8-week, double-blind, parallel-group study comparing fluvoxamine with placebo in 188 patients with DSM-III-R defined PD (with or without agoraphobia). Patients in this study were required to have at least one panic attack per week for at least 4 weeks. Patients were randomized to double-blind treatment if they had an average weekly panic attack severity score of 25 (of attacks × severity 0–10) and had at least one full panic attack in the final week of placebo washout. Treatment was initiated at 50 mg/day of fluvoxamine or placebo. It was titrated upward to 150 mg/day during the first 2 weeks. Thereafter, it was titrated to 300 mg/day as needed, based on side effects and efficacy. Fluvoxamine was significantly superior to placebo at endpoint on three of four primary outcome measures: proportion of patients free from panic attacks, percentage reduction in frequency of full panic attacks per week, and PD severity. Fluvoxamine was superior to placebo with respect to a global improvement in CGI-Sext Scale scores, 64% versus 42%. Pollack et al. (2003) extended Goddard and colleagues’ work by investigating the acute and continuation efficacy of combination treatment with benzodiazepines and SSRIs. In a double-blind, three-arm study, 60 patients with PD were randomized to paroxetine and placebo (PP), paroxetine coadministered with clonazepam followed by a tapered benzodiazepine discontinuation phase (PC-D), or paroxetine plus clonazepam with ongoing combination treatment (PC-M). All treatment groups demonstrated significant improvement by endpoint (PP 68.2%; PCM 60.0%, PC-D 77.8%). However, the results of this should be interpreted cautiously since this is a moderate size study and there was a high rate of early termination (60 subjects at baseline with only 34 study completers). Combined treatment with paroxetine and clonazepam resulted in a more rapid response than with the SSRI alone, but there was no differential benefit beyond the initial few weeks of therapy. This suggests that combined treatment followed by benzodiazepine taper may provide early benefit while avoiding the potential adverse consequences of long-term combination therapy.

In summary, the majority of data suggests that SSRIs as a class are effective in the treatment of PD. One of the advantages of SSRIs is that they tend to be fairly well tolerated in contrast to some of the other treatments available for PD. Although a few individuals may have some initial problems with restlessness and increased anxiety, data suggest that starting at lower doses such as 25 mg/day of sertraline or 10 mg/day of paroxetine may decrease the risk of antidepressant “jitteriness.” Patients will certainly experience other types of side effects such as headaches, nausea, and diarrhea. However, most of these side effects diminish with time and are well tolerated, particularly if the patients are informed of the possibility of these transient side effects. As is the case with our pharmacotherapies for other types of medical disorders, there will certainly be a need to fine-tune a treatment of PD as one sees patients over time.

Serotonin–Norepinephrine Reuptake Inhibitors—Venlafaxine and Reboxetine

There are several double-blind, placebo-controlled studies (Pollack et al. 1996, Bradwejn et al. 2005) suggesting that venlafaxine may be an effective treatment for patients with PD. Bradwejn et al. (2005) studied 361 adult outpatients with PDs. Subjects were randomly assigned to receive venlafaxine ER (75–225 mg/day) or placebo for up to 10 weeks in a double-blind study. Venlafaxine was associated with lower mean number of panic attacks (venlafaxine −5, placebo −3.7), higher response (venlafaxine 68.1% and placebo 55.4%) and remission rates (venlafaxine 35.6%, placebo 24.4%) in CGI-I. Pollack et al. (2007) were first to report a large-scale, controlled trial of venlafaxine XR, paroxetine, and placebo. Six hundred sixty-four nondepressed adult outpatients who met DSM-IV-TR criteria for PD (with or without agoraphobia) were randomly assigned to 12 weeks of treatment with placebo, or fixed doses of venlafaxine XR (75 or 150 mg/day), or paroxetine 40 mg/day. The primary efficacy measure was the percentage of patients free from full-symptom panic attacks, assessed with the PAAS. Response was defined as a CGI-I rating of very much improved or much improved; remission was defined as a CGI-I rating of no at all ill and no PAAS full-symptom panic attacks. Measures of depression, anxiety, phobic fear and avoidance, anticipatory anxiety, functioning, and quality of life were also assessed. Intent-to-treat, last-observation-carried-forward analysis showed that mean improvement on most measures was greater with venlafaxine XR and paroxetine than with placebo. No significant differences were observed between active treatment groups.
There have been a few studies suggesting that reboxetine is effective in the treatment of PD. Versiani et al. (2002) conducted a multicenter, randomized, placebo-controlled, parallel-group, double-blind clinical trial conducted in Brazil and Italy. Eighty-two patients with DSM-III-R diagnosis of PD with or without agoraphobia and who had experienced at least four panic attacks in the month preceding their admission to the study were included in the study. Participants had an initial 7-day washout period and then were randomly assigned to receive 6–8 mg/day of reboxetine or placebo for 8 weeks. Primary parameters of efficacy were the mean number of total panic attacks (spontaneous and situational) per week (as measured by the Sheehan Panic Attack and Anxiety Scale [SPAAS]), the global scores of severity and phobic symptomatology (Phobia Scale), and the score on the CGI. Efficacy measurements were determined by comparing baseline and last assessment scores. The study revealed that there was a significant reduction in the mean number of panic attacks and phobic symptoms in the reboxetine group compared with the placebo group. Consistent with the reduction of both major panic attacks and improvement in phobic symptomatology, significantly greater improvement in mean CGI scores for severity of illness was observed for patients in the reboxetine group (5.2 at baseline vs. 2.5 at last assessment) compared with those in the placebo group (5.0 at baseline vs. 3.8 at last assessment; p = 0.0002).

**Tricyclic Antidepressant Medication and Monoamine Oxidase Inhibitors**

Imipramine was the first TCA noted to effectively treat panic attacks and PD and is one of the best studied TCAs (Boyer 1995, Klein 1964, Klein and Fink 1962). Double-blind, placebo-controlled trials of desipramine and nortryptiline have also been performed (Kalus et al. 1991, Lydiard et al. 1993, Munjack et al. 1988); however, clomipramine has been the TCA most widely studied. There are a large number of double-blind, placebo-controlled trials demonstrating clomipramine’s efficacy as a treatment for PD (Callard et al. 1999, den Boer 1998). Interestingly, there are a number of both placebo-controlled and crossover design studies suggesting that clomipramine may be more efficacious than imipramine in the treatment of PD (Cassano et al. 1988, Modigh et al. 1992, Sasson et al. 1999). In contrast to these data demonstrating clomipramine’s efficacy, studies with maprotiline, a noradrenergic reuptake inhibitor, failed to differentiate from placebo (den Boer and Westenberg 1988). Longitudinal data suggest that patients who achieve complete remission with imipramine treatment will maintain their remission with continuous treatment (Mavissakalian and Perel 1992b). Mavissakalian and Perel (1992a) demonstrated that patients who met stringent remission criteria for at least 6 months could sustain their panic-free status even after their imipramine dosage was decreased by 50%. This finding is particularly important because such a dosage reduction might increase tolerability and thus the adherence of patients to therapy. Longer term adherence is important because Mavissakalian and Perel (2001) found that the longer periods of panic-free maintenance therapy were associated with a greater likelihood of remaining in remission after discontinuation of imipramine therapy. Eighteen patients participated in the second year of a double-blind extension study, 7 patients in the placebo group continued on placebo, 7 of the imipramine group were switched to placebo, and 4 continued with imipramine. Two patients from the imipramine-placebo switch group relapsed and two patients in the placebo continuation group relapsed. None of the imipramine continuation group subjects relapsed. This suggests that there may actually be an advantage of continued prophylaxis beyond the first year of maintenance imipramine therapy.

TCAs, unfortunately, are associated with a significant side effect burden. There is a problem with jitteriness associated with the initiation of TCAs. This jitteriness is frequently frightening and may be intolerable for some patients with PD. It requires that TCAs be started at very low doses and titrated up very slowly. Other problems with TCAs that decrease adherence include anticholinergic side effects, orthostatic hypotension, sexual dysfunction, and weight gain. In a naturalistic follow-up study by Noyes et al. (1989), the majority of patients discontinued TCA treatment because of side effects (Noyes et al. 1996). Although TCAs have been widely used for the treatment of PD, their side effect profile and slow time to onset of action makes them a difficult class of medication for many patients to tolerate.

The first-generation MAOIs such as phenelzine and tranylcypromine have been demonstrated to be effective in placebo-controlled trials (Sheehan et al. 1980). There are also a variety of smaller studies demonstrating that RIMAs, moclobemide, and buproprion are effective in the treatment of PD (Bakish 1992, Krueger and Dahl 1999, Tiller et al. 1999, Van Vliet et al. 1993). Unfortunately, it is unlikely that either of the newer reversible and selective MAOIs will be available in the US. Therefore our pharmacotherapy is limited to the older irreversible and nonselective agents.

The irreversible and nonselective agents have problems with dietary restrictions, weight gain, insomnia, sexual dysfunction, medication interactions, and orthostasis. They can be lethal in overdose and hypertensive crises can be precipitated by tyramine-rich food and by some commonly sold over-the-counter cold medicines. Despite these concerns, many expert clinicians feel that MAOIs may be a useful treatment for severely ill patients with PD, particularly those with comorbid PD and depressive disorder.

**Other Antidepressant Medication (Buproprion, Mirtazapine, Nefazodone, Trazodone)**

There have been a few double-blind trials of buproprion and trazodone for the treatment of PD, but neither was found to be more effective than placebo (Charney et al. 1986, Sheehan et al. 1983). Case series and some small studies suggest, however, that mirtazapine and nefazodone may be effective treatments for patients with PD (Carpenter et al. 1999, DeMartini et al. 1996, Falkai 1999, Papp et al. 2000). Ribeiro et al. (2001) compared mirtazapine and fluoxetine in a randomized double-blind, flexible-dose trial of 27 patients with DSM-IV-TR PD. Participants were required to have a minimum of three panic attacks during the 2 weeks before enrollment into the study. Patients had to have a score greater than 18 on the HAM-A, and could not have been previously treated with mirtazapine. Following a 1-week, single-blind, placebo run-in, patients were randomly assigned to mirtazapine 15 mg/day or fluoxetine 10 mg/day. At week 3, doses could be raised to 30 mg/day of mirtazapine or 20 mg/day of fluoxetine according to clinical response. Each patient maintained
a self-report diary of panic attacks. Clinician-rated assessments included the CGI-Seriousness and CGI-Improvement Scales, and the HAM-A. The Sheehan Phobic Scale provided patient global evaluation of phobic anxiety. Fourteen were treated with mirtazapine and 13 were treated with fluoxetine. Three patients treated with mirtazapine and two patients treated with fluoxetine dropped out because of side effects. Among completers, the mean daily dose of mirtazapine was 18.3 ± 1.3 mg/day and was 14.0 ± 1.0 mg/day for fluoxetine. HAM-A scores decreased from 15.7 ± 10.0 at baseline to 11.8 ± 7.5 at endpoint for fluoxetine-treated subjects, from 11.2 ± 11.8 at endpoint for the mirtazapine, and from 28.8 ± 6.5 at baseline to 11.8 ± 7.5 at endpoint for fluoxetine-treated subjects. In both groups, the number of panic attacks decreased from three at baseline to zero at endpoint, suggesting that both medications eliminated spontaneous panic attacks.

Benzodiazepine Medication

There are two high potency benzodiazepines that have been approved by the FDA and are widely used in the treatment of PD. The first high potency benzodiazepine to be approved was alprazolam. Alprazolam has a relatively short half-life, requires frequent dosing (up to four times a day), and may cause significant discontinuation problems in some patients. In the Cross-National Collaborative Panic Disorder Study, alprazolam at a mean dose of 5.7 mg/day was found to be more effective than placebo in decreasing the number of panic attacks and allowing patients to become free from panic attacks (Ballenger et al. 1988). In phase 2 of the Cross-National Collaborative Panic Study (1992), 1,168 PD patients were randomized to receive either alprazolam, imipramine, or placebo. Both imipramine and alprazolam were more effective in treating PD than placebo. Rickels and Schweizer (1998) have published a number of papers comparing alprazolam to imipramine and placebo. In a recent report of an acute 8-week study, they found that alprazolam and imipramine were equally effective in treating PD but there were a large number of dropouts in the imipramine-treatment group. During a 6-month maintenance phase, 62% of alprazolam-treated patients completed the study and were panic free in contrast to only 26% imipramine-treated and placebo-treated patients. The 15-month follow-up of the same cohort found that 85% of patients who completed the maintenance phase study remained panic free in contrast to 55% of patients who were not able to complete the maintenance study. In general, alprazolam has been demonstrated in both short-term and long-term studies to be effective. There has been considerable concern about the risk of dependency and also the difficulties discontinuing alprazolam for a significant minority of patients.

Although clonazepam has been used for the treatment of PD for a long time, it was not until the 1990s that two large definitive multicenter double-blind, placebo-controlled studies demonstrated clonazepam’s efficacy for patients with PD. In a large fixed-dose study, 413 patients were randomized to receive one of five doses of clonazepam (0.5 mg/day, 1.0 mg/day, 2.0 mg/day, 3.0 mg/day, 4.0 mg/day) or placebo. There was a 3-week dosage escalation period followed by 6 weeks of fixed-dose therapy and then a 7-week discontinuation phase. Doses of clonazepam greater than 1 mg were effective in decreasing the number of panic attacks and were well tolerated. There was some exacerbation of symptoms experienced by patients during the double-blind discontinuation phase, but patients with these symptoms did not approach the initial baseline level of dysfunction (Rosenbaum et al. 1997). In a flexible-dose study, 222 patients were randomized to clonazepam treatment and 216 patients received placebo. Patients randomized to clonazepam had a decrease in the number of panic attacks and an improvement in CGI-Seriously scores. Clonazepam was well tolerated but there was some worsening of symptoms during the discontinuation phase (Moroz and Rosenbaum 1999). There were no significant adverse effects associated with longer term clonazepam treatment (Pollack et al. 1997). Goddard et al. (2001) looked at early coadministration of clonazepam with sertraline for PD in a double-blind trial of 50 patients. Patients received open-label sertraline for 12 weeks (target dose of 100 mg/day) and were randomized to receive either 0.5 mg/day of clonazepam three times a day or placebo for the first 4 weeks of the trial. Response rates were markedly different at the end of week 1 with 41% of sertraline/clonazepam patients responding to treatment versus 4% of sertraline/placebo patients. At week 3, 63% of sertraline/clonazepam patients responded versus 32% of sertraline/placebo patients. Katzenick et al. (2006) investigated combination therapy with alprazolam ODT and SSRI/SNRI compared with SSRI/SNRI monotherapy. Two hundred forty-five subjects diagnosed with PD, with or without agoraphobia, were randomized to 8 weeks of open-label treatment with alprazolam. The primary efficacy measure was time to response, a ≥50% decrease from baseline in HAM-A total score. Secondary measures included change from baseline in HAM-A total scores, CGI-I, and PGI scales. Statistically significant difference between treatment groups in time to response was not found. Analyses did reveal that combination treatment was statistically significantly more likely to show an earlier response than monotherapy (p < 0.05). Combination treatment also demonstrated that a significantly higher proportion of subjects met response criteria than those receiving monotherapy (35% vs. 22%, p < 0.05). Additionally, combination treatment demonstrated statistically significant earlier improvement than monotherapy on the mean change from baseline in total HAM-A, CGI-I, and PGI scores. Both treatment regimens were generally well tolerated.

Other benzodiazepines have also been demonstrated to be effective in the treatment of PD. In an 8-week, double-blind, placebo-controlled trial, alprazolam (4.9 mg/day) and diazepam (40 mg/day) were equally effective and superior to placebo for the treatment of PD (Noyes et al. 1996). In a smaller comparative study, lorazepam was as effective as alprazolam in the treatment of PD (Schweizer et al. 1988). In summary, it is clear that two high potency benzodiazepines, alprazolam and clonazepam, are effective in the treatment of PD. There also are data suggesting that a number of the other benzodiazepines may be useful in the treatment of PD. Unfortunately, there are concerns about dependency and stigma associated with the use of benzodiazepine medication.

Buspirone

There is a case report suggesting that buspirone may be a useful adjuvant in some patients with treatment-resistant PD (Gastfriend and Rosenbaum 1989). In general, buspirone is not thought to be an effective monotherapy for PD.
Anticonvulsant Medication

There are published case reports, case series, and small studies investigating at least five different anticonvulsant medications. Sandford et al. (2001) conducted a small randomized, double-blind, placebo-controlled crossover trial of pagoclone versus placebo in 16 patients with PD. Pagoclone is believed to act as a partial agonist at the GABA_A benzodiazepine receptor. Patients were randomized to receive either pagoclone 0.1 mg t.i.d. during weeks 1 and 2 or pagoclone 0.1 mg t.i.d. during weeks 4 and 5. There was a decrease in the number of full panic attacks from baseline among pagoclone-treated patients but not among placebo patients. This decrease was observed for patients receiving pagoclone regardless of whether they received it in the first or second crossover arm; however, this difference did not reach statistical significance.

Zwanzger et al. (2001) investigated the putative anxiolytic properties of tiagabine in a clinical case series. Tiagabine has been shown to reduce neuronal excitability by increasing brain GABA levels, by inhibiting GABA reuptake. Four patients meeting DSM-IV-TR criteria for PD were treated. All patients reported a reduction of panic attacks and improvement in anxiety levels within 4 weeks, although one patient discontinued treatment because of side effects.

There are some scattered reports suggesting that the valproic acid and gabapentin may be useful, particularly in either atypical or treatment-resistant patients with PD (Keck et al. 1993, Woodman and Noyes 1994).

Papp (2006) reported the results of an open-label, flexible-dose study of levetiracetam treatment for 18 subjects meeting criteria for PD with or without agoraphobia. Eighteen patients completed this 3-month, open-label study and 85% of them were rated very much or much improved on the CGI-I. Panic attack frequency, total HAM-A scores, and CGI-S scores decreased significantly during these 12 weeks of open-label treatment. Median dose of levetiracetam used in the study was 1138 mg/day. The most common side effects were sedation, headaches, and some irritability.

Antipsychotic Medication

The largest study to date investigating the efficacy of atypical antipsychotic medication augmentation of SSR-resistant PD was published by Sepede et al. (2006). In this study of 31 adult outpatients with PD who were unresponsive to standard SSRRI treatment, subjects were given 5 mg/day of olanzapine. Twenty-six patients completed this 12-week, open-label study. By week 12, 82% of patients were defined as responders and demonstrated significant improvement on all the rating scales. Fifteen patients achieved remission status (no panic attacks and a HAM-A total score of less than 7). Common side effects in this 12-week study were weight gain and drowsiness. Further double-blind, placebo-controlled trials of atypical antipsychotic medication augmentation of SSRIs in resistant PD are needed.

Treatment Conclusions

Although panic attacks are a cardinal feature of PD, there are many patients who suffer from PD but rarely have spontaneous panic attacks. These individuals are plagued by problems with anxiety sensitivity and anticipatory anxiety. In general, patients with PD, with or without agoraphobia, tend to be exquisitely sensitive to their body’s somatic cues, and therefore they are remarkably sensitive to all of the potential somatic effects of pharmacotherapy. Clinicians treating patients with PD must help their patients have a sense of control and mastery as pharmacotherapy is initiated. One approach to ensuring that this occurs is to enlist the patient as an active participant in monitoring both the potential positive and negative effects of pharmacotherapy. At this time, there are a host of effective short-term treatments for PD including the SSRIs as a class, venlafaxine XR, MAOIs, TCAs, and benzodiazepines. SSRIs and SSNIs are generally accepted as first-line treatments for PD. However, if one does not daily, gradually titrate a patient with PD up on these medications, one can assure noncompliance due to their side effect burden. A second pharmacological technique that has been effective for patients who suffer from PD is to coadminister a small dose of a long-acting benzodiazepine such as clonazepam or alprazolam XR with an antidepressant, and then withdraw the benzodiazepine over a period of several weeks, after the patient has reached a therapeutic dosage of the antidepressant.

Panic attacks may be effectively controlled relatively early in the course of treatment; however, anticipatory anxiety and somatic sensitivity take significantly longer to resolve. Some form of behavioral intervention, even a brief one in a medication management session, can facilitate more rapid improvement in anticipatory anxiety and phobic behavior. Aside from the widely used augmentation of antidepressants with benzodiazepines, there are very few data guiding our choice of second- and third-line approaches to the treatment of patients with PD.

Posttraumatic Stress Disorder

Selective Serotonin Reuptake Inhibitors

There have been several open-label and double-blind, placebo-controlled studies demonstrating that SSRIs are effective for the treatment of PTSD. Open-label trials with the SSRIs currently available suggest that each may be effective in decreasing the core symptoms of PTSD. Three of the SSRIs have been studied in a double-blind, placebo-controlled fashion. Fluoxetine was the first of the SSRIs to be studied in randomized, controlled trials. In two small studies, civilian patients treated with fluoxetine demonstrated significant improvement as compared with placebo treatment. In one of these trials, Van der Kolk et al. (1994) included a veteran cohort as well; fluoxetine did decrease symptoms of PTSD in the veteran subgroup. Martenyi et al. (2002) conducted a double-blind, randomized study comparing fluoxetine and placebo’s effects on relapse prevention in 131 subjects meeting DSM-IV-TR criteria for PTSD. Subjects underwent 12 weeks of acute treatment; subjects who responded were rerandomized and continued in a 24-week relapse-prevention phase with fluoxetine or placebo. Subjects in the fluoxetine/placebo group were found less likely to relapse than those in the fluoxetine/placebo group ($p = 0.027$).

Two SSRIs have been approved by the FDA for the treatment of PTSD. The first agent approved for the treatment of PTSD is sertraline. There have been two published large placebo-controlled acute treatment trials of sertraline for noncombat-related PTSD. In these studies, Davidson et al. (2001) and Brady et al. (2000) found that sertraline
was more effective than placebo treatment in decreasing the Clinician Administered Posttraumatic Stress Disorder Scale 2 (CAPS-2), the patient-rated Impacts of Events Scale, and the CGI-Severi ty and Improvement Rating Scales. Both of the studies were flexible-dose studies where 50–200 mg/day of sertraline was administered. Londborg et al. (2001) published open-label continuation data for individuals who had participated in these acute trials (Davidson et al. 2001). They demonstrated that patients who responded during the acute phase not only maintained their response but continued to improve after 6 months of continuation treatment. Fifty-four percent of individuals who did not acutely respond to SSRI treatment during the initial 12-week trial had a significant decrease in their CAPS-2 scale scores by the end of 6 months of open-label treatment. Davidson et al. (2001) reported the results of the placebo discontinuation phase of this study. Individuals who responded to 6 months of open-label therapy were rerandomized to receive double-blind treatment with sertraline or placebo. Placebo discontinuation was associated with a significant risk of relapse (26% vs. 5%) and reemergence of the core symptoms of PTSD. Rapaport et al. (2002) investigated the effects of sertraline treatment on quality of life in the samples described in the Londborg et al. (2001) and Davidson et al. (2001) studies. By the end of the 12-week acute phase, 58% of sertraline responders had achieved Q-LES-Q total scores within 10% of community norms and had shown significant improvement on the Medical Outcomes Study 36-Item Short Form Health Survey (SF-36) subscale scores. Continuation of treatment resulted in a further 20% improvement in quality-of-life and psychosocial measures. During the double-blind maintenance phase, randomization to placebo was associated with significant worsening of Q-LES-Q scores and quality of life. These findings from Davidson et al. (2001), Londborg et al. (2001), and Rapaport et al. (2002) suggest that some patients with PTSD will require sustained SSRI treatment, possibly for years, in order to protect them from exacerbation of PTSD. Zohar et al. (2002) conducted a double-blind, placebo-controlled pilot study of sertraline (50–200 mg/day) in military veterans with PTSD. Forty-two patients were randomized to 10 weeks of sertraline or placebo. Primary efficacy measures included the CAPS-2 and CGI-I. Although the sertraline treatment group demonstrated improved scores on the CAPS-2, no statistically significant difference was observed. At study endpoint, mean CGI-I scores were lower in the sertraline-treated group compared to placebo (2.4 ± 0.3 for sertraline and 3.4 ± 0.3 for placebo (p = 0.016). CGI-I responders rates were 53% for sertraline and 20% for placebo (p = 0.057) and combining CGI-I and CAPS-2 responders rates (≥30% reduction in baseline CAPS-2 score) were 41% for sertraline and 20% for placebo (p = 0.238). Sertraline was well tolerated and may be an effective treatment for patients with combat-related PTSD, although larger studies are needed to confirm these results.

Paroxetine is also approved as an acute treatment for PTSD by the FDA. There has been one fixed-dose study demonstrating that both 20 and 40 mg/day of paroxetine were more effective than placebo for the treatment of PTSD (Marshall et al. 2001). In this study, patients treated with paroxetine had significantly greater improvement in the CAPS-2 and were more likely to have CGI-Improvement Scale scores of (2) “much improved” or (1) “very much improved.” In the 12-week flexible-dose study, 20–50 mg of paroxetine treatment was more effective than placebo treatment in decreasing the CAPS-2 scale, the Davidson Trauma Scale, and the SDS (Tucker et al. 2001).

In conclusion, data from open-label studies and double-blind, placebo-controlled studies suggest that SSRIs, as a class, are effective in the treatment of PTSD. In addition, longer term research with fluoxetine and sertraline confirms the continued benefit with extended treatment.

**Serotonin–Norepinephrine Reuptake Inhibitors—Venlafaxine and Reboxetine**

Davidson et al. (2006b) compared and contrasted venlafaxine ER, sertraline, and placebo in a 12-week, double-blind, randomized, flexible-dose, multicenter trial of adult outpatients. Patients met DSM-IV-TR PTSD criteria of at least 6 months duration and had a score ≥60 on the Clinician Administered PTSD Scale (CAPS-SX-17). Subjects were randomly assigned to receive placebo, venlafaxine ER (37.5–300 mg/day, mean maximum dose 225 mg/day), or sertraline (25–200 mg/day, mean maximum dose 151 mg/day). Mean changes in CAPS-SX-17 scores were −41.8, −39.4, and −33.9 for venlafaxine ER (p < 0.05 vs placebo), sertraline, and placebo, respectively. Week 12 remission rates were 30.2% for the venlafaxine XR group (p < 0.05 vs. placebo), sertraline 24.3%, and placebo 19.6%. Davidson et al. (2006a) also conducted a 6-month, double-blind, placebo-controlled trial, multisite study of venlafaxine ER with 329 adult outpatients. Patients were randomly assigned to placebo or venlafaxine ER (37.5–300 mg/day, mean maximum dose 221.5 mg/day) for 24 weeks. Mean changes from baseline to CAPS-SX-17 total scores at endpoint were −51.7 for venlafaxine ER and −42.9 for placebo (p = 0.006). Results from these studies suggest that venlafaxine ER is an effective short- and long-term (6-month) treatment for PTSD.

Spivak et al. (2006) compared reboxetine (8 mg/day) and fluvoxamine (150 mg/day) in the double-blind treatment of 40 patients presenting with motor vehicle accident-related PTSD. Both medications led to significant improvement in CAPS-2 scores during the 8-week study, with no significant differences between the treatment groups. In this fixed-dose study, fluvoxamine treatment was associated with lower withdrawal rates than reboxetine.

**Tricyclic Antidepressant Medication and Monoamine Oxidase Inhibitors**

There are several small double-blind, placebo-controlled trials suggesting that both amitriptyline and imipramine are more effective than placebo in decreasing signs and symptoms of PTSD. However, after the advent of SSRIs that have significant safety and tolerability advantages, additional studies with TCAs were not pursued (Davidson et al. 1990, Kosten et al. 1991).

There is little literature suggesting that MAOIs are more effective than placebo in the treatment of PTSD. The two best studied MAOIs are the irreversible nonselective MAOI phenelzine and the reversible selective MAOI, brofaromine. Placebo-controlled studies by Kosten et al. (1991) and Davidson et al. (1987) suggest that phenelzine is more effective than placebo in decreasing symptoms of PTSD. Their findings have been supported by work of Lerer et al. (1987), who demonstrated that phenelzine was a beneficial treatment for veterans with PTSD. As summarized by...
Stein et al. (2000), there have been several studies investigating the efficacy of brofaromine in the treatment of PTSD. International studies with brofaromine have demonstrated that it was more effective than placebo, while the initial work performed in the US differentiated brofaromine from placebo treatment. Although failed studies are not uncommon, this has unfortunately led to a discontinuation of the research program with brofaromine in the US. A third reversible selective MAOI is moclobemide. Moclobemide, fluoxetine, and tianeptine were compared and contrasted in a 12-week, open-label, randomized, flexible-dose study of 103 subjects who met DSM-IV-TR criteria for PTSD (Onder et al. 2006). The primary measure of efficacy was the CAPS. All three treatments led to a significant improvement in PTSD severity (CAPS; p < 0.001). CAPS subscales, reexperiencing, avoidance, and hyperarousal were significantly reduced by all three treatments (all p < 0.001). There was no significant difference observed in treatment effect between the three treatment groups.

Other Antidepressant Medication (Bupropion, Mirtazapine, Nefazodone, Trazodone)

Davis et al. (2004) conducted a 12-week, double-blind, placebo-controlled study of nefazodone’s effects on chronic PTSD. Forty-one individuals enrolled in this study, where all but one patient suffered from combat-related PTSD. Patients were given either placebo or 100–600 mg nefazodone twice daily. After 12 weeks, subjects showed significant improvement on CAPS total score, as well as the CAPS hyperarousal criterion and HAM-D scores. No significant difference observed in treatment effect between mirtazapine and sertraline in 95 outpatient and 18 inpatient Korean veterans who met DSM-IV-TR criteria for PTSD. Mirtazapine also was studied in an 8-week, placebo-controlled, double-blind trial of 29 subjects who met DSM-IV-TR criteria for PTSD. The primary measures of efficacy were the Short Posttraumatic Stress Disorder Rating Interview (SPRINT) Global Improvement item and the measure’s total score, with response defined as a score of very much or much improved. Approximately 65% of mirtazapine-treated subjects met response criteria versus 20% for the placebo-treatment group. Chung et al. (2004) conducted a 6-week, flexible-dose study comparing and contrasting mirtazapine and sertraline in 95 outpatient and 18 inpatient Korean veterans who met DSM-IV-TR criteria for PTSD. Efficacy measures included the CAPS-2, HAM-D-17, and CGI-I. Response was defined as a ≥30% decrease in CAPS-2 total severity, a ≥50% decrease in total HAM-D-17 score, and a CGI-I score <3. The mean daily dose of mirtazapine was 34.1 mg/day and 101.5 mg/day for sertraline. The mirtazapine-treated group showed a statistically significantly higher response rate than the sertraline-treated group on the CAPS-2 total score (88% vs. 69%, p = 0.039). The HAM-D-17 total score and the CGI-I score decreased in both treatment groups with no significant difference between the groups. There are also case reports suggesting that mirtazapine augmentation may be helpful (Good and Petersen 2001).

Beta-Blocker Medication

Results from two pilot studies that investigated a course of propranolol among individuals who had recently experienced an acute traumatic event indicated that propranolol was effective in decreasing PTSD symptoms and severity. Pittman et al. (2002) gave 40 mg propranolol four times a day for 10 days (with initial dosing beginning within 6 hours following the acute traumatic event) and found the dosing regimen to be effective in reducing PTSD symptoms 1 month later. Similarly, Vaiva et al. (2003) studied the efficacy of propranolol prescribed shortly after trauma exposure in the prevention of PTSD symptoms and diagnosis. Eleven patients were given 40 mg of propranolol 3 times a day for 7 days and the results were compared to those of 8 patients who refused the propranolol but agreed to participate in the study. PTSD rates measured 2 months after the trauma were higher in the refusal group (3/8) compared with the propranolol-treated group (1/11), as were the levels of PTSD symptoms.
Anticonvulsant Medication

Anticonvulsant medications may also prove useful for the treatment of PTSD. A series of small case studies using carbamazepine as a treatment for PTSD have been reported. In these open-label case series, patients seemed to have a decrease in intrusive thoughts and improvement in sleep associated with carbamazepine treatment. Two small studies have investigated the efficacy of tiagabine with PTSD patients (Taylor 2003, Connor et al. 2006). Taylor (2003) conducted a case series of 7 patients where 8 mg/day tiagabine was added to patients existing medication regimens. During the 16-week trial, 6 of the 7 patients markedly improved after 2 weeks of augmentation therapy. Tiagabine alleviated the severity of nightmares, avoidance, and arousal characteristics of PTSD. Complementing these results, Connor et al. (2006) enrolled 26 PTSD patients in 12 weeks of open-label treatment with 2–16 mg tiagabine daily. The 18 subjects who showed minimal response on the CGI-I scale were then randomized to 12 weeks of double-blind treatment with tiagabine or placebo, either being tapered off their medication or remaining at the same dose as they had taken at the end of the open-label phase. Among the 8 completers, symptoms decreased 68% in tiagabine-treated patients and 54% in placebo-treated patients, with relapse rates equal in placebo and tiagabine groups. These studies offer mixed results, which may be resolved through larger double-blind clinical trials of tiagabine better characterizing its value as a treatment for PTSD.

Berlant has pioneered the use of topiramate as a mono-therapy or an adjuvant treatment for PTSD. In his published case series (Berlant 2001), topiramate seems to be particularly useful in improving sleep, decreasing nightmares, and decreasing intrusive thoughts. More recently, two open-label studies have been published on the same topic, examining topiramate’s effects on PTSD patients with and without hallucinations (Berlant and van Kammen 2002, Berlant 2004). Berlant and van Kammen (2002) found higher response rates in nonhallucinatory patients, who experienced a definite reduction in nightmares or intrusions. In the second study noted, only nonhallucinatory PTSD patients were recruited. Among the 33 patients enrolled in this 12-week, open-label study, 70% were responders, as reflected by a 30% reduction in PTSD Checklist-Civilian Version (PCL-C) scores. Although these results are promising, both studies were open-label and had high attrition rates. Further research is called for on topiramate’s effects on PTSD, especially double-blind studies.

To date there has been one double-blind, placebo-controlled study of lamotrigine for the treatment of PTSD (Hertzberg et al. 1999). In this study, 15 patients were randomized in a 2:1 ratio to either lamotrigine or placebo. Five of the 10 patients who received lamotrigine had a significant decrease in their global PTSD Scale score as compared to one of four patients who received placebo. Lamotrigine-treated patients showed improvement in avoidance, numbing, and reexperiencing symptoms. Further studies will be necessary to determine whether anticonvulsant treatment, either as a monotherapy or as an adjuvant with antidepressants, will be beneficial for patients with PTSD.

Antipsychotic Medication

With the development of the atypical antipsychotics, there has been a reemergence of interest in the possible use of antipsychotic medication as both a primary treatment for PTSD as an adjuvant treatment for PTSD. However, in a large secondary analysis of veteran inpatients and outpatients with PTSD, only 9% of inpatients and 10% of outpatients had been treated with antipsychotic medications (Sernyak et al. 2001). These patients tended to have more severe PTSD, more intrusive thoughts, and be more dysfunctional, although their incidence of traumatic experiences did not differ significantly from those patients who were not treated with antipsychotic medications. In this study, the antipsychotic augmentation did not have any additional benefit.

More recently, risperidone has been examined as an adjunctive agent in the treatment of PTSD. Reich et al. (2004) studied 21 adult female outpatients who had a history of childhood abuse. In this 8-week, double-blind, placebo-controlled comparison of flexible-dosage risperidone (0.5–8 mg/day), risperidone-treated patients experienced a significant reduction in the total CAPS-2 and all subscales except for the avoidant subscale (nine patients took concomitant medications during this study). Two studies have explicitly examined risperidone as an augmenting agent in PTSD patients’ medication regimens (Hamner et al. 2003, Bartzokis et al. 2004). Hamner et al. (2003) randomized 37 combat veterans with PTSD to a 5-week, flexible-dose, double-blind, placebo-controlled trial of 1–6 mg/day risperidone augmentation to preexisting antidepressant/psychotic medication regimen. Outcome measures included the Positive and Negative Syndrome Scale (PANSS) and the CAPS. Among the 22 patients who completed the study, risperidone-treated patients showed a significantly greater decrease in psychotic symptoms, as measured by PANSS. Both groups showed a substantial decline in CAPS scores, with no significant difference between treatment groups. Bartzokis et al. (2004) recruited 65 patients with severe combat-related PTSD for a double-blind, placebo-controlled trial. These patients participated in a 5-week residential program followed by 3 months of outpatient follow-up. The mean CAPS score was 100. Both treatment groups showed significant improvement during the initial inpatient phase, but by week 16, risperidone treatment separated from placebo on the CAPS-Total, CAPS-D, HAM-A, and PANSS. Risperidone augmentation helps decrease intrusive thoughts and markedly improves symptoms of PTSD.

Four studies have examined olanzapine’s efficacy in PTSD. Stein et al. (2002a) studied 19 male war veterans with military-related PTSD in a 12-week, double-blind, placebo-controlled study of 10–20 mg/day olanzapine versus placebo. Outcome measures included CAPS, PSQI, and the Center for Epidemiologic Studies Depression Scale (CES-D). Olanzapine-treated patients experienced a significantly greater reduction in PTSD symptoms, depressive symptoms, and sleep disturbance. Response rates as measured by the CGI-I were fairly low (30%) among olanzapine patients, and they were not statistically superior to scores for placebo patients. In another small double-blind, placebo-controlled, flexible-dose study of olanzapine, 11 patients completed the study and there was no difference in the response rates between the two groups (Butterfield et al. 2001). Pivac et al. (2004) conducted an open-label trial of olanzapine versus fluphenazine. In this study, 55 male war veterans with combat-related PTSD received 5–10 mg/day olanzapine or fluphenazine for 6 weeks. Both medications helped alleviate symptoms of PTSD.
PTSD, but olanzapine was more efficacious than fluphenazine at reducing negative symptoms, avoidance and arousal. As expected, fluphenazine caused more extrapyramidal symptoms and olanzapine caused greater weight gain. Petty et al. (2001) published an open-label study of 48 individuals who were started on open-label olanzapine treatment. Thirty patients completed the 8-week trial and tolerated olanzapine well. These patients had clinically significant improvement in their CAPS-2 scores, HAM-D scores, and Brief Psychiatric Rating Scale (BPRS) scores. Large-scale studies are needed to examine the potential benefit of atypical antipsychotic medications as a monotherapy or an augmentation therapy for PTSD patients, especially those with psychotic symptoms.

**Novel Treatments**

Several alternative treatments for PTSD are being investigated. Raskind et al. (2003) compared and contrasted prazosin and placebo in a 20-week, double-blind, crossover study of 10 Vietnam combat veterans diagnosed with chronic PTSD and severe trauma-related nightmares. Prazosin is a centrally active adrenergic antagonist commonly used in treating hypertension. Primary efficacy measures included two items from the CAPS (recurrent distressing dreams item and difficulty falling/staying asleep item), and the change in overall PTSD severity and functional status according to the CGI. Prazosin was shown to be more effective than placebo at study endpoint in decreasing symptoms of recurrent distressing dreams (3.6 vs. 6.7, respectively, \( p < 0.001 \)) and with difficulty falling/staying asleep (4.0 vs. 7.1, respectively, \( p < 0.01 \)). At study endpoint, prazosin displayed an average of 57.3 on the CAPS compared to 86.5 for the placebo group (\( p < 0.01 \)). Prazosin was also associated with improved global functioning compared to placebo (prazosin mean CGI score 2.0, compared to placebo mean CGI score 4.5, \( p < 0.01 \)). Prazosin was well tolerated.

A small study by Heresco-Levy et al. (2002) investigated D-cycloserine (DCS) as a treatment for PTSD. D-cycloserine, a NMDA receptor partial agonist, is being investigated as a treatment for schizophrenia, chronic low back pain, SAD, and Alzheimer’s disease. In a double-blind, placebo-controlled crossover trial, eleven subjects who met DSM-IV-TR criteria for PTSD were treated with 50 mg/day D-cycloserine or placebo for 12 weeks. The CAPS was the primary efficacy measure. D-cycloserine therapy significantly decreased scores on the numbing and avoidance clusters of the CAPS but not total scores or other subscales.

**Treatment Conclusions**

Patients with PTSD typically fall into one of two broad categories: those who have recently experienced a trauma and are bothered by persistent symptoms of PTSD but do not have co-occurring other disorders, and those patients with more long-standing PTSD who frequently have one or more secondary co-occurring psychiatric condition(s). The former group is much more responsive in the short term to pharmacotherapy. At this time, SSRIs are the FDA-approved treatment of choice for patients with PTSD. In contradistinction to patients with PD and SAD, these patients do not seem to have as much antidepressant-induced anxiety. Patients who have had PTSD for a long time and present with comorbid psychiatric syndromes are far more difficult to treat. They generally respond very slowly to treatment and their care is frequently unfounded by their overall complex psychiatric presentation. The key to successfully treating such individuals is to be clear about the target symptoms and to give the patient sustained treatment because improvement many times will require months of therapy. There are some promising smaller studies suggesting that such patients may do well with an augmentation approach. Some of the most exciting data have used atypical antipsychotic agents to augment SSRIs. Another very intriguing approach is to add Prazosin, an alpha-adrenergic antagonist, to patients with PTSD suffering from problems with disrupted sleep. Recent studies suggest that this is very effective even in treatment-resistant PTSD. As previously stated, there are few data to guide clinical treatment beyond first-line treatment intervention.

**Obsessive–Compulsive Disorder**

**Selective Serotonin Reuptake Inhibitors**

There have been two large 12-week, parallel-group, double-blind, placebo-controlled multicenter trials of fluoxetine in fixed doses of 20, 40, and 60 mg/day versus placebo (Tollefson et al. 1994a, 1994b). Response was defined as a decrease of 35% or greater on the Yale-Brown Obsessive–Compulsive Scale (Y-BOCS). The three fluoxetine doses each had response rates of 33%. There was some suggestion that the 40 and 60 mg/day doses acted more rapidly and facilitated greater improvement in Y-BOCS scores. Montgomery et al. (1993) previously reported that 40 and 60 mg/day of fluoxetine, but not 20 mg/day, was more effective than placebo.

Although there are data available from a number of placebo-controlled multicenter trials contrasting paroxetine with placebo, only one 12-week fixed-dose trial (20, 40, and 60 mg/day) has been published (Ballenger et al. 1998). In this study, all patients were initially started at 20 mg/day, and the 40 and 60 mg/day groups were titrated to these doses by the end of week 2. The 40 and 60 mg/day groups demonstrated statistically significant decreases on the Y-BOCS and the CGI-Severity Scale. The greatest improvement seemed to be present in the 60 mg/day group. Paroxetine has also been studied as a treatment of OCD in children. Geller et al. (2004) performed a multisite, double-blind, placebo-controlled, flexible-dose study randomizing 203 patients to receive either 10–50 mg/day paroxetine or placebo for 10 weeks. One hundred and forty-five patients completed the study, with 33/98 (33.7%) treatment responders among patients receiving paroxetine in contrast to 25/105 (23.8%) responders among those patients receiving placebo. The Children’s Yale-Brown Obsessive–Compulsive Scale (CY-BOCS) scores demonstrated a significant decrease for the paroxetine-treated group when compared with the placebo-treated group. However, the two treatment groups did not differ in terms of CGI-S, CGI-I, and Global Assessment of Functioning (GAF) ratings.
There have been several smaller trials and one large 10-week, double-blind, placebo-controlled multicenter trial of fluvoxamine (100–300 mg/day) versus placebo in the treatment of OCD (Goodman et al. 1989, Greist et al. 1995c, Jenike et al. 1990, Perse et al. 1987). In the large study, Greist et al. (1995c) reported that 40% of fluvoxamine-treated patients were responders on the CGI-Improvement Scale as compared to 15% of placebo-treated patients. The fluvoxamine-treated patients also had a significantly greater decrease in the mean Y-BOCS scores (Greist et al. 1995c).

Riddle et al. (2001) conducted a 10-week, double-blind, placebo-controlled, multisite study investigating the efficacy of fluvoxamine in childhood OCD. Out of 120 individuals who were randomized, 24/57 (42.1%) treated with fluvoxamine and 17/63 (26%) treated with placebo were responders (defined as ≥25% decrease in CY-BOCS scores). These studies suggest that fluvoxamine is effective in treating both adults and children with OCD.

In addition, Pallanti et al. (2002) conducted an open-label study of intravenous citalopram infusion in 39 treatment-resistant OCD adult patients. Thirty-eight patients completed the 21-day study of 20–80 mg intravenous citalopram. Twenty-three patients (59%) had a ≥25% decrease in their Yale-Brown Obsessive–Compulsive Scale (Y-BOCS) scores. These patients were then given oral citalopram and they continued to improve daily during this 63-day phase. Although intravenous citalopram was rapidly effective in this study, an increased incidence of cardiovascular adverse events was noted. Furthermore, placebo-controlled, double-blind studies should be performed to extend these results. Montgomery et al. (2001) performed a 401-patient, multisite, double-blind, placebo-controlled study of 20, 40, and 60 mg/day doses of citalopram. In contrast to previous SSRI studies for OCD, during the 12-week study, 20 mg was found to be an effective dose, as measured by the change in Y-BOCS from baseline to study endpoint. All three doses were significantly superior to placebo in treating both obsessions and compulsion, although the study was not large enough to discriminate any difference between dose regimens. There are data from single-blind comparator trials of citalopram versus paroxetine and fluvoxamine that suggest that there is no significant difference in Y-BOCS scores between these medications (Mundo et al. 1997). These data are consistent with other open-label studies with adults and children suggesting that citalopram may decrease symptoms of OCD (Koponen et al. 1997, Thomsen 1997).

In one large 12-week, double-blind, placebo-controlled multicenter fixed-dose study of sertraline (50, 100, and 200 mg/day), all three doses of sertraline caused a significant reduction in Y-BOCS scores (Greist et al. 1995a). The higher doses did show selectively greater improvement on all measures but this did not reach statistical significance. There are two other double-blind, placebo-controlled multicenter flexible-dose trials of sertraline versus placebo in the treatment of OCD (Chouinard et al. 1990, Kronig et al. 1999). In both of these trials, sertraline was more efficacious than placebo on standard outcome measures. Greist et al. (1995a) also demonstrated the ability of sertraline to maintain improvement after 12 weeks of double-blind, placebo-controlled treatment during an additional 40-week double-blind fixed-dose trial of sertraline (50, 100, and 200 mg/day) (Greist et al. 1995b). At the 52-week endpoint, mean scores for all four outcome measures, Y-BOCS, the NIMH Global Obsessive–Compulsive Scale, and CGI-Severity and Improvement Scales, revealed significantly greater improvement for the sertraline group versus the placebo group (Noyes et al. 1997). Fifty-one of the patients who participated in the double-blind, placebo-controlled trial of sertraline entered into a 2-year sertraline open-label study. Outcome data suggested that efficacy was not only maintained, but improvement continued; first year mean Y-BOCS scores were 11.4 compared to second year mean Y-BOCS scores, 3.2.

Koran et al. (2002) performed a relapse-prevention study where patients who had achieved a sustained response during a 52-week single-blind treatment phase were randomized to an additional 28 weeks of double-blind treatment with either sertraline or placebo. This 80-week study was conducted at 21 sites in the US. Following a 1-week washout, 649 patients entered 16 weeks of single-blind treatment with flexible doses of sertraline. Patients were titrated up on a 50 mg incremental schedule to a maximum 200 mg/day depending on response and tolerability. Patients who failed to meet response criteria by the end of week 16 were withdrawn from the study. Response was defined as a decrease of 25% from baseline on the Y-BOCS, and a CGI-Improvement Scale score ≤3. Those who met responder criteria continued to receive single-blind sertraline treatment for an additional 36 weeks. Data from the single-blind trial revealed consistent improvement throughout the 52 weeks of treatment. Mean Y-BOCS scores decreased from 26.1 at baseline to 15.9 at the end of week 16 to 10.3 at the end of week 52. Symptomatic improvement was associated with improvement in quality of life as measured by Q-LES-Q scores from 60% at baseline to 73.7% at the end of week 16 to 78.2% at the end of week 52. (The mean Q-LES-Q score for a population of normal subjects is 80%.) At the end of week 52, patients who continued to meet responder criteria were randomized to the 28-week double-blind discontinuation trial. Those patients randomly assigned to sertraline treatment were continued on the same daily dose as at week 52. Patients assigned to placebo had their dose decreased by 50 mg/day every 3 days until they were taking only placebo tablets. Continued sertraline treatment was associated with sustained improvement during the 28-week relapse-prevention phase. Sertraline treatment was also significantly more effective than placebo in decreasing study discontinuation due to relapse or insufficient clinical response, and acute exacerbation of obsessive–compulsive symptoms. One third of patients experienced acute relapse, which is striking when compared to earlier discontinuation studies that show relapse rates of 90% or greater as measured by the Y-BOCS.

Another recent study evaluated the efficacy of long-term sertraline treatment of children and adolescents, ages 6–18 years with OCD (Cook et al. 2001). One hundred and thirty-seven patients were assigned to 12 weeks of double-blind, placebo-controlled treatment with subsequent open-label sertraline treatment (50–200 mg/day) for 52 weeks. At study endpoint, the mean daily sertraline dose was 108 mg/day for children (6–12 years), and 132 mg/day for adolescents (13–18 years). Outcome measures included the Children’s Yale-Brown Obsessive–Compulsive Scale (CY-BOCS), the NIMH Obsessive–Compulsive Scale, and the CGI-Severity and Improvement Scales. Mean CY-BOCS scores changed from 22.8 at study entry to 17.0 at the...
completion of the double-blind phase to 10.8 at the 52-week endpoint. The mean CGI-I Severity scores declined from 4.6 to 3.7 to 2.7, respectively. Only 12% of patients discontinued because of side effects.

These data suggest that SSRIs are a first-line pharmacotherapy for both acute and maintenance treatment of OCD in children and adults (Greist and Jefferson 1998, March and Frances 1997). Discontinuing SSRI treatment is associated with an exacerbation of symptoms and worsening in quality of life. (For more on OCD, please see the Chapter 71.)

**Serotonin–Norepinephrine Reuptake Inhibitors—Venlafaxine and Reboxetine**

Hollander et al. (2003) conducted an open-label trial of venlafaxine and venlafaxine XR treatment of OCD. There were 39 patients in this trial, where 74% of these patients had not responded to at least one previous SSRI trial. The CGI-I was used to assess global improvement. Sixty-nine percent of patients were classified as responders (CGI-I of 1 or 2) by the end of the 18 months of treatment. Future placebo-controlled studies with venlafaxine XR seem warranted at this time.

**Tricyclic Antidepressant Medication and Monoamine Oxidase Inhibitors**

There have been seven meta-analyses comparing and contrasting clomipramine and SSRIs (Abramowitz 1997, Cox et al. 1993, Greist 1998, Kobak et al. 1998, Piccinelli et al. 1995, Stein et al. 1995). In each case, clomipramine has been found to be significantly more effective than the SSRIs. There has been some concern that this conclusion may be biased because many of the clomipramine studies were performed in patients who had not been previously treated with an effective pharmacotherapy, while patients in the later studies of the SSRIs had failed treatment with clomipramine or other agents. There also is concern that differences in study design might bias these results in favor of clomipramine (Greist 1998). There have been double-blind comparison studies of clomipramine against fluoxetine, fluvoxamine, sertraline, and paroxetine (Bisserbe et al. 1997, Freeman et al. 1994, Koran et al. 1996, Lopez-Ibor et al. 1996, Milanchfranchi et al. 1997, Zohar and Judge 1996). None of these studies had the power to differentiate clomipramine from the SSRIs in question. Therefore, findings of no difference between the two groups is not surprising. However, if one takes the entire body of evidence as a whole into account, analyses suggest that clomipramine is at least as effective as the SSRIs and may, in some instances, be more effective (Greist 1998, Todorov et al. 2000).

Although there have been several studies with MAOIs, the results of these studies have been equivocal at best (Jenike et al. 1990, Vallejo et al. 1992). The two other strategies for enhancing serotonergic neurotransmission have involved manipulating the ratio of clomipramine to its metabolite desmethylclomipramine. One strategy has involved the use of intravenous clomipramine in order to decrease first-pass hepatic metabolism and thus increase the ratio of clomipramine metabolite desmethylclomipramine. These studies found that intravenous clomipramine reduces symptoms of OCD more rapidly than oral clomipramine (Koran et al. 1994, 1997, Warneke 1984, 1985, 1989). Yet, over time, patients treated with intravenous clomipramine did not have a greater response than patients treated with oral clomipramine. The second strategy combines giving clomipramine with an SSRI (fluvoxamine) that inhibits its hepatic metabolism. This, again, shifts the ratio of clomipramine to desmethylclomipramine in favor of clomipramine.

**Other Antidepressant Medication (Bupropion, Mirtazapine, Nefazodone, Trazodone)**

Mirtazapine treatment was studied in a 10-week open trial of 10 adult outpatients who met DSM-IV-TR criteria for OCD for at least 1 year and had a Y-BOCS score greater than 18 (Koran et al. 2002). Mirtazapine was started at a dose of 15 mg/day then increased after 4 days to 30 mg/day, and to 45 mg/day at the end of the second week. OCD severity was measured with the Y-BOCS and the CGI-Severity Scale. In this study, mean Y-BOCS scores decreased from 28.7 at baseline to 23.7 at week 10. Only 2 of the 10 subjects met responder criteria. These results suggest that mirtazapine may not be a useful treatment for subjects with OCD. Bupropion has also been studied in patients with OCD. Vulink et al. (2005) found that bupropion was an ineffective treatment for 12 patients with OCD in an open-label, fixed-dose study. Two patients responded (≥ 25% reduction in YBOCS score) while eight patients deteriorated during the 8-week study.

**Benzodiazepine Medication**

Harvey and Balon (1995) reviewed the double-blind augmentation studies of buspirone used for patients with treatment-resistant OCDs, noting that none have demonstrated any advantage over placebo treatment.

**Beta-Blocker Medication**

Pindolol augmentation has been evaluated in one small double-blind study for patients with treatment-resistant OCD. In this two-phase study performed by Dannon et al. (2000) 23 treatment-resistant patients were prospectively treated openly with 60 mg of paroxetine a day. Nonresponse was defined as a 25% improvement on the Y-BOCS during this open-label treatment phase. Sixteen patients were randomized to receive double-blind augmentation therapy with either pindolol 2.5 mg t.i.d. or matching placebo for 6 weeks. The primary outcome measure was a change in Y-BOCS score or secondary measures included changes in HAM-A scales total scores and MADRS total scores. A significant decrease in Y-BOCS score was noted, but there were no changes compared to placebo in the MADRS or the HAM-A rating scores. This suggests that pindolol might have a unique role in decreasing symptoms in OCD, but is consistent otherwise with findings in both major depressive disorder and in SAD where pindolol augmentation did not cause a significant change in ratings.

**Anticonvulsant Medication**

Anticonvulsant medications have begun preliminary testing as an adjunctive agent in OCD treatment. Rubio et al.
Antipsychotic Medication

Patients with OCD frequently do not respond to mono-
therapy with SSRIs or clomipramine. One possible aug-
mentation strategy has been to block the dopamine type-
2 receptor. Preliminary studies suggest that blockade with
typical neuroleptics for patients with tics may be beneficial
(McDougle 1997). Open case series suggest that the newer
typical neuroleptics, risperidone and olanzapine, may be
useful in augmenting clinical response in treatment refrac-

tory OCD (McDougle 1997, Weiss et al. 1999). Pfanner
et al. (2000) investigated the use of risperidone as an adjunct
to SSRI therapy in an 8-week open-label trial of 20 patients
with refractory OCD. Patients in this study had a DSM-IV-
TR diagnosis of OCD with duration of illness of at least 2
years, had demonstrated less than a 25% improvement with
an SSRI after 6 months of treatment, and had a baseline
Y-BOCS score of 30. Risperidone was added at 1 mg/day
titated up to 3 mg/day over 2 weeks. The mean Y-
BOCS score decreased 26% over the course of the trial from
36.1 at baseline to 24.8 at week 8. At endpoint, 8 patients
had a CGI-Improvement score of 1 (very much improved),
9 patients had a 2 (much improved), while only 3 patients
had a 3 (minimally improved). Li et al. (2005) published the
results of a 16-patient, 9-week, crossover design study inves-
tigating the efficacy of risperidone and haloperidol augmenta-
tion of SSRI-resistant OCD. Individuals were randomized
to different sequences of the 3 augmentation strategies
(placebo–risperidone–haloperidol). Each active treatment
sequence was followed by a 1-week washout phase in order
to minimize carryover effects between augmentation strate-
gies. Twelve individuals completed all three arms of this
study. In this study, risperidone was better tolerated than
haloperidol. Neither risperidone nor haloperidol differen-
tiated placebo augmentation on Y-BOCS scale scores or
other outcome variables.

Marazziti et al. (2005) added olanzapine to patients’ previ-
ous medication regimen at a dose of 2.5 mg/day, titrating
the medication up to 10 mg daily within 2 weeks. In this
study, a significant number of patients had at least a 35%
reduction in total Y-BOCS score, which was maintained
during one year of follow-up. Due to the variability of
SSRIs, future studies may benefit from conducting double-
blind procedures involving olanzapine and a specific SSRI.

There have been at least three double-blind, placebo-
controlled augmentation trials of quetiapine augmentation in
SSRI-resistant patients with OCD. Denys et al. (2004)
randomized 40 SSRI nonresponding subjects with OCD
to either quetiapine up to 300 mg/day or placebo for 8
weeks. Forty percent of the quetiapine-treated cohort were
classified as responders as compared to 10% of placebo aug-
mented subjects. Fineberg et al. (2006) recently performed a
combined analysis of the three double-blind, placebo-con-
trolled quetiapine augmentation studies and published in li-

terature. They suggested that there seemed to be a clinically
significant signal associated with quetiapine augmentation.

However, large-scale placebo-controlled studies are clearly
indicated in order to confirm and extend these findings.

A preliminary study conducted by Metin et al. (2003)
investigated the efficacy of amisulpride augmentation (200–
600 mg) in 20 OCD patients who did not respond to SSRI
treatment. In this open-label trial, 35% of patients reported
significant improvement with combination therapy and 60%
of patients reported moderate improvement.

In summary, preliminary studies suggest that augmenta-
tion with a variety of atypical antipsychotic agents may
result in a substantial benefit for a subset of patients with
treatment refractory OCD. However, at this time, it is dif-
cult to identify who these patients are.

Treatment Conclusions

The SSRIs and clomipramine are the only FDA-approved
treatments for OCD. These agents require individualized
titration and there are many instances where patients end
up on much higher doses than those used in the treatment of
mood disorders. Although this clinical observation is
not unambiguously supported by existing clinical trial data,
there seems to be merit to this approach. Patients who have
comorbid tic disorders with OCD may be more responsive
to the combination of an antipsychotic with a serotonergic
agent. Although a myriad of augmentation strategies are
used in clinical practice, there are few data to support this

Ms. K is a 46-year-old Hispanic female who presents
with a chief complaint of recurrent major depressive disor-
der. Ms. K has had multiple brief treatments for depressive
disorder but always discontinues her treatment. Ms. K
reports that she was physically abused by her older brother
while in adolescence and 2 years ago was involved in a car
jacking. Although Ms. K was not harmed during the car
jacking, she developed a depressive disorder immediately
following the incident. When questioned further, it is clear
that Ms. K has recurrent nightmares about this event, has
flashbacks, startles easily, avoids driving on all streets ex-
cept main arteries and the freeway, and has complained of
feeling distant from her husband and children. During the
interview Ms. K breaks down and is tearful. She discusses
how ashamed she feels for being “weak” and having these
pervasive symptoms. When the concept of posttraumatic
stress disorder is introduced to Ms. K, she is relieved to
know that she is not the odd person out.

Ms. K was started on sertraline 25 mg/day and this dose
was gradually tapered up by 25 mg/week until 100 mg. Ms.
K had a gradual reduction in her intrusive thoughts and
nightmares that began during the second week of treat-
ment. Ms. K’s depressive symptoms began to resolve as
well by week 4. Since Ms. K was not having side effects and
still was symptomatic at 6 weeks, the dosage of sertraline
was increased to a 150 mg/day. Over the next 8 weeks, Ms.
K had continued improvement on both her depressive
symptoms and many of her symptoms of posttraumatic
stress disorder. She became more active with her family and
affectionate with her husband. She began to expand the
areas where she felt comfortable driving. Over time Ms. K
continued to demonstrate improvement in symptoms. She
is currently maintained on 150 mg/day of sertraline and
has been able to return to work and most of her normal
activities over a period of 2 years.

(2006) examined topiramate augmentation to current anti-
depressant medications in 12 treatment-resistant patients
during a 12-week study. Topiramate was titrated from 25
mg/day to 400 mg/day as tolerated, and 10 of the 12 subjects
were treatment responders with a ≥30% reduction in their
Y-BOCS scores.
approach. Recent studies suggest that the combination of pharmacotherapies with behavioral modification may be the optimal approach for the care of these patients.

Future Directions

The development of future pharmacological treatments for anxiety disorders may take new and exciting avenues. There is a growing body of preclinical evidence suggesting that basic fear involves the interaction between 3 of the 13 nuclei of the amygdala with decreased activation of the medio-prefrontal cortex and concomitant increased activation of the hypothalamus, the noradrenergic system, and specific areas related to fear such as the peri-aqueductal gray region of the brain. This has led investigators to begin to explore the use of both NMDA antagonists in an attempt to inhibit the development of fear responses as well as other compounds such as NMDA receptor agonists, which might be used to facilitate new learning and thereby decrease fear. In particular, there is ongoing research investigating whether one might be able to potentiate the effects of psychotherapy by using compounds like D-cycloserine. This research may be the harbinger of a variety of new pharmacological approaches targeted at specific aspects of anxiety, instead of merely using strategies that massively perturb neurotransmitter systems such as SSRIs or SNRIs; future treatments may target more specific receptors and secondary messenger systems. Pilot studies employing medication augmentation strategies are currently on their way for SAD and PTSD.

Conclusion

In closing, clinicians have a wide array of medications available for the treatment of anxiety and anxiety disorders. The breadth of accessible treatment options greatly facilitates our ability to help patients. We have safe and effective treatments for everything from short-term treatment of pathological anxiety to previously intractable anxiety disorders like OCD. Yet, the most important therapeutic agent we possess is still sound clinical skills and judgment. Appropriate diagnosis and rapport are the foundations of any pharmacological intervention we make with our patients.

Introduction

Insomnia is a common complaint in the general adult population, and the prevalence is significantly greater in patients with psychiatric disorders. Approximately 30% of adults experience occasional insomnia and about 10% suffer with chronic symptoms. (National Institutes of Health 2005) Insomnia may occur idiomatically or may arise with distressing circumstances, psychological conditioning, environmental factors, jet lag and shift work schedules, medication effects, and medical, psychiatric, and sleep disorders. Insomnia among psychiatric patients may be influenced by particular disorders, the severity of the illness, and the treatment approaches. Individuals with mood and anxiety disorders are especially likely to experience insomnia; however, most psychiatric disorders increase the risk of sleep disturbances. Often insomnia is the earliest symptom heralding a depressive episode, and it may remain a residual symptom following effective treatment of the mood disturbance (Nierenberg et al. 1999, Perlis et al. 1997).

The relationship of sleep and psychiatric illness has many different dimensions. In addition to psychiatric illness increasing the likelihood of insomnia, the presence of persistent insomnia increases the future risk of relapses or the new onset of mood, anxiety, and substance abuse disorders. Several psychotropic medications include insomnia as common side effects. Certain psychiatric disorders, particularly major depression, may be associated with changes in the distribution and amount of sleep stages. There are commonalities among neurotransmitters known to regulate sleep, mood, and anxiety. Strategic manipulations of sleep may have antidepressant effects, while sleep deprivation can precipitate mania in bipolar disorder patients.

Although insomnia simply may describe the inadequate quantity or quality of sleep when one has the opportunity to be sleeping, insomnia nosologies typically require the presence of difficulty falling asleep, staying asleep, excessively early awakening, or unrefreshing sleep in conjunction with daytime consequences (American Psychiatric Association 1994). These daytime effects may include fatigue, poor concentration, irritability, and excessive worry about sleep. Insomnia episodes may be acute or chronic and may be primary or associated with comorbid medical, psychiatric, or other sleep disorders. Chronic insomnia has been associated with increased absenteeism, decreased quality of life, higher health-care costs, and a significant societal economic burden.

Insomnia treatment generally addresses the context of the sleep disturbance, with the goal of optimizing the management of comorbid disorders and creating an environment conducive for sleep to improve. Typically this requires a comprehensive evaluation to identify associated conditions and specific factors that may undermine the experience of good-quality sleep. Treatment approaches may involve a variety of general sleep hygiene recommendations, as well as specific behavioral recommendations. Psychotherapeutic interventions may be valuable for selected patients. Cognitive behavioral therapy for insomnia has been shown to be an effective modality for chronic insomnia subjects. Pharmacologic approaches to the treatment of insomnia often are recommended in combination with these educational, psychotherapeutic, and behavioral modalities (Smith et al. 2002).

Sleep–Wake Cycle Regulation

Under normal conditions, sleep and wakefulness are strongly influenced by a network of central nervous system processes that promote sleepiness or arousal according to time-dependent mechanisms. Key brainstem arousal pathways include acetylcholine-producing cell groups activating the cortex through thalamic relay neurons and monoaminergic cell groups with projections to hypothalamic and basal forebrain regions. These latter arousal mechanisms include noradrenergic and serotonergic, as well as hypothalamic histaminergic pathways. The hypothalamic ventrolateral preoptic nucleus (VLPO) has been identified as a critical sleep-active cell group that inhibits the stimulation
from the monoaminergic arousal pathways. Inhibitory gamma-aminobutyric acid (GABA) and galanin-related VLPO activity serve as a switch that stabilizes the states of sleep and wakefulness, which are further modulated and reinforced by the neuropeptide orexin. The hypothalamic suprachiasmatic nucleus (SCN) maintains 24-hour periodicity through a complex transcription–translation feedback loop involving multiple genes. The primary input to the SCN is retinal photoperiod information, which entrains the circadian rhythm to the environmental day–night cycle (Saper et al. 2001).

Homeostatic and circadian process interactions have been postulated to explain the normal human pattern of daytime and evening wakefulness for approximately 16 hours alternating with about 8 hours of nighttime sleep. The homeostatic process represents the overall balance of sleep and waking whereby a sleep drive increases with continued wakefulness. The homeostatic sleep drive is low in the morning following nighttime sleep but then increases steadily until nighttime sleep again occurs to reverse the process and reduce the sleep drive. In spite of the increased homeostatic evening sleep drive, people generally are the most awake and alert during the evening hours. This is due to the circadian arousal that peaks in the evening and opposes the homeostatic sleepiness. As bedtime approaches, the circadian arousal declines and allows sleep onset to occur due to the unopposed homeostatic sleep drive. The SCN directs the pineal gland activity in producing and releasing the hormone melatonin. The SCN contains a high concentration of melatonin receptors. Agonist activity at these SCN melatonin receptors reduces their firing rate, which contributes to the arousal decline and subsequent sleep onset. Essentially, the homeostatic process determines the sleep need, while the circadian process optimizes sleep to occur at nighttime (Richardson 2005).

## Historical Overview

A wide assortment of substances and medications with sedating characteristics has been employed in the attempt to promote sleep. Fermented beverages and opium have been available for millennia. Sedating concoctions, such as opium-containing laudanum, were very commonly used for ailments including insomnia from the seventeenth through the nineteenth centuries. Numerous patent medicine compounds were promoted as sleep aids. Chloral hydrate and paraldehyde became available in the mid-nineteenth century. Barbiturates and related compounds frequently were recommended for insomnia from the early twentieth century until recent decades. Meprobamate, methyprylon, etchlorvynol, glutethimide, and methaqualone commonly were prescribed for insomnia in the mid-1900s. Benzodiazepine receptor agonist hypnotics, including the structural benzodiazepines and the newer nonbenzodiazepine agonists, have been the predominant selection for pharmacologic insomnia management since the 1970s. Compounds currently taken with the intention of treating insomnia include bedtime alcohol, unregulated complementary and alternative substances, over-the-counter (OTC) antihistamines, sedating prescription medications (e.g., antidepressants and antipsychotics) used on an off-label basis, and Food and Drug Administration (FDA)-approved insomnia treatment medications. A useful historical generalization is that efficacy has always been present with many older substances being capable of inducing sleep. However, earlier remedies often were associated with serious safety problems, including lethality and dependence. The predominant evolutionary theme of insomnia pharmacotherapy has been the trend of improved safety. Current treatment options represent significant progress regarding tolerability, adverse events, and abuse liability.

### FDA-Approved Insomnia Treatment Medications

Currently, the insomnia treatment medications approved by the US FDA include a variety of benzodiazepine receptor agonists and a single selective melatonin receptor agonist. Table 105–1 shows the available doses, approximate elimination half-lives, and US Drug Enforcement Administration (DEA) schedule for each of these medications. All have demonstrated efficacy in treating one or more insomnia symptoms and have been shown to have satisfactory safety characteristics in clinical trials with populations of normal subjects and individuals suffering with chronic insomnia. Generally, insomnia treatment medications have been evaluated with objective sleep laboratory and outpatient

subjective assessments. These two types of evaluations provide complementary efficacy information. In recent years, there has been a trend toward longer-term efficacy and safety trials and primary outcome measures reflecting sleep-onset latency and sleep maintenance. These directions have paralleled the approved prescribing guidelines.

Previously, all of the insomnia treatment medications were approved with indications for short-term use; however, the three new medications approved by the US FDA since 2005 (eszopiclone, ramelteon, and zolpidem extended release) have had no implied limitation on their duration of use. Accordingly, these may be prescribed as long as medically appropriate. Recent approvals have also included language specifying sleep onset and/or sleep maintenance indications. This information can help direct appropriate medication selection for individual patient insomnia patterns. Abuse liability is reflected in the DEA scheduling. All of the benzodiazepine receptor agonist hypnotics are categorized as Schedule IV controlled substances due to a relatively low risk of abuse; however, the melatonin receptor agonist has no abuse liability and is classed as a nonscheduled medication.

Benzodiazepine Receptor Agonist Hypnotics

The benzodiazepine receptor agonist hypnotics have been the primary medications prescribed for the treatment of insomnia for over 35 years. This class includes agents with the benzodiazepine structure and newer compounds that do not have the benzodiazepine structure but that are agonists for the benzodiazepine recognition site. The typical benzodiazepine structure is a seven-member diazepine ring fused with a benzene ring.

The benzodiazepine hypnotics were approved by the FDA in the 1970s and 1980s. All of the benzodiazepine receptor agonist hypnotics approved since the 1990s have had unique nonbenzodiazepine structures. There has been a trend toward short to intermediate half-life hypnotics, in contrast to earlier long-acting medications. Until recently, all of these hypnotic medications have depended on standard pharmacokinetics; however, at least one controlled-release formulation hypnotic has now become available. Some investigational benzodiazepine receptor agonist hypnotics employ rapid-acting alternate delivery formulations, such as oral dissolvable tablets and a liquid spray.

Mechanism of Action

The medications in this class function as positive allosteric modulators of GABA receptors at the GABA_A receptor complex, which is a five-subunit, ligand-gated, transmembrane structure with a central chloride ion channel (see Figure 105–1). GABA is the primary inhibitory neurotransmitter in the central nervous system, and it influences the intracellular–extracellular negative chloride ion balance. In humans, the GABA_A receptor complex most typically comprises two α, two β, and one γ glycoprotein subunits. A benzodiazepine recognition site exists at the interface of α and γ subunits. When a benzodiazepine agonist is present at this site and GABA activates the receptor, a greater number of chloride ions are able to enter the cell due to an increase in the frequency of ion channel opening. The result is greater hyperpolarization and enhanced inhibitory activity. The action of all of the benzodiazepine receptor agonists can be reversed by the benzodiazepine receptor antagonist, flumazenil. Although the wide distribution of GABA_A receptors may lead to global sedating effects, targeted action at VLPO GABAergic neurons likely plays a key role in the hypnotic effect of the medications in this class. Various benzodiazepine receptor agonist medications may also be employed as sedatives, anxiolytics, muscle relaxants, and anticonvulsants. Other medications and substances influencing the function of the GABA_A receptor include barbiturates, propofol, ethanol, and picrotoxin.

Multiple subtypes have been identified for the glycoprotein subunits constituting the GABA_A receptor complex (Bateson 2006). The α subunit, which has at least six subtypes, serves a key role in the pharmacodynamic effects of this receptor. The most common configuration in the central nervous system is α1β2γ2. Benzodiazepines are relatively nonspecific among the α subunits, with affinity for the 1, 2, 3, and 5 α subunit subtypes. The nonbenzodiazepine hypnotics have greater selectivity for the α1 subtype, which is associated with sedation, but also amnesia and ataxia (Mohler et al. 2002). This subtype selectivity may contribute to improved tolerability and decreased discontinuation effects among the nonbenzodiazepine agents.

Pharmacokinetic properties vary widely among the benzodiazepine receptor agonist hypnotics. All of these medications approved for the treatment of insomnia are absorbed relatively rapidly and may enhance sleep onset. The elimination half-life predicts the relative duration of sedating effects during the desired sleep period, but also potential undesired sedation or impairment during waking hours. Generally, tolerance to the sleep-enhancing effects of the benzodiazepine receptor agonist hypnotics has not been demonstrated in controlled clinical trials.

The benzodiazepine receptor agonist hypnotics generally are well tolerated. Adverse effects may include somnolence, headache, dizziness, nausea, diarrhea, and anterograde amnesia. Rarely patients may exhibit sleep walking or confused behaviors within a few hours after taking a hypnotic dose. Longer elimination half-lives and dosages increase the risk for next-day residual daytime effects and associated impairment. Rebound insomnia, characterized by worsened sleep for several nights relative to the pretreatment baseline insomnia, may occur upon sudden discontinuation of the medications in this class. Tapering the dose may reduce the magnitude of this effect. Recrudescence of the original insomnia symptoms also may occur with hypnotic discontinuation. New withdrawal symptoms rarely will occur with
rapid discontinuation of shorter-acting benzodiazepines (Roehrs and Roth 2006).

**Benzodiazepine Hypnotics**

Generally, benzodiazepines have sedative, antianxiety, muscle-relaxant, anticonvulsant, and amnestic properties. The five benzodiazepine hypnotics currently available in the USA are estazolam, flurazepam, temazepam, triazolam, and quazepam. Their elimination half-lives range from a few hours (triazolam) to a few days (flurazepam and quazepam). Estazolam, flurazepam, and quazepam have active metabolites. Benzodiazepine hypnotics not available in the USA include flunitrazepam, loprazolam, lorazepam, and nitrazepam. Flunitrazepam is considered an abused substance in the USA.

**Nonbenzodiazepine Hypnotics**

There are four nonbenzodiazepine hypnotic formulations available in the USA: eszopiclone, zaleplon, zolpidem, and zolpidem extended release. The elimination half-lives range from the ultrashort zaleplon at 1 hour to eszopiclone at approximately 6 hours in adults. Zopiclone is available in selected countries outside of the USA. Eszopiclone and zolpidem extended release are approved by the FDA, with indications for treating insomnia associated with difficulty with sleep onset and sleep maintenance, and both have no implied limitation on their duration of use.

While the clinical trials for benzodiazepine hypnotics have been relatively short term, nightly and non-nightly dosing studies with the nonbenzodiazepine hypnotics have been conducted for extended periods. These have included placebo-controlled, double-blind subjective efficacy assessments for 6 months of treatment and open-label safety and tolerability studies for 1 year of use. It has been demonstrated that efficacy is maintained without the development of tolerance and that adverse events remain relatively infrequent with extended use (Ancoli-Israel et al. 2005, Erman et al. 2006a, Krystal et al. 2003, Perlis et al. 2004, Roth et al. 2005).

**Prescribing Guidelines**

The benzodiazepine receptor agonist hypnotics should generally be taken when one is going to bed. Doses prior to bedtime may risk psychomotor impairment, confusion, and amnesia. Patients should avoid hazardous activities after taking the hypnotic and should be prepared to spend at least 7–8 hours in bed following ingestion of the medication. The exception is the very short-acting zaleplon, which no longer is the very short-acting zaleplon, which no longer should be active 4 hours following ingestion. Although none of these hypnotics specifically is indicated for middle-of-the-night dosing, the short half-life of zaleplon does allow greater flexibility in the timing of the dose.

Lower doses generally are recommended for older adults and patients with hepatic impairment. The concomitant use of other CNS depressants, including alcohol and various psychotropics, may lead to excessive sedation, as well as cognitive and psychomotor impairment. There is a relatively low risk of pharmacokinetic interaction with these approved hypnotics, as none are significant inducers or inhibitors of hepatic metabolic isozymes. Concomitant medications will rarely inhibit the metabolism of the hypnotics and increase their pharmacokinetic area under the curve and the peak serum concentration (Hesse et al. 2003). All of the benzodiazepine receptor agonist hypnotics are pregnancy category C, with the exception of immediate-release zolpidem, which is category B.

**Clinical Considerations**

The benzodiazepine receptor agonist hypnotics have durations of action ranging from very short to very long. Accordingly, medication selections can be made to optimize insomnia efficacy for individual patients while minimizing the risk of undesired daytime effects. The newer nonbenzodiazepine hypnotics have been popular choices due to the short to moderately short half-lives and the generally positive tolerability and safety profiles. Although primarily intended for bedtime dosing and nighttime sleep, they may be employed later during the night or when schedules require daytime sleep. Caution regarding the hypnotic duration of action is necessary when less than 8 hours is available for sleep. Patients taking longer-acting hypnotics should avoid hazardous daytime activities until they can assess potential impairment from the medications. The long half-life benzodiazepine hypnotics can accumulate with nightly dosing so that daytime blood levels increase and reach a steady state only after 1 week or longer (Vermeeren 2004).

Hypnotic medications may be taken nightly or on an as-needed basis, which may be episodic, frequent, or rare. Patients may begin with nightly use and transition to intermittent dosing. Placebo-controlled clinical trials with both zolpidem formulations have demonstrated continued efficacy for several months of non-nightly use (Erman et al. 2006a, Perlis et al. 2004, Walsh et al. 2000). Rebound insomnia was not evident on discontinuation from intermittent use. Insomnia is a chronic disorder, and some patients clearly benefit from chronic treatment. The formal indications for the two most recently approved hypnotics, eszopiclone and zolpidem extended release, do not include any implied restriction on the duration of use.

The potential for abuse or dependence of benzodiazepine receptor agonist medications has been a long-standing concern. Although these hypnotics do share some degree of abuse liability, the risk is very low with insomnia patients who do not have substance abuse comorbidity. Most patients taking hypnotics use them for up to a few weeks. Longer-term bedtime use at therapeutic doses generally reflects therapy-seeking behavior, rather than abuse. Dose escalation of hypnotics is rare (Roehrs and Roth 2006, Walsh et al. 2005).

**Selective Melatonin Receptor Agonist**

Several investigational agents have targeted the sleep-promoting and circadian rhythm-entraining activity associated with the SCN and the effects of endogenous melatonin. One selective melatonin receptor agonist is currently available: however, others are in developmental phase.

Ramelteon is the single (S)-enantiomer of a tricyclic indan derivative. It was developed to target the sleep-enhancing role performed by the melatonin receptors in the SCN. Ramelteon is unique in being a non-sedating, sleep-promoting medication with a novel mechanism of action. It does not interact to a significant degree with other neurotransmitter systems, including GABA and the monoamines. The FDA approval is for the treatment of insomnia characterized by difficulty with sleep onset. There is no implied limitation for...
the duration that it may be used. Clinical trials have demonstrated efficacy in improving sleep onset in both objective and subjective assessments in adult and older adult subjects (Seiden et al. 2005, Zammit et al. 2005).

**Mechanism of Action**
Ramelteon attenuates the circadian arousal signal that normally is present in the evening (see Figure 105–2). Over time it may improve sleep onset through stabilization of the circadian system. It is a selective agonist for the MT1 and MT2 melatonin receptor subtypes, which are present in high concentrations in the SCN. Agonists at the MT1 subtype promote sleep onset by decreasing the firing rate of selected SCN neurons, while the MT2 subtype appears to have a central role in the reinforcement and entrainment of the circadian rhythm that strongly influences the timing of the sleep–wake cycle (Kato et al. 2005). Animal studies have shown greater potency in comparison with exogenous melatonin (Miyamoto et al. 2004, Yukuhiro et al. 2004). Human studies have shown a relatively flat dose–response relationship (Erman et al. 2006b).

**Pharmacokinetics**
Ramelteon is rapidly absorbed and reaches a peak concentration within 1 hour. A high fat meal will decrease absorption and may decrease efficacy. The elimination half-life is under 3 hours. Ramelteon is metabolized primarily through the CYP1A2 isozyme and secondarily through the CYP2C subfamily and CYP3A4 isozymes. There is one active metabolite (M-II), which has an elimination half-life of 2–5 hours and the same pharmacodynamic characteristics as the parent compound, but at markedly reduced potency (Karim et al. 2006, Takeda Pharmaceuticals North America 2005).

**Prescribing Guidelines**
Ramelteon is available in a single 8-mg strength, which is the dose recommended for adults and older adults, and in patients with mild-to-moderate COPD, sleep apnea, and hepatic impairment. It should not be coadministered with fluvoxamine, which may inhibit the metabolism of ramelteon. It may be taken approximately 30 minutes prior to bedtime, as there are no psychomotor or cognitive impairments associated with the medication. However, patients should avoid hazardous activities after taking the medication due to the anticipated sleepiness. It may be used on a chronic basis and is classed as nonscheduled by the DEA (Takeda Pharmaceuticals North America 2005).

**Clinical Considerations**
Ramelteon may be beneficial for patients with difficulty falling asleep and remaining asleep during the early part of the night. It may not help with symptoms of sleep maintenance or early morning awakening. Patients taking ramelteon may not experience the medication’s maximum benefit in reducing the sleep-onset latency until they have taken it for several nights or, perhaps, a few weeks. They should be informed that their experience with ramelteon will not cause the presleep sedation that they may have noted with other sedating OTC or prescription medications.

Ramelteon generally is well tolerated. The adverse events reported by at least 2% more of the ramelteon subjects compared to placebo subjects during the clinical trials included somnolence, dizziness, and fatigue (Takeda Pharmaceuticals North America 2005). It is not associated with any discontinuation effects, such as withdrawal symptoms or rebound insomnia. Ramelteon has been assessed for up to 1 year of nightly use in an open-label study (DeMico et al. 2006).

Ramelteon has been shown to have a complete absence of abuse liability in studies with animals and humans. In a double-blind, crossover study, sedative abusing subjects were given ramelteon (16, 80, and 160 mg), placebo, and an active control (triazolam). Measures of drug likeability, behavioral and cognitive performance, and ataxia all showed no differentiation between ramelteon and placebo, whereas high-dose triazolam was associated with impairment and elevated likeability (Johnson et al. 2006).

**Prescription Medication Off-Label Use**
A wide assortment of sedating medications without formal indications for the treatment of insomnia is prescribed

with the primary intention of improving sleep onset, maintenance, and quality (Roehrs and Roth 2004). These antidepressants are largely divided into sedating and non-sedating antidepressants. A survey of prescribing practices during the year 2002 showed that three of the top four medications prescribed in association with insomnia were sedating antidepressants (Walsh 2004). Historically, a decline in benzodiazepine prescriptions for insomnia during the 1980s and 1990s coincided with a significant rise in the use of trazodone (Walsh and Schneiter 1999).

Several factors likely have contributed to the widespread off-label use of these medications. Although these sedating agents may be selected for psychiatric patients with prominent insomnia symptoms, often they are prescribed for individuals with no psychiatric comorbidity. Since insomnia frequently is associated with depressive disorders, it may seem that an antidepressant always would be beneficial. The appeal of these medications may be enhanced by the lack of abuse liability and an absence of restrictions on their duration of use. Until recently, all FDA-approved insomnia treatment medications were DEA Schedule IV controlled substances and were indicated for short-term use. In some cases, cost may also have been an issue due to the availability of generic formulations of older antidepressants.

Generally, there is limited insomnia efficacy evidence in nonpsychiatric populations, and there are significant safety concerns with all of these medications. Many clinical studies are short term, have few subjects, are not placebo controlled, have only subjective outcome measures, and do not incorporate dose–response analyses. Moreover, risk–benefit considerations have not been well delineated for insomnia populations without psychiatric comorbidity. Common to all of these medications is the risk of undesired daytime sedation and related impairment due to the relatively long elimination half-lives, generally in the range of 15–30 hours. Although prominent withdrawal effects are unlikely, rebound insomnia may occur with sudden discontinuation.

Sedating Antidepressants

Antidepressant medications with sedating properties are among the most widely prescribed drugs for insomnia patients with and without psychiatric comorbidity (Walsh 2004). In mood and anxiety disorder patients, they may be employed as a single agent to promote both improved sleep and other psychiatric symptomatology. Often this is associated with residual daytime sedation. More commonly, these agents are prescribed at a relatively low dose, sometimes in combination with other psychiatric medications. The antidepressants most commonly recommended for the treatment of insomnia have been the tricyclic antidepressants amitriptyline and doxepin, trazodone, and mirtazapine. Nefazodone previously had been used to enhance sleep but currently is prescribed infrequently due to an increased risk of liver failure. The majority of sleep-related studies with sedating antidepressants have been with populations of depressed patients, although some have been done with insomnia subjects and healthy individuals with no sleep complaints.

Most available antidepressants have varying degrees of serotonin (5-HT) and norepinephrine (NE) presynaptic reuptake inhibition and assorted postsynaptic receptor interactions. While these are thought to be fundamental to the antidepressant effects, sedation likely results from the postsynaptic antagonist activity of medications on 5-HT, NE, and histamine receptors.

Tricyclic Antidepressants

Tricyclic antidepressants include both tertiary and secondary amines. The tertiary amine tricyclics, which tend to be more sedating, include amitriptyline, doxepin, imipramine, and trimipramine. Doxepin has been shown to decrease sleep-onset latency, increase total sleep time, decrease the amount of REM sleep, and delay the onset of the first REM episode (Hajak et al. 2001, Roth et al. 1982). The tricyclic antidepressants may exacerbate periodic limb movements in vulnerable individuals and are associated with a wide range of adverse effects. Potential toxicity includes cardiac arrhythmias and seizures. Anticholinergic effects may include blurred vision, dry mouth, constipation, urinary hesitancy and retention, confusion, and delirium. Antihistaminic effects may include sedation, increased appetite, and weight gain. Hypotension may result from postsynaptic alpha 1 adrenergic receptor antagonist activity. Amitriptyline is strongly anticholinergic, and doxepin is strongly antihistaminic. Recent studies have examined the sleep-enhancing effects of ultra-low-dose doxepin in strengths less than 10 mg.

Trazodone

Although trazodone is widely prescribed to treat insomnia, there is minimal clinical trial evidence to support its efficacy (Mendelson 2005, Montgomery et al. 1983, Saletu-Zyhlarz et al. 2002). Antidepressant doses often range from 300 to 600 mg; however, it generally is prescribed for insomnia in the range from 25 to 150 mg. Studies have reported improved sleep latency, total sleep time, and sleep efficiency. Trazodone has postsynaptic antagonist activity at 5-HT 1A , 5-HT 1C , 5-HT 2 , histamine H 1 , and alpha 1 adrenergic receptors, as well as weak presynaptic serotonin reuptake inhibition. It has an elimination half-life of approximately 5–9 hours and is metabolized to a serotonergic metabolite, meta-chlorophenylpiperazine (mCPP). Residual sedation is a common complaint. Orthostatic hypotension may occur due to the alpha 1 antagonism. Priapism is a rare adverse event. Case reports suggest that trazodone may contribute to ventricular arrhythmias and the development of serotonin syndrome (Janowsky et al. 1983, Rao 1997).

Mirtazapine

Mirtazapine is commonly associated with sedation that may be beneficial for nighttime sleep, but undesired during waking hours. The elimination half-life is approximately 20–40 hours. It has presynaptic antagonist activity at alpha 2 autoreceptors and postsynaptic antagonist effects at 5-HT 2 , 5-HT 3 , histamine H 1 , and alpha 1 adrenergic receptors. The sedating property likely results from a combination of these actions. Clinical studies have demonstrated improvements in sleep-onset and maintenance parameters in normal subjects and patients with major depression (Aslan et al. 2002, Winokur et al. 2003). Mirtazapine also has been shown to increase slow-wave sleep (Schmid et al. 2006). It has been suggested that mirtazapine may be more sedating at lower doses due to the balance of serotonergic and histaminic effects relative to noradrenergic activity. Adverse effects may include increased appetite and weight gain.
Sedating Antipsychotics
Patients with psychiatric disorders often report improved nighttime sleep when taking antipsychotic medications. Among the atypical antipsychotics, clozapine, olanzapine, and quetiapine are especially sedating. Although the clinical studies are limited in size and number, they have examined the subjective and polysomnographic sleep effects of sedating antipsychotics in populations of psychiatric patients, insomnia subjects, and healthy subjects without sleep complaints. Studies have reported improvements in sleep latency, total sleep time, and sleep efficiency (Cohrs et al. 2004, Salin-Pascual et al. 1999). There have been variable effects on specific sleep stages. Beneficial sleep effects may result from combinations of antagonist activity at histaminic and multiple subtypes of 5-HT receptors. Both typical and atypical antipsychotics are associated with a wide spectrum of potential adverse effects. The atypical antipsychotics increase the risk of weight gain and impaired glucose utilization. Undesired sleep effects may include excessive sedation, sleep fragmentation, and increased periodic limb movements during sleep. The antipsychotics are employed optimally as sleep-promoting agents within the confines of the approved psychiatric indications.

Miscellaneous Prescription Medications
Aside from approved insomnia treatment medications, antidepressants, antipsychotics, and antihistamines, various other psychotropic agents occasionally are prescribed for the treatment of insomnia. Among these are barbiturates, chloral hydrate, cyclobenzaprine, gamma-hydroxybutyrate (GHB), and assorted anticonvulsants. All may have sedating effects but are associated with significant safety concerns, including toxicity and potential lethality.

Chloral Hydrate
Currently chloral hydrate most commonly is used for its acute sedating effects in preparation for medical tests and procedures. It rarely is recommended for the treatment of insomnia due to toxicity and the development of tolerance and dependence. Chloral hydrate is available in oral capsule, syrup, and suppository formulations. It is very rapidly metabolized to trichloroethanol, which modulates the GABA\textsubscript{A} receptor complex. The elimination half-life is approximately 5–10 hours. Chloral hydrate has been shown to improve sleep onset and continuity, but tolerance to the beneficial effects evolves with repeated doses. Discontinuation may result in withdrawal symptoms. Adverse effects may include unpleasant taste, GI distress, respiratory depression, hypotension, and ataxia. It can be lethal in overdose.

Gamma Hydroxybutyrate
GHB is a sedating abused substance, which simultaneously is classed by the DEA as Schedule I and III. As sodium oxybate (Xyrem), GHB is approved by the FDA for the treatment of the cataplexy and excessive daytime sleepiness in narcolepsy patients and is distributed through a single centralized pharmacy. Clinical trials have shown that it enhances nighttime slow-wave sleep. Typically it is given in a liquid form in two nighttime doses. The approximate elimination half-life is less than 1 hour. The pharmacodynamic actions are not fully elucidated; however, there are effects on dopamine activity and the GABA\textsubscript{A} receptor. The improvements to nighttime sleep have led some practitioners to prescribe GHB on an off-label basis for insomnia patients who have not benefited from standard treatments. Potential adverse effects include nocturnal enuresis, confusion, mental depression, respiratory depression, coma, and death. GHB should not be combined with alcohol or other CNS depressants.

Anticonvulsants
Several anticonvulsant medications have been observed to have sedating properties that may be beneficial for nighttime sleep but represent an undesired effect during the daytime. Clinical trials assessing insomnia treatment efficacy have been performed with selected anticonvulsants, and some are occasionally prescribed with the primary intention of improving sleep. Two examples are gabapentin (Neurontin) and tiagabine (Gabitril).

Gabapentin is indicated for the treatment of epilepsy and postherpetic neuralgia. The mechanism of action is unknown. The observed sedating effects have led to clinical use with insomnia patients and controlled clinical trials (Bateson 2006). It has been reported to increase slow-wave sleep in normal subjects (Foldvary-Schaefer et al. 2002). Adverse effects include dizziness, somnolence, fatigue, and ataxia.

Tiagabine presynaptically inhibits GABA reuptake through binding at the GAT-1 transporter. The result is increased GABA availability at the synapse. It is indicated as adjunct therapy in the treatment of partial seizures. Clinical studies have demonstrated increases in slow-wave sleep (Walsh et al. 2006). Adverse effects include dizziness, somnolence, nervousness, and tremor. An FDA warning has noted that tiagabine has been associated with new-onset seizures and status epilepticus in individuals without epilepsy.

OTC Medications
OTC antihistamine sleep aids are regulated substances that are available without a prescription. Most of these first-generation, centrally acting antihistamine products contain diphenhydramine hydrochloride; however, some have diphenhydramine citrate or doxylamine succinate as the active ingredients. They are marketed as single agents or in combination with acetaminophen or aspirin and are approved for occasional sleeplessness for people having difficulty falling asleep. None are specifically indicated for the treatment of insomnia. There are very limited efficacy data in the treatment of sleep disturbances (Kudo and Kurihara 1990). In the USA, OTC diphenhydramine is available in doses up to 50 mg and doxylamine up to 25 mg.

Sleep may be promoted by a sedating action resulting from postsynaptic H\textsubscript{1} receptor blockade that inhibits the stimulating effect of histamine in the mammillary nucleus of the posterior hypothalamus. Normally, these histaminergic neurons promote wakefulness through extensive projections to the cerebral cortex and brainstem (Tashiro and Yanai 2007). The OTC sleep aids are rapidly absorbed and typically reach a peak blood level within 1 hour. The relatively long half-lives of these compounds (approximately 8 hours) may lead to residual next-morning sedation and a complaint of grogginess. Tolerance to the sedating effects may develop (Richardson et al. 2002). Adverse effects may include paradoxical stimulation and restlessness, and thickening of bronchial secretions. Postsynaptic muscarinic
receptor blockade may produce anticholinergic effects, such as blurred vision, urinary incontinence, and confusion and delirium. Elderly patients and those concomitantly on medications with anticholinergic effects are especially vulnerable for these adverse reactions. Additionally, there may be additive effects with other CNS depressants.

**Complementary and Alternative Substances**

Numerous unregulated compounds are marketed as sleep aids. Limited efficacy evidence supports the claims, and safety data generally are lacking. Common ingredients in these homeopathic and herbal preparation sleep aids are valerian, hops, kava, passion flower, skullcap, and lavender. Generally these compounds include large numbers of individual chemicals. Therefore, specific active ingredients and mechanisms of action are difficult to determine. Valerian preparations have been the best studied one in this category. Improved sleep parameters have been reported in some studies; however, the overall findings remain inconclusive (Bent et al. 2006).

Melatonin preparations have been used extensively in the attempt to improve sleep. Endogenous melatonin has a central role in the regulation of the sleep–wake cycle. Since endogenous melatonin normally is elevated during the nighttime when humans sleep, theoretically supplementing the body’s melatonin could enhance sleep onset, duration, and quality. Melatonin is synthesized primarily in the pineal gland. Exogenous melatonin is rapidly absorbed and has an elimination half-life of less than 1 hour. Melatonin has been studied across a wide dose range. Meta-analyses of clinical trials examining the efficacy of melatonin for various insomnia populations have failed to provide consistent positive findings. However, it appears to be safe for short-term use. Potential long-term risks are unknown. While bedtime use to enhance sleep onset may have limited value, melatonin may be beneficial in the treatment of circadian rhythm disorders, particularly the delayed sleep phase syndrome.

**Insomnia in Psychiatric Patients**

In recent years, the relationship between psychiatric disorders and insomnia has come to be appreciated as circular and synergistic. Psychiatric illnesses, particularly anxiety and mood disorders, have long been recognized as frequent causes of insomnia. The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV)* diagnostic criteria formalize this association in some cases (American Psychiatric Association 1994). Clinical experience suggests that almost all patients with mood and anxiety disorders have sleep disturbances either chronically or surrounding exacerbations of their psychiatric illnesses. However, it has become evident that insomnia also increases the risk of future relapse or the development of new onset mood, anxiety, and substance abuse disorders. This association can promote a downward spiral of symptom severity and quality of life for patients that may further complicate treatment efforts. On the other hand, the close relationship of insomnia, depression, and anxiety symptoms can be viewed as an opportunity for targeted approaches that may provide significant benefits for patients.

In addition to major depression and dysthymic disorder, insomnia often occurs with bipolar disorder during depressive and manic episodes. Although manic patients may report a decreased need for sleep, many others feel distressed due to an inability to sleep. Sleep loss from any cause, including jet lag and work schedules, may lead to the onset or progression of mania in patients with bipolar disorder. Early sleep-targeted interventions may prevent or limit exacerbations for these patients (Leibenluft et al. 1996, Young 1995).

Insomnia is especially problematic for anxiety disorder patients with panic disorder, posttraumatic stress disorder, generalized anxiety disorder, and social phobia. Patients with panic disorder often will experience distressing panic episodes that awaken them from sleep. They may evolve considerable anticipatory anxiety about going to sleep, which ultimately may lead to sleep insufficiency and increased anxiety. Posttraumatic stress disorder patients often experience poor sleep quality and vivid nightmares (Green 2003). Patients with generalized anxiety disorder often experience chronic anxiety that affects them throughout the night, with resulting difficulty falling asleep and repeated awakenings. Social phobia patients report significantly worse sleep quality and difficulty falling asleep in comparison with healthy control subjects (Stein et al. 1993).

Treating the insomnia symptoms of patients with concurrent psychiatric disorders is a two-pronged approach. Specific therapeutic interventions addressing the primary psychiatric condition may include psychotherapeutic, behavioral, and pharmacologic strategies. Optimizing the treatment of the underlying disorder should ultimately improve sleep. However, many commonly prescribed antidepressants, such as the SSRIs, rarely improve the sleep symptoms rapidly, and some patients develop insomnia as a side effect from the medication. The use of a sedating antidepressant to treat depression and insomnia is limited by daytime sedation and other adverse effects.

General approaches to insomnia are those applicable to a broad range of patients and include sleep hygiene and behavioral interventions, cognitive behavioral therapy, and insomnia treatment medications. These therapies may be employed concurrently, with specific treatment strategies targeting the psychiatric disorders. There are several advantages to this two-pronged approach. First, there is greater choice among medications for the psychiatric symptoms, rather than restricting the options to sedating agents. There also is greater opportunity for flexibility in the dosage, timing, and duration of use of medications targeting different symptoms. Second, hypnotic medications may provide immediate relief and, subsequently, decreased distress and improved quality of life. A hypnotic can offset the stimulating effect of some antidepressants. Finally, these general insomnia treatment approaches can directly address the perpetuating factors that reinforce chronic insomnia.

In clinical practice, hypnotics often are prescribed concurrently with antidepressants for patients with mood and anxiety disorders. Pharmacokinetic and pharmacodynamic studies of fluoxetine and sertraline combined with zolpidem have been performed in healthy, nondepressed women (Allard et al. 1998, 1999). No clinically significant interactions were identified. In another clinical study, patients prescribed an SSRI concurrently with zolpidem or a placebo were assessed. The study population included individuals successfully treated for depression with an SSRI, but who were complaining of persistent insomnia. The hypnotic-treated...
patients reported significantly improved sleep and daytime functioning (Asnis et al. 1999). Estazocplone was studied in a placebo-controlled trial in depressed patients treated with fluoxetine. The patients in the estazocplone-fluoxetine group demonstrated rapid improvement in sleep parameters as well as a greater magnitude of the antidepressant effect (Fava et al. 2006).

While it is important to recognize and manage the insomnia symptoms that may result from psychiatric illnesses, it is also critical to evaluate psychiatric patients for other potential causes of their sleep disturbances. These may include the stimulating effects of psychotropic and other medications, medical disorders, underlying primary sleep disorders, circadian rhythm disorders, irregular schedules, and maladaptive habits and routines. Sleep apnea patients may present solely with insomnia complaints. Restless legs syndrome and periodic limb movements, which can be exacerbated by most antidepressants, can result in difficulty falling asleep and repeated awakenings. Agoraphobic or socially withdrawn patients may spend excessive time at home, sleep at irregular times, and avoid the photoperiod.

Summary or Conclusions
A wide assortment of substances and medications has been recommended for individuals suffering with insomnia. Compared with older insomnia treatment medications, the current-generation medications maintain efficacy but have significantly improved safety profiles. The diversity of approved agents allows for the medication selection to be customized for individual patients, depending on their clinical histories. Recently, there have been significant advances in both pharmacodynamic and pharmacokinetic approaches in promoting improved sleep. The most recently approved insomnia treatment medications no longer have an implied limitation of their duration of use, and the indications specifically note efficacy for sleep onset and sleep maintenance. New pharmacologic approaches continue to be developed.

Treatment of Children with Disruptive Behavior Disorders

This chapter concentrates on the use of psychostimulants in the long-term treatment of children with disruptive behavior disorders—in particular, attention-deficit/hyperactivity disorder (ADHD). The indications for stimulants use, the methods for initiating treatment, as well as the interactions of their effects with comorbid psychiatric problems and developmental disorders are discussed. Especially important will be evidence for the efficacy of the sustained-release preparations.

Medications

Amphetamines and methylphenidates (MPHs), and magnesium pemoline are two groups of stimulants that received U.S. Food and Drug Administration (FDA) approval for the ADHD treatment in pediatric population. They are available in both brand and generic formulations, as well as in long- and short-duration (immediate-release) preparations. In the past decade, there has been a flurry of new stimulant drug approvals by the FDA for the pediatric ADHD treatment. Previously, only dextroamphetamine (DEX), MPH, and pemoline (PEM) were sanctioned for use in children. More recently, osmotic-release methylphenidate (OROS-MPH), beaded methylphenidate (B-MPH), dexamethasphenidate, long-duration mixed salts of amphetamine (MAS), and several other formulations have been approved. Characteristics of these medications can be found in Tables 106-1 and 106-2. Both DEX and MPH form the active ingredients of these new preparations. Structurally, they are related to the catecholamines, dopamine (DA), and norepinephrine (NE). The term psychostimulant used for these compounds refers to their ability to increase CNS activity in some, but not all, brain regions.

As demonstrated by more than 200 placebo-controlled investigations, psychostimulants are highly effective in reducing core symptoms of childhood ADHD. Approximately 70% of patients respond to stimulants compared with 13% responding to placebo. Short-term efficacy is more pronounced for behavioral rather than cognitive and learning abnormalities. The stimulant treatment evidence has been supplemented by two large multisite randomized controlled trials (RCTs)—the Multimodal Treatment Study of ADHD (MTA Study; MTA Cooperative Group 1999) and the Preschool ADHD Treatment Study (PATS)—that further support the short-term efficacy in young children. These studies, plus the 1998 NIH Consensus Development Conference on ADHD and the publication of the McMaster Evidence Based Review of ADHD Treatments (Jahad et al. 1999), have emphasized a strong evidence base for the ADHD treatment with stimulants.

RCTs conducted prior to 1998 reported a few key adverse events associated with stimulants—insomnia,

Pharmacology

The exact CNS mechanism by which stimulants ameliorate ADHD symptoms is unknown. The drug’s effect based on a single neurotransmitter has been discounted (Zametkin and Rapoport 1987), as well as its ability to correct the under- or overaroused CNS (Solanto 1984). According to the two-part theory of stimulant action (McCracken 1991), stimulants increase DA release, thus producing enhanced autoreceptor-mediated inhibition of ascending DA neurons. Simultaneously, stimulants increase adrenergic-mediated decreased appetite, stomachache, and headache—but did not support rarer and unexpected problems, such as visual hallucinations, cardiovascular accidents, or sudden unexpected death (SUD), which were reported in 2006 in the FDA’s Adverse Event Report System (AERS). Although psychostimulants have been shown to retain their efficacy for as long as 14 months, concern remains that the long-term academic and social benefits of these medications have not yet been adequately demonstrated.

Stimulants demonstrate substantial efficacy in ameliorating the target ADHD symptoms by reducing gross motor overactivity, decreasing off-task behavior, increasing compliance with adult requests, and decreasing aggressivity (Greenhill et al. 1999). Not only are they effective, but they are also well tolerated and have a low rate of adverse events, with only 4% of children having to change to another medication in a controlled study of adverse events (Barkley et al. 1990). Their rapid action, relatively low-priced generic forms, the frequency with which the ADHD diagnosis is made, and wide range of tolerated doses are other reasons for popularity among practitioners.

Stimulants reduce disruptive behaviors cross-situationally (classroom, lunchroom, playground, and home) when repeatedly administered throughout the day. Compared to placebo, they have a significantly greater ability to decrease ADHD symptoms that interfere with classroom environment and have negative impacts on social relationships (Jacobvitz et al. 1990). Children interrupt and fidget less (Abikoff and Gittelman 1985b). In social situations, stimulants improve social behaviors, such as stealing and property destruction (Goldman et al. 1998). While stimulants show a large 0.8–1.0 effect size for behavioral measures, smaller 0.6–0.8 effect sizes are reported on cognitive measures (Spencer et al. 1996a). However, cognitive effects are still significant with major improvements observed during experimenter-paced continuous performance tests (Halperin et al. 1992, Pelham and Bender 1982, Spencer et al. 1996a). Some studies show correlations between plasma levels of MPH and performance on laboratory tasks (Greenhill et al. 2001a). Notably, these levels correlate with performance effects only if the plasma sampling timing is exact.

Similar beneficial effects of stimulants on behavior and attention have been shown in children without psychiatric disorders (Rapoport et al. 1980); thus, stimulant response is not diagnostically specific to ADHD. Stimulants continue to play a therapeutic role in other medical conditions such as narcolepsy and depression (Goldman et al. 1998). In addition, they can reduce manifestations of covert antisocial behaviors, such as stealing and property destruction (Hinshaw et al. 1992). Hyperactive conduct-disordered children treated with stimulants show reductions in aggressive behavior (Hinshaw 1991).
inhibition of the noradrenergic-locus coeruleus via epinephrine activity. This theory awaits confirmation from basic research in animals and imaging studies in humans.

According to the positron emission tomography (PET) research, adults with a past history of ADHD have 8.1% lower levels of cerebral glucose metabolism compared to control subjects (Zametkin et al. 1990). The greatest differences were found in the superior prefrontal cortex and premotor areas. These areas are involved with functions deficient in children with ADHD, such as the modulation of attention and the ability to inhibit inappropriate responses. While several PET and 18F-fluorodeoxyglucose studies showed that stimulants increase brain glucose metabolism in the striatal and frontal regions (Ernst and Zametkin 1995), other studies (Matochik et al. 1993, 1994) did not find any changes in glucose metabolism during acute and chronic stimulant treatment. Also, no changes in cerebral glucose metabolism were found with PET scans for 19 MPH-treated and 18 DEX-treated adults with ADHD, even though significant changes in behavior were observed.

In related studies, single-photon emission computed tomography (SPECT) showed reduced frontal cerebral blood flow in five children with ADHD when given MPH compared to normal subjects (Vyborova et al. 1984). This agrees with another SPECT finding of greater overall uptake asymmetry present in ADHD children compared to normal subjects. Investigations of neuroanatomical relationships further support these findings. The midsagittal cross-sectional area of the corpus callosum, a structure that has multiple connections to frontal cortical areas, was measured using magnetic resonance images (MRIs) of 15 boys with ADHD and 15 matched boys without psychiatric disorders. Two out of seven anatomical areas were found to be significantly smaller in boys with ADHD.

Dopamine transporter (DAT) blockade is regarded as the putative mechanism for psychostimulants in the human CNS. For instance, MPH has high affinity for the DAT. PET scan data in adult substance abusers show that [11C] MPH concentration is maximal in striatum, an area rich in DA terminals where DAT resides (Volkow et al. 1995). These scans reveal a significant difference in the pharmacokinetics of [11C] MPH and [11C] cocaine. Although both drugs display rapid uptake into striatum, MPH is more slowly cleared from brain. The authors interpret the slow reversal of binding to DAT to mean that MPH is not as reinforcing as cocaine, and why it is less likely to lead to self-administration. More recently, the same authors (Volkow et al. 2001) showed that therapeutic oral MPH doses significantly increase extracellular DA in the human brain: “Because DA decreases background firing rates and increases signal-to-noise in target neurons, we postulate that the amplification of weak DA signals in subjects with ADHD by MPH would enhance task-specific signaling, improving attention and decreasing distractibility.”

Other hypotheses regarding the neurochemical basis of ADHD have focused on roles for both NE and DA, because all stimulant medications have their primary effects on these two neurotransmitter systems. Since DA has been associated with the maintenance of the activity levels and NE is important for the central regulation of attention, arousal, and vigilance, ADHD may be the result of a dysregulation in the NE and/or DA neurotransmitter systems. Drugs that selectively block the NE reuptake, including atomoxetine and the tricyclics, such as desipramine, imipramine, and clonidine, have been found to reduce ADHD symptoms in children.

One of the non-catecholamine neurotransmitters not affected by stimulants is serotonin (5-HT). However, data from several animal studies raise the possibility of the involvement of central 5-HT mechanisms in the ADHD pathophysiology. For instance, in rats, lesions and pharmacological manipulations that result in diminished 5-HT activity have been consistently reported to induce an increase in impulsive and aggressive behavior, and lead to a persistent pattern of overactivity. Furthermore, developmentally early DA-depleting lesions, which can result in hyperactivity, cause sprouting of 5-HT terminals. It is conceivable that this early interaction between the DA and the 5-HT neurotransmitter systems could have a substantial impact on the clinical presentation of ADHD in children.

Human biological data also raise the possibility of central 5-HT mechanisms involved in those children with ADHD who are comorbid for aggressive behavior. In a group of boys with disruptive disorders, approximately two-thirds of whom had ADHD, reduced cerebrospinal fluid levels of the serotonin metabolite 5-hydroxyindoleacetic acid were associated with high aggression ratings at the 2-year follow-up (Castellanos et al. 1994). A reduced number of (3H)-imipramine binding sites, a putative index of presynaptic 5-HT activity, was reported in another study (Stoff et al. 1987). Halperin et al. (1994) found enhanced prolactin responses to a challenge dose of the 5-HT release reuptake inhibitor fenfluramine in a subgroup of children with ADHD characterized by aggressive behavior.

Neuroendocrine studies have indicated that psychostimulants produce central effects in children, suggesting that psychoneuroendocrine responses may be mediated by monoamine neurotransmitters. DEX releases DA, which exerts a tonic inhibitory control over prolactin release. DEX was reported to produce a suppression of mean sleep-related prolactin levels in 13 boys treated with 0.8 mg/kg per day for 6 months. Reports of the MPH effect on human growth hormone secretion have been divergent. This may be due to the 2.5-hr half-life of MPH, which is shorter than the 6–8-hr half-life of DEX. However when given acutely, MPH does not suppress prolactin release during the sleep period the way DEX does. However when given chronically, MPH has been shown to suppress prolactin levels and release human growth hormone, while increasing beta-endorphin levels. Psychostimulants also suppress somatomedin in vitro, which would limit long bone growth if it occurred in vivo. This could explain the decrease in height velocity that has been reported during treatment. For example, the prolonged use of DEX (0.8 mg/kg) during a 12-month period in 13 boys with ADHD produced a trend (P < 0.07) toward decreased somatomedin. These same patients had shown medication-related decreases in height and weight velocity (Greenhill and Schwartz 1989, unpublished manuscript).

Psychostimulants are rapidly absorbed from the gut and thus act quickly, often within the first 30 min after ingestion. The metabolism of MPH is fast and complete, because it is not highly bound to plasma protein and does not disappear into fat stores. MPH peaks in plasma in 2–2.5 hrs and falls to half the peak (half-life) after 3 hrs. The parent compound
is metabolized by hydrolysis of the ester group to yield ritalinic acid. Approximately 20% is oxidized to p-hydroxy and -oxomethylphenidate by the liver. Although early pharmacokinetic data reported bioavailabilities of MPH in the 80% range, more recent studies have placed the actual figure close to 30%. Plasma concentrations of DEX in children with ADHD range between 40 and 120 ng/mL. Compared to DEX, clinically effective MPH oral doses produce much lower plasma concentrations—as low as 7–10 ng/mL—suggesting a large first-pass effect. However, relatively low MPH concentrations are surprisingly effective. It is due, in part, to the low plasma-binding rate (15%) of MPH, which makes it highly available to cross the blood–brain barrier. This situation creates a favorable brain–plasma partition, with a higher MPH concentration in the CNS than in plasma (Patrick et al. 1987). The concentration-enhancing and activity-reducing MPH effects can disappear well before the medication leaves the plasma, a phenomenon termed clockwise hysteresis.

Animal studies have shown a wide therapeutic/toxic ratio for MPH; a 100:1 margin of safety exists between a single dosage, approximating a human clinical dose, and one that produces lethality in two other animal species. As a result, MPH is considered as one of the safest medications used in pediatric treatment when given in the standard 0.3–1.2 mg/kg per day oral dose range. The median lethal MPH dose in dogs is 48.3 mg/kg, via intravenous route, and 367 mg/kg, by oral route. On the other hand, the median lethal amphetamine dose in rats is 55 mg/kg.

The stereochemical structure of the psychostimulants is related to their CNS activity. MPH is thought to block reuptake of DA into presynaptic neurons in the CNS, increasing its concentrations in the interneuronal space. The MPH molecule has two asymmetrical carbon atoms, resulting in four optical isomers: both d- and l-forms of the threo- and erythro-racemates. The threo-isomer appears to have more potency than the erythro, perhaps owing to the 60° skew relationship between the tertiary amine and the carbomethoxy groups, which may increase their ability to block DA reuptake. In the erythro form, these groups are transstaggered, and therefore no bond is formed between the nitrogen and carbonyl atoms (Patrick et al. 1987). The commercial manufacturing process produces equal parts of d- and l-isomers of threo-methylphenidate (d,l-MPH).

A double-blind crossover study was carried out to compare the two isomers. The d-isomer was found to act more quickly and to produce greater improvements on measures of attention than the l-isomer. It appears that the d-isomer also has a greater effect on locomotor activity and reuptake inhibition of labeled DA (Patrick et al. 1987). This has been incorporated into a new MPH preparation, dextrmethylphenidate (d-MPH), that has shown efficacy in controlled trials (Wigal et al. 2004). Two brand formulations of d-MPH (Focalin, Focalin XR) are currently marketed in the US.

OROS-MPH is a racemic mixture of d- and l-threo-methylphenidate. The d-enantiomer appears to be not only the more effective of the two, but also better absorbed; plasma concentrations of d-methylphenidate taken orally are 10–40 times higher than those of the l-enantiomer (Ding et al. 1997, Modi et al. 2000b). MPH is primarily metabolized extra-hepatically by de-esterification to an inactive metabolite. About 90% of radiolabeled MPH can be recovered from urine (Drugs for Treatment of ADHD 2006a).

Differences between the short- and long-acting preparations relate primarily to pharmacokinetic considerations, not necessarily to clinical ones. Standard short-acting MPH 10 mg b.i.d. tablets produce higher peak plasma concentrations and yield a steeper absorption phase slope than does the longer acting MPH-SR20 (Dexedrine Spenules) preparation. Greenhill (1992) studied a sample of 42 ADHD children in a parallel-group 8-week design comparing MPH 10 mg b.i.d. and MPH-SR20. Despite the differences in lower peak concentration ($C_{max}$) between MPH-SR20 and MPH 10 mg b.i.d., no differences were seen in Continuous Performance Task (CPT) performance, motor activity levels, or teacher reports for the two groups. One speculation concerning MPH-SR20 is that its longer duration of action may alter pharmacokinetics or receptor pharmacodynamics (Table 106–3), therefore inducing tolerance.

Pharmacokinetic studies show that the sustained-release stimulant preparations have properties different from those of the standard tablets. For example, the pharmacokinetic curves of MPH-SR20 are flattened, with no sharp peaks. Lower peak concentration ($C_{max}$) and longer time from ingestion to peak ($T_{max}$) are also observed. In a pharmacokinetic study of nine ADHD males by Birmaher et al. (1989), the $C_{max}$ was 20 ng/mL for standard MPH (10 mg t.i.d. or b.i.d.), but only 7 ng/mL for MPH-SR20. The $T_{max}$ for MPH at 10 mg b.i.d. was 90 min but was much longer (3.4 hrs) for MPH-SR20. This may explain why behavioral and cognitive studies show that the peak MPH-SR20 benefit occurs at 3 hrs, an hour later compared to the standard preparation. A mean plasma elimination half-life value (using a single-compartment model with a monoexponential decline in plasma levels from $C_{max}$) was calculated to be 2.5–3.3 hrs for standard MPH and 4.1 hrs for MPH-SR20. As with the standard preparation, the MPH-SR20 concentrations of the d-enantiomer were 8 to 10 times higher than those of the l-enantiomer.

Lisdexamfetamine dimesylate is a new once-a-day formulation of amphetamine manufactured by Shire. It is an inactive pro-drug in which d-amphetamine is covalently bonded to l-lysine, an essential amino acid. After ingestion, the pharmacologically active d-amphetamine is released when the covalent bond is cleaved by proteolytic enzymes in the digestive tract. Lisdexamfetamine dimesylate is rapidly absorbed from the gastrointestinal tract and is converted to d-amphetamine and l-lysine by non-cytochrome P450 hepatic enzymes or intestinal metabolism. Lisdexamfetamine dimesylate was designed to have much less potential for abuse, diversion, or overdose toxicity compared to amphetamine. Its efficacy on measures of academic performance, mechanisms of action, diagnostic specificity, and the ability to enhance other therapies (Bradley 1977, Conners 2000). During this period, first controlled investigations of these drugs were carried out between 1960 and 1970 (Conners 2000). During this period, it was known that stimulant effects can be maintained over periods ranging from 12 (Gillberg et al. 1997) to 24 months (H. Abikoff, personal communication 1994). Other long-duration trials have shown that stimulant effects can be maintained over periods ranging from 12 (Gillberg et al. 1997) to 24 months (Abikoff et al. 2004b). Unfortunately, most stimulant RCTs end in less than 3 months, with only 22 published studies lasting longer (Schachar and Tannock 1993). Most long-duration studies before the 1990s were constrained by their retrospective methods, lack of nonstandard outcome measures, irregular medication prescribing patterns, restrictive inclusion criteria of rejecting patients with comorbid disorders, and irregular prescribing patterns (Richters et al. 1995, Sherman 1991).

Although 70% of ADHD subjects respond to stimulants and less than 13% respond to placebo (Greenhill et al. 2001b), investigators have studied stimulant non-responders. Some drug trials (Douglas et al. 1988) report a 100% response rate in small samples in which multiple MPH doses were used. Elia et al. (1991) reduced the 32% nonresponse rate to a single psychostimulant to less than 4% when a second stimulant was titrated sequentially in the same subject. However, only noncomorbid children with ADHD were included in these studies. The rate of medication nonresponse might have been higher if children with comorbidities had been included. Although current RCTs have parallel designs, which can determine if the placebo response emerges at some point over the entire clinical trial, these data have not been reported. Since treatment studies rarely prescreen out placebo responders, the numbers of actual medication responders in any sample of children with ADHD might be closer to 55%, not the 75–96% often quoted. These estimates apply to group effects, and thus cannot inform clinicians about the individual patient.

The NIMH MTA Study was conducted to assess the relative effectiveness of different treatment modalities on...

long-term outcomes of ADHD in school-age children. Four randomly-assigned 14-month treatment modalities consisted of medication management (MedMgt), behavioral treatment (Beh), combination (Comb), or community comparison group (CC) that received treatment as usual (Arnold et al. 1997). The null hypotheses were postulated as follows: (1) Beh and MedMgt treatments would result in comparable levels of improvement over time; (2) participants assigned to Comb would show similar improvement over time compared to those assigned to either MedMgt or to Beh; (3) participants assigned to any of the three MTA-intensive treatments would show similar improvement over time compared to those assigned to treatment as usual in the CC.

To have sufficient power to address these questions, 579 children with ADHD, combined subtype, ages 7–9 were recruited at seven sites nationwide. They were assessed across six domains at four different points in time (Hinshaw et al. 1997). At the study entry, they were randomized to 14 months of treatment in one of four groups: (a) MedMgt, (b) Beh (parent, school, and child components, with therapist involvement gradually fading over time), (c) Comb, or (d) CC. Treatment outcomes were assessed in multiple domains before, during, and at treatment endpoints (with Comb and MedMgt subjects taking medication at the time of assessments). Children randomized to MedMgt (N = 144) or to Comb (N = 145) also participated in a 28-day double-blind, placebo-controlled titration study designed to identify optimal individual MPH dose. Three doses of MPH and placebo were used three times daily (Greenhill et al. 2001b), with medication conditions switched daily to reduce error variance. Parents and teachers rated ADHD symptoms and impairment on a daily basis.

During medication titration, the repeated-measure analysis of variance (ANOVA) revealed a main effect of MPH/placebo dose with greater effects on teacher ratings (F[3] = 100.6, N = 223, P = 0.0001; effect sizes 0.8–1.3) compared to parent ratings (F[3] = 55.61, N = 253, P = 0.00001; effect sizes 0.4–0.6) (Greenhill et al. 2001b). Dose did not interact with between-subjects factors (period, dose order, comorbid diagnosis, site, or treatment group). Parents reported more medication-related adverse events than teachers. Contrary to parents’ reports, teachers’ ratings for irritability were highest when the children were on placebo, not the active drug. The distribution of the best MPH starting doses ranged between 10 and 50 mg/day and the response rate was 77%. The effect sizes and adverse event rates found in the MTA study replicated those previously reported in small-duration studies (Elia et al. 1991, Thurber and Walker 1983). The domain of showing greatest improvement differs among studies, with some having greater effects at home (Gillberg et al. 1997), and others demonstrating greater effects at school (Schachar et al. 1997). The total mean MPH daily doses reported by these long-duration studies ranged between 33 and 37.5 mg. One DEX study reported a mean dose half of this level, agreeing with the general DEX to MPH dose ratio.

Stimulant treatment in preschoolers was described in a comprehensive review (Connor 2002) of nine controlled studies (N = 206) in children under the age of 6 (Barkley 1988b; Barkley et al. 1984, Conners 1975, Mayes et al. 1994, Musten et al. 1997, Schleifer et al. 1975, Handen et al. 1999). In these studies, the MPH doses were weight-adjusted (0.15–1.0 mg/kg per day) and ranged from 2.5 to 30 mg/day. The treatment efficacy was comparable to that found for older children, producing improvements in structured situations but not in free play (Schleifer et al. 1975). However, the findings also indicated that preschoolers, especially those with developmental delays, may be prone to higher rates of side effects, including tearfulness and irritability, compared to school-age children (Handen et al. 1999). Therefore, it was concluded that preschoolers should be started on low MPH doses. Interpretations of these early data are difficult due to the methodological differences among the nine studies, which varied in their inclusion/exclusion criteria, diagnostic definition, ratings forms, and study designs, thus making a meta-analysis impossible. Without conclusive data, the FDA package insert instructions warn against using MPH in children younger than age 6. In spite of these warnings, there has been a 180% increase in the MPH prescriptions for preschoolers since 1996.

To address the lack of methodologically sound safety and efficacy data in preschoolers, the NIMH launched a randomized, placebo-controlled, multisite MPH trial entitled Preschool ADHD Treatment Study (PATS). This trial randomized 303 children. Two hundred seventy-nine families enrolled in a 10-week course of parent training. After completing the parent training, only 183 of these families agreed to participate in the PATS medication protocol. Of these, 165 families were randomized into a double-blind, placebo-controlled, crossover, dose-optimization study.
Prior to entry into the double-blind phase of the protocol, all children received medication treatment as part of the 1-week, open, stepwise, safety phase. In the following double-blind phase, they were administered placebo or active medication (1.25, 2.5, 5, or 7.5 mg) three times daily, with their dose switched weekly. Blind raters selected the MPH dose for each child that produced the best compromise between lowering ADHD symptoms and not creating significant adverse events (Kollins et al. 2006). The mean “best” MPH daily dose was determined as 14 mg or 0.75 mg/kg per day. This dose was lower than the mean 1.0 mg/kg per day MPH daily dose reported in the MTA Study (Greenhill et al. 2006). On their optimal MPH doses, all preschoolers had a significantly higher decrease in ADHD symptoms compared to that on placebo.

A subset of the 114 children in PATS remained in the study to be randomized into a later double-blind, parallel design phase, with half of the sample randomly assigned to their optimal MPH doses and the other half to placebo. The teacher reports showed significant continued improvements for children assigned to MPH.

However, 11% of subjects discontinued the trial due to the MPH-associated adverse events, which is far more than 2% of subjects who terminated from the MTA Study for MPH-associated adverse events. The preschool group showed a significantly higher rate of irritability, decreased appetite, delay in sleep onset, and proneness to crying in the MPH condition compared to placebo (Wigal et al. 2006). An open, pharmacokinetic, pilot study conducted in a small subset of the PATS sample indicated that preschoolers show significantly lower MPH clearance than do school-age children, even when corrected for weight (Wigal et al. 2006).

One of the most important findings in the stimulant treatment literature is the high degree of short-term efficacy for behavioral targets, with weaker effects for cognition and learning. Conners (personal communication) notes that 0.8, 1.0, and 0.9 effect sizes are reported for behavioral improvements in type 4 meta-analytic reviews of stimulant drug actions (Kavale 1982, Ottenbacher and Cooper 1983, Thurber and Walker 1983). Less powerful effects are found for laboratory measures of cognitive changes, in particular on the CPT, for which medication effect sizes range between 0.6 and 0.5 for omissions and commissions, respectively, in a between-subject design (Milich et al. 1998); and 0.6 and 1.8 in a within-subject design (Schechter and Keuezer 1985).

Behavioral changes in children treated with psychostimulants are often identified as decreases in the intensity of target ADHD symptom scores based on teacher and parent global ratings. Commonly used forms include the 93-item Conners Parent Rating Scale (CPRS), the 39-item Conners Teacher Rating Scale (CTRS), the 28-item Conners Teacher Rating Scale–Revised (CTRS–R), the Iowa Conners Teacher Rating Scale (ICTRS), and the ADD–H Comprehensive Teacher Rating Scale (ACTeRS). These scales and their psychometric properties have been summarized in detail by Barkley (1988a). Subjecting the results of these scales to factor analysis, Conners et al. (1994) produced threshold scores useful for screening children in treatment studies. Approximately 75% of children treated with psychostimulants show moderate to marked improvement when assessed using teacher rating scales. Changes can be picked up as early as 30 min after the first MPH dose is administered.

Neurocognitive ADHD theories have played a crucial role in our understanding of the functional deficits underlying symptomatic behavior. These theories explain the disorder etiology by connecting behavioral sequences with neuronal mechanisms (Barkley 1997). Neuropsychological research, particularly as it relates to concepts of executive functioning, has addressed the validity of ADHD subtypes. Nigg defines executive functions as mental processes governing the regulation of response to context and maintenance of behavior on goal (Nigg et al. 2002). Research has shown that, relative to placebo, psychostimulants improve the performance of children with ADHD on various laboratory measures of cognitive functioning.

The CPT is an experimenter-paced task, in which the subject is seated in front of a display and told to press a button whenever certain letters or numbers (the targets) appear on the display. The task generally lasts between 8 and 15 min and tests the subject’s ability to sustain attention. Typical CPT outcome measures indicate a reaction time to the target, a correct identification of a target signal (“a hit”), a mistaken identification of a nontarget (“a false alarm”) stimulus, or a complete response lack when a target appears (“a miss”). Virtually all studies report that children with ADHD have a significant reduction in the number of CPT omission errors and/or in the reaction time after taking stimulants (Matier et al. 1992, Rapoport et al. 1980). The reduction in omission errors and response latency is generally interpreted as improved attention and impulse control. However, data suggest that the commission errors are less sensitive to stimulant effects than the omission errors. Studies, which found significant stimulant medication-induced reductions in the omission errors, have either failed to identify reductions in the number of the commission errors or only detected some reductions at high doses.

Findings regarding the shape of the dose–response curve have been less consistent. Whereas large medication effects relative to placebo have been reported, some investigators have failed to find significant between-dose effects, while others have reported linear dose–response effects, and yet others have found quadratic effects indicating that performance somewhat decreases at the highest dose (Rapport et al. 1989a). The causes of these differences are not fully apparent, but it is likely that they can be at least partially attributed to task differences. A review of various CPTs (Epstein et al. 2003) suggested that task difficulty, as indicated by the overall number of errors, is related to the ability of individual CPTs to distinguish among different diagnostic groups. Furthermore, data from these authors show that the decline in performance at peak doses may be apparent only on the most difficult CPT versions.

Although it has been shown that the CPT performance is enhanced with stimulants, the clinical utility of this measure for either predicting or monitoring medication response is less clear. To evaluate its utility, two questions must be addressed: Is the CPT performance prior to stimulant intake predictive of clinical or behavioral response to medication? Do changes in the CPT performance post medication administration parallel clinically observed changes in the natural environment? To date, research studies have been unable to answer these questions positively for individual patients. Relatively few studies have directly
addressed these issues, yet the majority of data suggest that
the answer to both questions is negative.

The utility of one CPT version, known as the Test
of Variables of Attention, was assessed by comparing
performance before and after stimulant treatment in chil-
dren classified as medication responders and nonrespond-
ers. Following the 6 weeks of MPH treatment, medication
response was assessed via parent and child reports, clinical
observations, and teacher rating scales. Medication respond-
ers and nonresponders did not differ significantly on any
premedication CPT measure, suggesting that baseline per-
formance could not be used to predict treatment response.
However, the responders, compared with the nonresponders,
showed greater improvement on several CPT measures after
psychostimulant treatment, indicating that the CPT may
be useful for assessing medication response. In a separate
experiment, the same group of investigators assessed per-
formance changes on the Test of Variables of Attention in
a different sample of children with ADHD after a single 10
mg challenge MPH dose. They reported that the respond-
ers had a significantly greater enhancement in performance
after the initial medication dose and suggested using the
CPT changes for predicting medication response.

However, other investigators have generated only lim-
ited evidence to support the clinical CPT utility for predict-
ing and/or monitoring response to stimulants. The fact that
normal and ADHD children appear to respond similarly to
stimulants with regard to improved attention and reduced
activity level, even though normal children make relatively
few CPT errors at baseline, suggests that laboratory per-
formance does not predict medication efficacy (Rapport et
al. 1980). One study (Aman and Turbott 1991) assessed the
ability of several measures for predicting MPH response in
children. The investigators found no significant relationship
between the CPT performance and clinical improvement,
even though both measures were altered by the medication.
Alternatively, Taylor et al. (1987) reported that before medi-
cation, poor performance on a battery of attentional tests,
which included CPT, was among the strongest predictors of
pediatric clinical response to MPH.

In two separate studies using different CPTs, Rapport
and DuPaul (1986) and Rapport et al. (1987) found large
clinical and CPT changes following MPH treatment. In their
first study (1986), the dose–response curve for the number of
omission errors for the entire sample closely paralleled the
curve generated for on-task behavior in classroom
environments. However, there was considerable intersubject
variability. In the subsequent study with a larger sample,
the same authors (1987) noted similar medication-induced
CPT and behavioral changes. However, the CPT per-
formance was highly variable and not predictive of behavioral
response to medication on an individual level. Consistent
with this, Nigg et al. (unpublished manuscript) reported
similar dose–response curves for several CPT performance
variables and direct behavioral observations in 22 boys
enrolled in a summer treatment program for children with
ADHD. Nevertheless, despite similarities across the group,
individual medication response could not be predicted by
the CPT performance. Even though substantial evidence
indicates that the CPT performance changes as a function of
stimulants, limited data suggest any clinical utility for these
instruments with regard to predicting medication response.

Further research is warranted to prove their usefulness to
the physician planning to medicate an ADHD child. In the
meantime, CPTs should be considered only in the context of
a thorough clinical assessment.

In addition to the neurocognitive testing in the labora-
atory environment, stimulant effects on cognition have
been measured in school settings. Classroom arithmetic
tasks (Carlson and Thomeer 1991) and concentration dur-
ing sports (Pelham et al. 1990) show medication-placebo
effects. Sprague and Slerot (1977) demonstrated that
higher psychostimulant dosages may interfere with complex
memory tasks involving effortful cognitive processing. In
their study, 10 hyperkinetic school-age children were given
a short-term memory paired associates task. The best per-
cent correct score was reported on the lowest, 0.3 mg/kg,
dose whereas increasing the dose to 1 mg/kg elevated the
error rate. In contrast, these same children obtained the best
teacher global ratings of improved behavior on the higher,
1 mg/kg, dose. One might conclude, as did many clinicians,
that the use of behavioral ratings for dosage adjustment may
select doses that impair cognitive processes. This “window of
response” can be modeled best as an inverted-U curvilinear
dose–response curve.

Although Sprague’s findings have not been replicated
in other studies, a question of stimulant-induced cognitive
overfocusing remains a concern to physicians, parents, and
teachers. They report that children on high stimulant doses
can become perseverative, repetitive, and less spontaneous. A
review of 11 studies, evaluating the stimulant dose–response
relationship on cognitive tasks in 180 children, reported lin-
ear dose–response curves, with only two studies showing
the decrease of cognitive abilities at higher doses (Rapport
et al. 1989b). One ADHD study (Solanto and Wender 1989)
found no cognitive problems on the Wallach-Kogan battery
when 19 boys were treated with three different MPH doses
(0.3, 0.6, and 1.0 mg/kg). Another study (Tannock et al.
1989) replicated these findings, showing that attention was
enhanced, with no overfocusing, at higher MPH dosages.
Short-term pediatric ADHD studies reveal that stimulants
enhance arithmetical productivity, efficiency, and accuracy
with children spending less time between problems. These
studies were characterized by optimal experimental pro-
cedures, including standardized medication dosages and rel-
levant dependent measures.

Even with this lack of replication of Sprague’s find-
ing, the impact on practice of this one study has been pro-
found. Prior to its publication, investigators used higher
MPH dosages in their research, for example, 51 mg/day
(Gittelman-Klein et al. 1976), and individual dosages were
titrated to maximum effect or toxicity. From 1977 to 1990,
clinicians adopted an increasingly conservative approach to
MPH dose adjustments. Rather than increasing the drug
through its full range to 60 mg when starting treatment, dos-
ing was often weight adjusted on a mg/kg basis according to
Sprague’s published optimal MPH dose for fewest errors (0.3
mg/kg). This resulted in total daily MPH doses between 15
and 25 mg, which are lower than the mean total dose used in
the large multisite trials, such as the MTA Study. There is a
great diversity among children in their dose–response curves,
both between individuals and across domains of behavior
and learning (Murphy et al. 1986, Solanto 1991). Pelham
recommends that optimal dosing of the individual ADHD
child should not be done a priori, but must be carried out carefully on an empirical basis, adjusting the dose level to correct the child’s most serious area of difficulty (Pelham and Milich 1991).

Rapport et al. (1989a) suggested that a subset of children have divergent dose–response curves for behavior and academic output. This might explain why earlier reports indicated that psychostimulants could not maintain the improvements seen during the first week of treatment on academic tasks in hyperactive children. The idea was further strengthened by the results of a reading remediation study in 61 children, half assigned to MPH (mean dose of 44 mg/day) and half to placebo. No differences in reading skills between groups were found 6 months following the 18-week treatment. A 2-year MPH follow-up study of 72 reading-disabled children also did not show any significant differences between children taking MPH and those treated with other therapies. These long-term studies suggest that stimulants do not affect the clinical course or outcome of the ADHD treatment in children.

Prospective longitudinal studies (Klein and Mannuzza 1991) that reviewed high school histories found more failing marks on report cards, failure to advance, and higher dropout rates in adults with childhood ADHD than those present among control subjects. Swanson (1993, personal communication) has suggested that certain factors obscure the “expected long-term benefits of psychostimulants,” including the diagnostic heterogeneity of the ADHD syndrome, the task specificity needed to measure stimulant response, and the possible cognitive toxicity associated with clinical dose titrations.

A number of double-blind, placebo-controlled crossover studies have reported variable reductions in aggressivity in stimulant-treated children with ADHD. This is a critical area of concern, because childhood aggressivity predicts future morbidity. Klorman et al. (1988, 1990) carried out two studies of MPH treatment (0.6 mg/kg) in 63 school-age patients and noted that children with and without aggressive features showed improvement. On the other hand, Hinshaw et al. (1989) found only slight reductions in aggressivity in 24 school-age ADHD children treated with the same MPH dose. Another ADHD study (Gadow et al. 1990) reported dose-related reductions in verbal aggressivity in 11 boys treated with MPH (0.3 and 0.6 mg/kg). Aggression in 9 severely aggressive adolescent inpatients with ADHD was reduced by MPH treatment, as measured by ratings on a standardized nursing form, the Adolescent Antisocial Behavior Checklist. Klein et al. (1997) also found that MPH treatment reduced aggression in children with ADHD comorbid for conduct disorder.

Matier et al. (1992) found that aggressive and nonaggressive subgroups of children with ADHD responded differentially to a low MPH dose (5 mg) and demonstrated various subtypes of CPT errors. The error subtypes used in this study distinguished among inattention, impulsivity, and dyscontrol errors. Whereas the inattention score was primarily (although not exclusively) based on the number of omission errors, the impulsivity and dyscontrol scores were derived from distinct subsets of the commission errors, which are believed to assess different underlying cognitive processes. Both aggressive and nonaggressive children demonstrated reductions in the inattention score after taking the medication. However, neither group showed a significant change in the impulsivity score, which was elevated only in the aggressive ADHD subgroup relative to normal subjects. Finally, the nonaggressive ADHD subgroup had a greater reduction in dyscontrol errors (as well as objectively assessed motor activity) than did the aggressive ADHD subgroup, even though, prior to taking medication, both subgroups scored equally high on this measure compared to control subjects.

These data were interpreted as reflecting differential neurochemical mechanisms in aggressive and nonaggressive ADHD children, as well as distinct neurochemical mechanisms underlying the various types of CPT errors. Specifically, impulsivity and aggressive behavior were hypothesized to be associated, at least in part, with the central serotonergic function, whereas inattention was thought to be more closely related to the catecholaminergic mechanisms. Since stimulants act primarily on the central catecholaminergic mechanisms, they had a greater impact on the CPT measure of attention (omission errors) compared to the measure of impulse control (commission errors).

Several studies have found significant reductions of excessive motor behavior in children with ADHD. Early studies were limited to brief laboratory observations using stabilometric chairs and mechanical (modified automatically winding wristwatches) wrist or ankle actometers. Other approaches, such as counting grid crossings, did not measure restlessness and fidgetiness but frequently reported problems among these children. Some postulated that the levels of motor activity did not differentiate children with ADHD from normal subjects, but rather the purposelessness of their activity did. Advances in miniaturization and solid-state memory devices were needed to obtain activity level data outside the laboratory in the very settings reporting the motor overactivity (i.e., home and school). Colburn, at the NIMH, developed an actometer that consisted of an acceleration-sensitive device with a solid-state memory, which stored data on the number of movements per unit time during a 10-day period (Porrino et al. 1983). This technology measured acceleration, thus capturing impulsivity in addition to activity within many brief periods, so it was possible to determine the child’s ability to modulate his or her activity level to the levels appropriate for the situation on hand.

Using the Colburn device, activity level readings taken on 12 boys with undulated hyperactivity were consistently higher than those of control subjects at all times, including during sleep and weekends. Thus, an elevated motor activity is not a response to situational set demands, but rather a trait of these children. The same research team treated ADHD boys with DEX (15 mg/day) in a 4-week double-blind study. Motor activity was significantly decreased for 8 hrs after dosing, followed by a slight increase in activity, which served as the first objective demonstration of “rebound.” These readings confirmed improvements reported during both global ratings and direct observations. Borchering et al. (1989), working in the same laboratory and using the Colburn NIMH actigraph, replicated this work with 18 ADHD boys in a day hospital setting in an 11-week, double-blind, crossover trial comparing DEX (0.2–0.6 mg/kg b.i.d.) and MPH (0.45–1.25 mg/kg b.i.d.). Although plasma drug concentrations failed to directly correlate with activity level
changes, the parent compounds were substantially higher than those reported elsewhere. This may have produced a ceiling effect, restricting the range of response and reducing the correlation. Both MPH and DEX decreased motor activity, with MPH producing lower activity readings compared to DEX. Borcherding et al. (1989) were among the first to differentiate the effects of these two stimulants on gross motor activity, which is a cardinal sign of ADHD.

The problem of validating hyperactive behaviors and their treatments has been greatly ameliorated by direct classroom observations with raters blind to the student’s psychiatric and medication status. One such study (Whalen and Henker 1976) evaluated 23 hyperactive and 39 comparison boys. The study design had a number of systematically varied conditions, including difficulty of work materials, self-versus other-paced activities, and a single morning MPH dose (mean 12.3 mg). Hyperactive boys on placebo were more often off task and displayed higher rates of gross motor movement, verbalizations, noise, and disruption than control subjects. These findings were replicated in another crossover design study with a higher mean MPH dose (41.5 mg/day; Abikoff and Gittelman 1985a), whereby placebo-treated hyperactive children had much higher rates of off-task, out-of-seat, or verbalization behaviors compared to children treated with MPH, whose ADHD symptoms were normalized.

**Side Effects**

Stimulant side effects are dose dependent and range from mild to moderate in most children. These have been described by Barkley in a placebo-controlled study comparing the baseline and on-medication double-blind parent ratings (Barkley et al. 1990). Common side effects include insomnia, decreased appetite, weight loss, headache, heart rate elevation at rest, stomach pain, and minor increases in systolic blood pressure. Many of these side effects can be managed with temporary dose reduction. Severe insomnia can be alleviated by changing time of dosing, with most of the medication given early in the day. Complaints of upset stomach, nausea, or pain may benefit from a change to transdermal MPH, or give the oral medication in the middle of the meal. Otherwise, the problem can be treated symptomatically with antacid tablets or by switching to sustained-release MPH, which is absorbed more slowly.

Infrequent side effects include motor tics and reductions in weight velocity. The appearance of minor facial tics is a frequent reason for stopping stimulants in clinical practice. Despite a lack of studies demonstrating a causal link between stimulant treatment and tic disorders, the Physicians’ Desk Reference (PDR) warns against the use of stimulants in children with preexisting tic disorders. A history of chronic or episodic involuntary muscle movements (tics) or a family history of Tourette’s disorder has become a contraindication to the MPH use, as it may unmask or exacerbate Tourette’s disorder. Switching to another stimulant, such as d-amphetamine, may worsen the adventitious movement disorder, so it is best to discontinue all psychostimulants and consider a clonidine trial.

However, both ADHD and tic disorders are quite prevalent and may coexist in the same individual, so the question of the risk of stimulant treatment can frequently arise. This worry was expressed in an editorial that accompanied a retrospective chart review (Cohen and Leckman 1989). The report included 17 patients with both ADHD and Tourette’s syndrome who had been previously treated with stimulants, and whose tics were exacerbated by stimulant therapy (Lowe et al. 1982). Another study (Erenberg et al. 1985) examined 48 patients with Tourette’s disorder who had prior stimulant treatment. Of the 39 patients who had both ADHD and Tourette’s disorder, 11 showed a worsening of the tics when stimulants were restarted.

The two controlled prospective stimulants studies in ADHD children comorbid for Tourette’s syndrome have included long-term longitudinal follow-ups extending 2–4 years (Castellanos et al. 1997, Gadow et al. 1995). Conclusions derived from these studies are tentative, because they are based on a sample of only 56 subjects. However, in both studies, stimulants produced improvements in ADHD symptoms and no long-term worsening in tics, even after the tics worsened on high MPH or DEX doses. Despite the variable adverse event rates across the entire sample in the Castellanos study (1997), up to one-third of subjects did not continue long-term treatment with stimulants because of tics worsening. Thus, both sides of the argument have been validated: tics are unacceptably, although reversibly, worsened for a minority of comorbid children, but the majority can be treated cautiously with low-to-moderate doses of stimulants, particularly MPH (Comings and Comings 1987).

Some argue that since a child with ADHD and Tourette’s disorder already has both conditions, Tourette’s disorder could no longer be triggered by the stimulants. Treatment of these cases with stimulants sometimes improves both the ADHD and the tics, whereas others find that the tics worsen. Overall, caution is still indicated when treating children with tic disorders. To date, there has been no prospective published study showing that stimulants have any effect whatsoever on the tic severity. Nevertheless, the most conservative and safe approach would be a trial of clonidine or desipramine.

Many stimulant treatment studies in school-age ADHD children exclude patients who are considered to have mental retardation (MR) as indicated by the full-scale IQ score below 70. This is unfortunate, for the ADHD signs are far more prevalent in children whose IQs are in the MR range (Aman et al. 1991). Pharmacotherapy reviews have reported that institutionalized patients with severe or profound MR respond poorly to stimulants. However, studies with community samples of MR children have shown that they do respond to MPH. Thirty children with MR treated in a double-blind crossover study using MPH (0.4 mg/kg per day), thioridazine (1.75 mg/kg per day), and placebo showed consistent MPH-related improvement on teacher global ratings of behavior. This same report found that three “cognitive maturity parameters” (breadth of attention, mental age greater than 4.5 years, and full-scale IQ above 45) predicted a good MPH response on 21 outcome variables. In contrast, children with IQs below 45 or mental age of less than 4.5 years had more adverse side effects or a poor response to MPH. Another controlled study reported responses to MPH doses of 0.3 and 0.6 mg/kg given to 27 ADHD children with IQs ranging between 49 and 74. Although 67% of this group was deemed stimulant responders, 6 of the 27 children had side effects of such severity that medication had to be discontinued. These included motor tics in three children and symptoms of social withdrawal in two children. Therefore,
it appears that children with ADHD and mild or moderate MR might be more vulnerable to certain stimulant-related adverse side effects.

Children comorbid for fragile X syndrome and MR often have avoidance of eye contact, perseverative behaviors, and severe ADHD symptoms. These children can be misdiagnosed with ADHD, even though their behavior disorder is only a phenocopy of the ADHD seen in children without an inborn genetic disorder. This misdiagnosis is possible due to the lack of clear differentiation among disorder etiologies in the DSM-IV-TR. However, stimulant treatment is effective in this population, as shown by a double-blind crossover study of 15 patients with fragile X syndrome who were treated with MPH, DEX, and placebo.

The DSM-IV-TR guidelines state that a diagnosis of pervasive developmental disorder (PDD) or early infantile autism rules out the ADHD diagnosis, even if the patient meets all criteria for the disorder. Symptomatically, children with PDD may exhibit severe overactivity, inattentiveness, and impulsivity that require treatment. Early studies cautioned that children with PDD may be sensitive to stimulant side effects and may show increased irritability, motor activity, and stereotypies. On the other hand, Birmaher et al. (1988) reported improvements in global parent and teacher rating scales for hyperactivity and inattentiveness in nine PDD children treated with open-label MPH at doses of 10–50 mg/day. Although these findings are based on an open study, they are encouraging, particularly because many of these children have been treatment failures on other medications. It was shown that MPH reduced overactivity in subjects with autism (Research Units on Pediatric Psychopharmacology (RUPP) Autism Network 2005).

Children with ADHD taking psychostimulants routinely show appetite suppression when starting treatment. For this reason, dosing should optimally occur after breakfast and lunch. Even though the daytime appetite is reduced, hunger rebounds in the evening. These effects on appetite often weaken within the first 6 weeks of treatment. Safer and Allen (Safer et al. 1972, 1975, Safer and Allen 1973) were first to report that treatment for two or more years with MPH and DEX can produce decrements in weight velocity on age-adjusted growth rate charts. Stopping the medication can produce a quick return to baseline growth velocities. DEX, with a half-life two to three times that of MPH, produces more sustained effects on weight velocity and on mean sleep-related prolactin concentrations suppression compared to MPH (Greenhill 1981). In MPH-treated children with ADHD, followed for 2–4 years, dose-related decreases in weight velocity were seen (Gittelman-Klein et al. 1988, Satterfield et al. 1979), with some tolerance of the suppressive effect developing in the second year. Hechtman et al. (1984) reported growth slowdown in untreated children, suggesting that there may be differential growth associated with the ADHD disorder itself. Pliszka et al. (1996b) detected similar differential growth rates for children with ADHD, and also suggested an association with the disorder itself, rather than with the stimulant treatment alone.

In addition to changes in weight trajectory, it has been reported that the MPH-related growth effects appear to be minimal. Satterfield et al. (1979) followed 110 children and found decreases in height velocity during the first year of psychostimulant treatment, but this reversed during the second year of treatment. An initial growth loss during MPH treatment was seen in 65 children followed to age 18, but these children “caught up” during adolescence and reached heights predicted from their parents’ heights (Gittelman and Mannuzza, 1988). These results confirm the observations by Roche et al. (1979) that psychostimulants have mild and transitory effects on weight and only rarely interfere with height acquisition.

Most recently, growth slowing for height and weight was reported for children, ages 7–10, treated with MPH at mean doses of 30 mg/kg per day in the MTA Study (Swanson et al. 2002). School-age children grew 1.0 cm less per year and gained 2.5 kg less than the predicted norms from the Centers for Disease Control growth charts. Similar effects were observed for preschool children in the NIMH PATS Study (Swanson et al. 2006), who grew 1.5 cm less height and gained 2.5 kg less than predicted by the Centers for Disease Control growth norms while treated with mean MPH doses of 14 mg/kg per day. Two major reviews (Faraone et al. 2005, Poulton 2005) have concluded that stimulant treatment most likely slows height acquisition in children, at least during the first 1–3 years of treatment. Patients who were randomized to the stimulant treatment arms in the MTA Study showed significantly less height acquisition over the first 2 years of treatment compared to patients in the nonstimulant arms (MTA Cooperative Group 2004). Interestingly, compared to average children, ADHD participants in both MTA and PATS studies were heavier and taller than average at the start of treatment. Thus, clinicians may not observe growth slowdown as often as predicted, because the ADHD-treated children do not slow down in height acquisition to become shorter than average.

The actual psychostimulant mechanism for any growth slowdown is unknown. Early theories attributed the drug’s supposed growth-suppressant action to its effects on growth hormone or prolactin. Although research studies on 13 children treated for 18 months with DEX at 0.8 mg/day (Greenhill et al. 1981), and on 9 children treated for 12 months with MPH at 1.2 mg/kg per day (Greenhill et al. 1984) failed to demonstrate a consistent change in growth hormone release. The most parsimonious explanation for this drug effect is the appetite suppression that leads to a reduced caloric intake. No study, however, has collected the standardized diet diaries necessary to track calories consumed by children on psychostimulants (Greenhill et al. 1981).

Even if height acquisition is reduced during the first year of stimulant treatment, this effect has been shown to attenuate afterwards (Faraone et al. 2005). Pliszka et al. (2006) found that amphetamine more than MPH affected the rate of weight acquisition, but neither had significant effects on the rate of height acquisition. The American Academy of Child and Adolescent Psychiatry (AACAP) Work Group on Quality Issues (2007) for ADHD recommends that no adjustment in treatment should occur until the patient has a change in height or weight percentile that crosses two percentile lines on the Centers for Disease Control chart. If this happens, the clinician can reduce the dose, switch to another ADHD medication, or temporarily discontinue stimulant treatment.

MPH has an excellent safety record, probably because the duration of action is so brief. When side effect reports have been gathered on children with ADHD
taking placebo, anxiety, staring, disinterest, and sadness were observed. Only parent reports of decreased appetite, stomachaches, and insomnia differentiated children with ADHD on stimulants from those taking placebo. In that study, less than 4% of children had to discontinue their medication due to these side effects.

One adverse effect, commonly known as behavioral rebound, appears when children experience psychostimulant withdrawal at the end of the school day. These children present with afternoon irritability, over talkativeness, and insomnia that occur 5–15 hrs following the last dose. In one study involving 14 hyperkinetic boys treated with DEX, rebound was reported by three quarters of the group on stimulants and no placebo subjects. In a later study, the same authors reported significant increases in afternoon activity for 21 and no placebo subjects. In a later study, the same authors involving 14 hyperkinetic boys treated with DEX, rebound that occur 5–15 hrs following the last dose. In one study involving 14 hyperkinetic boys treated with DEX, rebound was reported by three quarters of the group on stimulants and no placebo subjects. In a later study, the same authors reported significant increases in afternoon activity for 21 boys treated with DEX. This finding was the first quantitative evidence for the rebound phenomenon. Although no evidence for an afternoon symptom worsening was found in a third study, which used a controlled crossover design of 21 boys with ADHD taking MPH at doses of 0.6 and 1.2 mg/kg per day or placebo. At this time, it is not clear if these contradictory reports represent differences between DEX and MPH. Furthermore, it is not known whether longer acting stimulant preparations produce fewer rebound effects. The controlled drug treatment literature does not report rebound effects, which may be due to the use of global parent rating forms that are not specific for time of day. If rebound occurs, many physicians add a small dose of afternoon MPH or a tricyclic antidepressant.

It has been shown that higher than therapeutic doses of amphetamines reliably induce brief paranoid psychoses in adult volunteers. Stimulant-related toxic psychosis, including MPH-induced visual hallucinations, is a rare phenomenon in children, with fewer than 30 cases having been reported. Even though the psychotomimetic effects are short lived, this side effect can be serious and requires immediate cessation of stimulant treatment. Since psychosis is a contraindication for psychostimulant use (Greenhill et al. 2002b), the physician should consider dispensing neuroleptics instead of psychostimulants to agitated children with psychotic symptoms. The neuroleptics addition to the treatment regimen of a severely disturbed ADHD child raises the possibility that the hyperactivity and poor attention span were secondary to an underlying psychotic condition. Although neuroleptics and psychostimulants do not interact in a negative fashion, the Psychotherapeutic Drug Manual for Use in New York State Mental Health Facilities warns against prescribing a stimulant along with an antipsychotic.

The PDR lists a number of other adverse reactions, without stating frequency, which are not found in standard clinical practice or published reports from treatment studies. Rare side effects of stimulants include alopecia and leukocytosis. This suggests an inclusion of a yearly routine complete blood count in the therapeutic drug monitoring plan. Other rare adverse effects are hypersensitivity (i.e., rash, urticaria, fever, arthralgia, exfoliative dermatitis, erythema multiforme with histopathological findings of necrotizing vasculitis and thrombocytopenic purpura), angina, and cardiac arrhythmia.

Clinical benefits associated with stimulant use have to be weighed against reports of serious unexpected adverse events. Concerns arose from a series of reviews conducted by the FDA of cardiovascular and psychiatric adverse events associated with use of an approved stimulant medications. On June 30, 2005, the agency began this review by examining the passive surveillance reports concerning treatment with OROS-MPH (Concerta) (http://www.fda.gov/ohrms/dockets/ac/05/slides/2005–4152s2.html). The review uncovered 135 adverse events, including 36 psychiatric and 20 cardiovascular adverse events. In particular, the reports documented 12 instances of tactile and visual hallucinations (classified under “psychosis”). These OROS-MPH adverse event reports represent 135 per 1.3 million cases, and thus seem to be rare unexpected adverse events.

More worrisome were reports of 20 cases of SUD in 14 children and 6 adults, as well as 12 cases of stroke in patients taking MAS. These reports led to Health Canada suspending the sales of MAS extended release formulation (Adderall XR) (http://www.hc-sc.gc.ca/ahc-asc/media/advisories-avis/2005/2005_01_e.html). The deaths occurred in five patients with preexisting structural heart defects, and the rest of the victims had “family history of ventricular tachycardia, association of death with heat exhaustion, dehydration and near-drowning, very rigorous exercise, fatty liver, heart attack, and type 1 diabetes mellitus” (http://www.fda.gov/cder/drug/advisory/adderall.htm). Pliszka (AACAP Work Group on Quality Issues 2007) notes that the SUD rate on MAS is estimated at 0.5 per 100,000 patient-years, the rate on MPH is estimated at 0.19, whereas the rate of SUD in the general population has been estimated at 1.3–8.5 (Liberthson 1996). Nevertheless, patients with preexisting heart disease should be referred to a cardiologist prior to initiating stimulant treatment.

In summary, serious unexpected cardiac or psychiatric adverse events associated with stimulants have been known for years and are extremely rare. The rates of cardiac adverse effects are too low to prove a causal association with stimulants in patients with no history of previous heart disease. Routine EKGs and echocardiograms are not indicated before initiating stimulant treatment for a patient with unremarkable medical history and physical examination. It is advised that the physician prescribing stimulants first asks patients and their families about a history of structural heart disease, and if they have previously consulted a cardiologist. Known cardiac problems that raise a caution include postoperative tetralogy of Fallot, cardiac artery abnormalities, and obstructive subaortic stenosis. If the patient has a history of hypertension and/or complains of syncope, arrhythmias, or chest pain, then the clinician should be concerned because these symptoms may indicate hypertrophic cardiomyopathy, which has been associated with SUD.

An important serious and unexpected adverse reaction associated with PEM use is liver failure (Safer et al. 2001). Changes in liver function tests suggesting hepatotoxicity can also occur, thus necessitating routine liver function tests every 2 weeks for patients taking PEM.

Mixing psychostimulants with other psychotropic medications is generally not advisable. Most serious is the addition of a psychostimulant to a monoamine oxidase inhibitor antidepressant regimen, a potentially lethal combination that can elevate blood pressure to dangerous levels. Zametkin et al. (1987) do not recommend using the monoamine oxidase inhibitor medication tranylcypromine...
for ADHD children, despite its efficacy, because of a possibility that a parent might mistakenly substitute MPH for tranylcyromine causing a potentially lethal blood pressure surge. Addictive effects between psychostimulants and the systemic agents used to treat asthma can produce feelings of dizziness, tachycardia, palpitation, weakness, and agitation. Theophylline, for example, when taken orally, can have this undesirable agitating effect. It is best to ask the pediatrician or allergist to switch from the orally ingested preparation to an inhalant to avoid such additive sympathomimetic effects.

The psychostimulants can also interfere with the action of other medications. MPH can block the antihypertensive action of guanethidine. DEX blocks the action of some beta-adrenergic antagonists (e.g., propranolol) and slows down the intestinal absorption of phenytoin and phenobarbital. The renal clearance of DEX is enhanced by urine acidifying agents, so that grapefruit juice will shorten the elimination half-life of the medication. Conversely, urine alkalizing agents decrease clearance. This is also true for ritalinic acid, although this metabolite is not active in the CNS.

Published case reports do not show an additive increase in side effects when combinations of other drug classes are used. However, MPH may elevate plasma levels of antidepressants, anticonvulsants, coumarin anticoagulants, and phenylbutazone. One group of researchers (Pataki et al. 1993) treated 12 boys with ADHD in a double-blind crossover study of combined MPH and imipramine. They reported an increase in nausea and dry mouth but no incidences of blood pressure elevation were recorded. Theoretically, MPH may increase the concentration of the serotonin reuptake inhibitor, fluoxetine, potentially enhancing agitation. Although no such side effect was described in a single case report concerning the treatment of an 11-year-old boy comorbid for ADHD and obsessive-compulsive disorder. Clonidine has been added to reduce sleep disturbances associated with stimulant medications. Other medications have been successfully combined with MPH, such as clonazepam to reduce tics. The combination of fenfluramine and MPH proved effective when tested in a double-blind crossover study of 28 children with ADHD and MR. However, when bupropion was added to MPH, the tics in ADHD children were exacerbated.

Although psychostimulants have been abused by adults, the risk for addiction in children with ADHD is low. Klein (1980) found that the psychostimulants differ in their ability to induce euphoria, with “DEX the most euphorogenic, MPH, less so, and magnesium PEM, hardly at all.” Adolescents and young adults with ADHD do not list the psychostimulants among medications used recreationally, regardless of whether they had stimulant treatment. Adolescents previously diagnosed with ADHD during school-age years are at greater risk for substance abuse than control subjects, but those who do abuse medications tend not to pick stimulants. Reports of MPH abuse include adolescents who snort ground up MPH tablets. A review assessing the MPH abuse potential noted that there is evidence, from non-scientific sources, that MPH use and abuse may be widespread among adolescents (Kollins et al. 2001). One should also be aware that there is a distinction between MPH clinical abuse and its misuse or diversion. There are only a few case reports of MPH abuse that have lead to role impairment. Kollins et al. (2001) believe that these issues are important for consideration when MPH is prescribed in clinical practice.

Even though the evidence from the literature suggests that the abuse potential of psychostimulants by children with ADHD is low, DEX and MPH have been classified by the US FDA as potentially drugs of abuse (schedule II) and have warnings concerning abuse in the PDR. MPH was reclassified as a schedule II medication in 1971, due to a concern that the order issued by the Bureau of Narcotics and Dangerous Drugs to schedule methamphetamine and DEX would direct potential drug abusers to MPH. American physicians prescribing these psychostimulants for childhood psychiatric disorders first are required to obtain a US Drug Enforcement Administration (DEA) registration number. As a schedule II medication, the annual amount of manufactured stimulants must be approved or allocated. This requirement led to widely publicized MPH shortages in the fall of 1993. As a result, a parent special-interest group, Children and Adults with Attention Deficit Disorder (CHADD), petitioned the US DEA of the Department of Justice in May 1994 to reclassify MPH from schedule II to III, as to “eliminate all likely future MPH shortages.” After a thorough review of the substance abuse literature, this scholarly petition could find “no substantial dependence liability and a very limited potential for significant MPH abuse or diversion into illegal drug channels.” However, MPH classification was not changed, and it has remained a schedule II drug of abuse.

In the US, nine states (California, Hawaii, Illinois, Idaho, Indiana, Michigan, New York, Rhode Island, and Washington) adopted multiple-copy prescription programs between 1967 and 1982 to monitor schedule II drugs, including DEX and MPH (PEM, on the other hand, is classified as a schedule IV medication and does not require such forms). Physicians practicing in these states are required to use multiple prescription copy pads (triplicates) to order DEX and MPH. The resulting data have been instrumental for exposing illicit distribution of psychostimulants, as well as for conducting research on local trends in office practice. With such data, it is possible to compare the MPH treatment prevalence of children in primary school in Suffolk County in 1988 (0.04%) to the percentage of 3rd graders treated in 1987 in Baltimore County (7%; Safer and Krager 1988).

The New York State Department of Public Health (Eadie J, personal communication) reported that four times as many prescriptions were written for MPH as for DEX in the second quarter of 1990 (20,271 for MPH, and only 4,514 for DEX). This was partly due to public and professional concern about amphetamine. On the other hand, many physicians view MPH as a nonamphetamine. Amphetamine’s notoriety as a highly euphorogenic and addictive substance has greatly reduced its use, as shown by a 95% drop in triplicate prescriptions for DEX in New York State in the decade following introduction of triplicate prescriptions (Eadie, personal communication). In addition, pharmacists may refuse to carry DEX once they stock MPH.

Clinical Use

The PDR has two main indications for the MPH use, which are narcolepsy and ADHD. Other stimulants differ somewhat, with the indications for methamphetamine including...
ADHD and obesity, and for PEM including only ADHD. The decision to use medication for any pediatric psychiatric condition should be based on a balance of risks and benefits. Risks must be examined not only in terms of when medication is used, but also when medication is not used and the child continues to be impaired in social and academic functioning. Before stimulants can be prescribed for treatment of behavioral problems, the child must meet the DSM-IV-TR ADHD diagnostic criteria.

Other health conditions might prevent one from using a stimulant. If the child has Tourette's disorder, stimulants would not be used because of the likelihood of exacerbating the motor or vocal tics. Malignant hypertension might also prevent one from using a psychostimulant because of the risk of raising the blood pressure. Otherwise, the risks from these compounds are few.

The short-term benefits of stimulants are unequivocal, whereas the long-term outcomes are less well documented. Similarly, evidence supporting efficacy is strongest for preadolescents, weaker for adolescents, and equivocal for adults (Shaffer 1994).

Medication treatment begins with a choice of medication. Although the MPH or DEX psychostimulant types have equal efficacy, MPH is often used first. Elia and Rapoport (1991) strongly suggested for the physician to try both MPH and DEX, "because the overlap of who is a nonresponder is not great." These researchers defined nonresponders as those patients given medication, but whose behavior remained unimproved, or those who suffered severe adverse effects from the drug. Because of PEM's hepatotoxicity, it is used infrequently. If it is used, liver function studies should be done and repeated at 6-month intervals.

Standard MPH package instructions warn against its use in patients with tics or in patients with a family history of tics. One study showed that stimulant treatment of ADHD children maintained on effective anticonvulsant doses did not produce any increases in seizure frequency, changes in the electroencephalogram waveforms, or difficulties in regulating anticonvulsant blood levels. Current practice is to give children with both ADHD and epilepsy a combination of anticonvulsant and MPH. Plasma levels of the anticonvulsant should be monitored to avoid toxicity resulting from MPH competitive inhibition of metabolic pathways. At the doses used to treat ADHD in children, the psychostimulants have variable but minimal effects on the seizure threshold.

Table 106-1 is an inventory of stimulants and doses. Immediate-release DEX (IR-DEX) is usually started at 2.5–5 mg/day and gradually increased in 2.5–5 mg increments. Immediate-release MPH (IR-MPH) is usually initiated at 5 mg b.i.d. and then titrated in increments of 5 mg/dose every 4–7 days. Peak behavioral effects are noted 1–3 hrs after ingestion and dissipate in 3–6 hrs for both IR-MPH and IR-DEX. Although stepped-dose open-label IR-MPH and IR-DEX trials are the rule in clinical practice, double-blind, placebo-controlled, titration trials—using parent and teacher ratings plus an "objective" measure of attention, such as the CPT—can be helpful in distinguishing a true drug effect from a placebo response and in establishing the optimal individual dose.

Medication titration serves two purposes: acclimatization of the child to the drug and determination of his or her best dose. School-age children should be started with low doses to minimize adverse effects. Psychostimulant medication should be taken at or just after morning to lessen the anorectic effects. Studies have also shown that food may enhance drug absorption. IR-MPH treatment can be initiated with a single 5 mg dose at 8:00 a.m. for 3 days; then a 5 mg dose at 8:00 a.m. and at noon for the next 3 days; then 10 mg at 8:00 a.m. and 5 mg at noon for 3 days; and finally 10 mg at 8:00 a.m. and 10 mg at noon for at least 2 weeks. Preschoolers may start as low as 2.5 mg at 8:00 a.m. but build to the same total 20 mg/day IR-MPH total daily dose. The dosing instructions should be written down for the parent, with dates and times specified in detail.

Because MPH's short half-life prevents it from reaching a steady state in the plasma, the standard tablet must be given several times a day to maintain behavioral improvement throughout the school day. Although the PDR suggests giving MPH before meals, standard administration times are after breakfast (8:00 a.m.), after lunch (noon), and before homework (about 3:30 p.m.). Three-times-daily stimulant administration has been utilized in treatment studies (Greenhill et al. 1996) with doses given before school, at lunch, and at home prior to homework. The dose can be increased in 5 mg increments every 5–7 days, up to a maximum of 20 mg t.i.d. Preschool children generally need a total daily dose of about 15 mg, and school-aged children need about 30 mg daily (Greenhill et al. 2006). Although not FDA-approved, some older children may require more than 60 mg/day.

A brand formulation (Methylphenidate) of a single-pulse MPH is available in chewable tablets. It is designed as an oral solution for young children who have difficulty swallowing tablets or capsules. Peak plasma concentrations are achieved within 1–2 hrs; high-fat meals delay the peak by 1 hr. No large CRTs using this formulations have been published (Drugs for Treatment of ADHD 2006a).

Dexmethylphenidate (Focalin), the d-threo-enantiomer of MPH, can be given in half the dose of racemic MPH. Patients switching from another immediate-release MPH should start with half as much dexmethylphenidate. Stimulant-naïve subjects should begin with 2.5 mg doses twice daily, 4 hrs apart. Dosage can be increased in weekly increments to a maximum of 20 mg daily (Drugs for Treatment of ADHD 2002).

Current practice recommends switching as soon as possible to a long-duration preparation, such as OROS-MPH or modified-release MPH (MPH MR; Greenhill et al. 2002a, Wolraich et al. 2001). There are three reasons for the implementation of longer acting stimulant preparations. First, children who take medications in school can be subjected to peer ridicule when they leave activities to go to the nurse. Second, some school officials refuse to allow school personnel involvement in the administration of medication. Third, the time-action course of standard stimulant medications allows only a brief 1–3-hr effect window, therefore, some medicated children may experience periods of little or no drug action during important parts of the school day.

Long-acting MPH formulations include single-pulse and beaded double-pulse preparations (Drugs for Treatment of ADHD 2006a). Both generic and brand formulations are available. Single-pulse, sustained-release formulations use a wax matrix to prolong release. Compared to the IR-MPH, they have a slower onset of action with duration for up to
8 hrs. Some clinicians have found the duration of action to be highly variable and consider these medications as less effective in practice than immediate-release or osmotic-release MPH preparations. Often, the single-pulse formulations are prescribed twice daily, and sometimes an immediate-release tablet is added in the morning.

Beaded MPH (Ritalin LA) products use an extended-release formulation with a bimodal release mechanism. The long-acting MPH capsules are designed with half the dose being contained in the immediate-release beads and the other half in the enteric-coated, delayed-release beads. The beaded products can be opened allowing the medication to be sprinkled into small amounts of apple sauce or ice cream to disguise its bitter taste.

The OROS-MPH (Concerta) tablet uses an osmotic delivery system to extend the duration of MPH action to up to 12 hrs (Wolraich and Doffing 2004, Swanson et al. 2004). The tablet is coated with IR-MPH for immediate action. The rest of the dose is delivered by an osmotic pump that gradually releases the drug over a 10-hr period, producing slightly ascending MPH serum concentrations. Taken once daily, serum concentrations are similar to those produced by IR-MPH taken three times daily, but with less variation (Modi et al. 2000a). The tablets themselves are excreted in the stool.

Three double-blind RCTs have compared OROS-MPH to IR-MPH in children with ADHD. The results showed that the reductions in ADHD symptoms that occur with once-daily doses of OROS-MPH match those achieved with multiple doses of IR-MPH (Pelham et al. 2000, Swanson et al. 2003, Wolraich et al. 2001). Studies in adolescents have also demonstrated the effectiveness of OROS-MPH (Wilens et al. 2006).

Transdermal MPH patch appears to be as effective as other long-duration MPH preparations. Adverse effects such as anorexia, insomnia, and tics have occurred more frequently with this formulation. Especially common are mild skin reactions (Drugs for Treatment of ADHD 2006b). After application of the transdermal patch, MPH is steadily absorbed and reaches peak concentrations in serum after 7–9 hrs. Chronic dosing with the patch leads to higher MPH levels than with equivalent OROS-MPH doses. The MPH duration of action for a 9-hr wear period is about 12 hrs. A double-blind, placebo-controlled crossover study conducted in a laboratory classroom showed significantly lower ADHD symptom scores and higher math test scores with the MPH patch compared to a placebo patch during post-dose hr 2 through 12 (McGough et al. 2006). An advantage of the transdermal formulation is that it can be removed early in patients who have insomnia problems.

Similar to MPH formulations, amphetamine preparations are available as either the d-isomer, DEX, or in racemic forms, which are mixtures of d- and l-amphetamine. DEX has been equally effective to MPH in ameliorating pediatric ADHD symptoms. Some children unresponsive to MPH may respond to DEX, and vice versa. DEX absorption is rapid; the onset of action occurs within 1 hr of ingestion; plasma concentrations reach a peak 3 hrs after oral administration; and the duration of action is up to 6 hrs, which is somewhat longer than that of MPH. Twice-daily DEX administration is needed to extend the treatment through out the school day. Taking the medication with ascorbic acid or fruit juice tends to decrease amphetamine absorption, while taking alkalinizing agents such as sodium bicarbonate tends to increase its absorption, acidification of the urine increases amphetamine excretion.

Short- and long-acting mixtures of amphetamine salts are available in both generic and brand formulations. Long-acting preparations are manufactured in double-pulse capsule formulations containing immediate- and extended-release beads. There is no evidence that these medications offer any advantage over MPH or DEX, although clinically some patients respond to one and not to another.

Lisdexamfetamine dimesylate (Vyvanse) was recently approved by the FDA for the ADHD treatment in children aged 6–12 years. It has not yet been investigated in children younger than 6 or older than 12 years of age. Lisdexamfetamine dimesylate is available in 30-, 50-, and 70-mg capsules, which are equivalent to 10, 20, and 30 mg of mixed amphetamine salts, respectively. The starting dose should be 30 mg once daily in the morning. The dose can be raised in 20 mg/day increments no more often than once per week. The maximum dose for school-aged children is 70 mg (Drugs for Treatment of ADHD 2007).

Two double-blind, placebo-controlled, randomized clinical studies in 342 children with ADHD demonstrated that subjects taking lisdexamfetamine dimesylate in doses between 30 and 50 mg for 3–4 weeks showed more improvement on the ADHD ratings scales compared to children on placebo. The first study, a phase 2, double-blind, placebo-controlled, randomized, crossover trial in 52 children with ADHD found significant reductions for lisdexamfetamine dimesylate and MAS compared to placebo. The ratings were completed by trained and blind observers across 8-hr sessions in a 12-hr day (Biederman et al. 2006). The second study, a multisite, phase 3, parallel-design, randomized controlled clinical trial of 290 children demonstrated significant decreases in ADHD behaviors reported by parents for mornings, afternoon, and early evening on the CPRS. (Biederman et al. 2007). Adverse effects occurred in at least 5% of children assigned to active medication at a rate twice that of placebo group. Common adverse effects included upper abdominal pain, decreased appetite, nausea, vomiting, decreased weight, dry mouth, irritability, rash, and insomnia. Children taking lisdexamfetamine dimesylate have also had minor but statistically significant increases in blood pressure and pulse. Rash had occurred in 3% of patients taking the active medication versus none in the placebo group. A total of 21 out of 297 children terminated the trial due to adverse events.

Lisdexamfetamine dimesylate should not be used in patients with symptomatic cardiovascular disease, moderate to severe hypertension, advanced arteriosclerosis, hyperthyroidism, glaucoma, during or within 14 days following treatment with monoamine oxidase inhibitors (hypertensive crises may result), or known hypersensitivity to sympathomimetic amines. It should not be taken by patients with known cardiac structural abnormalities, cardiomyopathy, serious heart rhythm abnormalities, or coronary artery disease without a prior consultation with a cardiologist. Monoamine oxidase inhibitors and lisdexamfetamine dimesylate should not be used together or within 2 weeks of each other.

There is no evidence that lisdexamfetamine dimesylate offers an advantage over other amphetamine formulations.
Although, it may prove useful for the ADHD treatment in adults and adolescents with current or past history of stimulant abuse. In general, older medications with better established dosages and safety records are preferred.

PEM has been removed from many formulations and is no longer used in Canada because of the rare hepatic failure noted. When used, it is usually started at 37.5 mg once in the morning and titrated in 18.75 mg increments to maximal clinical effectiveness. Most children respond at a total daily dose of 56.5 mg/day or about 2 mg/kg per day in a single dosing. For patient safety, consent forms should be presented to the parents for their signature, and hepatic function tests should be gathered biweekly.

Drug response may be altered by comorbid ADHD. In anxious ADHD children, it has long been speculated that comorbid anxiety may influence the outcome of ADHD treatment. For example, Pliszka compared children with nonanxious ADHD to children comorbid for ADHD and anxiety disorder and found that the latter combination reduced the risk of comorbid conduct disorder, decreased impulsive responding on a CPT, and produced sluggish reaction times on a Memory Scanning Test (Pliszka 1989). These children also showed a poorer response to MPH and more side effects than subjects with ADHD alone. Although failing to replicate the results of Pliszka (1989) with respect to behavioral outcomes, Tannock and others later demonstrated that children comorbid for anxiety and ADHD have an enhanced risk for tics and dysphoria associated with MPH treatment. These children also had less improvement in memory when given a single MPH dose.

Conversely, using a flexible clinically appropriate titration trial, Diamond et al. (1999) found no difference in short-term outcome or side effects in children with ADHD alone and those comorbid for ADHD and anxiety, implying that a method variance may in part account for conflicting results in these studies. Analyses of the MTA Study, which addresses a priori questions about the individual and combined effects of pharmacological and psychosocial (behavioral) treatment for ADHD children ages 7–9 (Arnold et al. 1997), suggested that parent-reported child anxiety differentially moderated the treatment outcome. In particular, it generally favored the addition of psychosocial treatment for anxious ADHD children irrespective of the presence or absence of comorbid conduct problems. Contradicting earlier studies, no adverse effect of parent-reported child anxiety on medication for core ADHD symptoms or other outcomes were found. For some outcome domains, anxious ADHD children showed significantly greater gains than nonanxious children even when treated with medication only. On the other hand, exploratory analyses documented that child self-reported anxiety on the Multidimensional Anxiety Scale for Children (MASC) was only weakly correlated with parent- or teacher-reported anxiety at baseline, and changed little with treatment, raising questions whether the parent Diagnostic Interview Schedule for Children (DISC) accurately detects anxiety in ADHD children.

Response to a stimulant may not be related to child’s attitude. Concerns that medications may create negative attributions or dysphoric effects in ADHD children have not, as a rule, been confirmed in direct tests. Excellent studies show that there is considerable variability in children’s attributions, as well as their mood response to pills. Pelham et al. (1992) identified a subgroup of “depressogenic” children who gave external credit for positive events and felt internal blame for negative events. This group was above the median on success attributions to their medications. Comorbidity and family history for anxiety and/or depression seemingly are relevant variables in prediction of such attributional effects. During treatment, a small percentage of stimulant-treated children become dysphoric, weepy, and mournful. Since depressed children can present with symptoms of irritability, children who respond with depressogenic attributions or dysphoria may be the ones whose depressive diathesis is indistinguishable from ADHD. They are mistakenly diagnosed with ADHD and treated with stimulants. Given the overlap of depression and ADHD, as well as the findings that depressogenic cognitive styles predict later depression, it is important to identify children prone to attribute their success to medication rather than to their own effort, even though the majority of patients do not do so.

Children often have negative attitudes about treatment, thinking of it as a punishment. Taking medication can be socially stigmatizing to the child if the daily trips to the nurse generate peer ridicule. Discussing the problems of in-school medication administration may be of great help to the child. He or she should be included in all discussions about dosing and changing of doses. Optimally, these discussions may enhance treatment compliance.

Since ADHD is a chronic disorder, an effective treatment plan for follow-up and monitoring is imperative. Techniques encompass regular follow-up visits, the use of parent and teacher rating scales, and the monitoring of academic progress in school. Seeing the patient and a family member regularly is essential, often on a once-monthly basis when the medication prescription must be renewed. Medication therapy can be divided into baseline, titration, and maintenance phases. Before the first pill is given, baseline data on height, weight, blood pressure, heart rate, and complete blood count should be collected. Progress assessment is handled by a timetable of regularly scheduled visits to the physician’s office. Based on the success of the MedMgt strategy of the MTA Study (MTA cooperative group 1999), children on stimulants should be monitored with monthly or bimonthly visits. These visits work well if scheduled for 30 min in duration and involve both parent and child. They allow the physician to observe the child’s activity level and attentiveness, to collect information on beneficial effects and adverse reactions, and to review the teacher reports on the academic and social progress. Clinical progress is reviewed so that the physician can track ADHD symptoms, academic progress, and success with peers. Any counseling, therapy, or educational guidance can be provided at that time. With the parental permission, report cards can be copied and placed in the medical chart. The physician can keep anecdotal records about social events, including invited play dates and sleepovers, teams joined, and Boy or Girl Scout activities.

Maintenance plans should incorporate schedules for the regular collection of information that constitutes the therapeutic drug monitoring. Each child’s response to psychostimulants is different. Likewise, each family’s needs are different. Plans for medication vacations, weekend and after-school dosing must be individualized. Many parents,
concerned about long-term side effects, feel most comfortable with their child not taking medication every weekend and through the summer, despite the costs to family harmony. A summer off medication, although it may seem idyllic, may become much less desirable if the child’s summer camp has difficulty with the ADHD symptoms. On the other hand, a child with MPH-induced anorexia and some weight loss can benefit from a summer without medication.

Medication compliance should be monitored at each visit. The parent is to be instructed to bring the medication bottle along, so that pill counts can be done monthly and compared with the prescription dates. Height and weight should be taken every 6 months, and the child’s pediatrician can be requested yearly to perform a complete physical examination and blood work (complete blood count and liver function studies). The visit frequency depends on the other therapies recommended. These may include once-monthly parental counseling, twice-monthly individual therapy, and weekly meetings for individual psychotherapy or behavioral modification management. A minimal frequency should be once monthly, particularly in the nine states requiring multiple-copy prescription forms, which limit the amount of psychostimulant ordered to a 30-day supply.

The next component of monitoring is the use of structured rating scales. These have been the backbone of psychostimulant treatment research but also have utility in clinical practice. Each physician should choose a scale that she or he finds easy to interpret and convenient to use. It should be available in both parent and teacher versions. The rating scales, however, should not be used as substitutes for an open discussion with the teacher. They should be collected every 4 months, and whenever the physician needs to make decisions about dosage adjustment, time of dosing, or continuation of medication treatment.

Although the original 39-item CTRS is ubiquitous in the field of child psychopharmacology, Satin et al. (1985) have shown the validity of the shorter, 10-item Abbreviated Rating Scale both as a repeated measure and as a screening tool for identifying school-age ADHD children. This short form is effective for tracking children in maintenance treatment. Like most scales, the Abbreviated Rating Scale assigns weights to each scale point. In the 10-item scale, each point is weighted between 0 (“not at all”) and 3 (“very much”). Ten checks by a parent in the “very much column” yield a total score of 30. The physician should use these forms prior to the initiation of treatment. Two copies of each form are to be collected from both parents and the teacher 1 week apart. Each pair of forms is averaged to determine the child’s baseline pretreatment score. The average score counters any tendency for the rating scores to drift downward. Current thinking indicates that a 25% drop (with a lower total score indicating improvement) from baseline is required after medication is started to establish that the child has had a positive clinical response. Once the maintenance stimulant dose is set, the teacher and parent rating scales can be repeated at 4-month intervals.

Unlike the findings with anticonvulsants, it has not proved effective to monitor psychostimulants by maintaining plasma concentrations within a therapeutic range. Once absorbed, levels of the parent compound, MPH, can be obtained in bodily fluids. However, they do not prove to be a practical aid in the treatment of ADHD children according to the studies of saliva and plasma samples. Because MPH concentration is not independent of saliva flow, saliva MPH concentrations cannot be used to predict its concentrations in plasma or brain. In addition, plasma levels do not correlate with behavioral or cognitive measures. Nevertheless, MPH saliva levels provide a good check of pill-taking compliance.

As stated above, MPH plasma levels do not correlate with clinical response and provide no more predictive power than teacher and parent rating scales, because therapeutic drug monitoring efforts are hampered by MPH short half-life, as well as its tendency to degrade unless strict collection and storage methods are used. Its short half-life means that no true steady-state level is reached. This hampers the usual standard peak or trough collection time strategies used with the other psychotropics, such as lithium and carbamazepine, monitored with blood tests. There is no exact agreement in the literature concerning a standard time after oral dosing to draw blood for MPH levels. A variation of ½ hr can make an enormous difference in the resulting blood level of MPH if the physician is restricted to only one sample. Furthermore, there is considerable intradividual variability, with poor intertest reliability for peak MPH plasma levels. Alternative medications such as desipramine, however, do lend themselves to regular plasma level monitoring every 3 months.

Treatment duration is an important step in generating a therapeutic plan for an ADHD child. Although there is no clear-cut recommendation for the length of psychostimulant treatment, many parents have a reasonable expectation that it will not be open ended. The onset of puberty is one possible stopping point for psychostimulant medication. School-age children were thought to respond “paradoxically,” calming down on stimulant medication, an effect that was supposedly lost at puberty. Adolescents with ADHD, who may be at risk for substance abuse, have been regarded as vulnerable to psychostimulant euphoria and to abuse of their medications. In addition, more recent prospective follow-up studies suggest that the motor hyperactivity of ADHD diminishes between ages 16 and 23. Although, hyperactivity does not necessarily go away. Prospective follow-up studies have shown that approximately 25% of children with the full ADHD syndrome at age 10 will continue to show all signs of the disorder at age 18, including motor hyperactivity. These adolescents demonstrate the same beneficial response to MPH, in magnitude and direction, as do school-age ADHD children. Furthermore, MPH produces no more signs of euphoria in adolescents than it does in school-age children. With clear evidence that some individuals continue to suffer from ADHD in adult life, one could advocate psychostimulant treatment indefinitely. As such, what is the physician to tell the parents?

Dulcan et al. (1997) and Greenhill et al. (2002b) recommended that treatment duration should be planned on an individual basis. One method is to plan in single school year units, starting at the present time, and projecting treatment to last through the current school year plus at least one additional month into the following academic year. Once the child has responded to an initial level of medication, maintenance doses can be set at slightly lower levels. Treatment can be continued, if need be, and the next decision point can be set for the following fall.
This provides a framework for the second concept, a trial-off medication, which can be used to determine whether the treatment should be continued for another year. Medication can be discontinued during the school year at some stable period. This should not be the beginning of the school year or during crucial placement examinations. Since placebo tablets are no longer available from the companies manufacturing MPH, the psychostimulants are to be simply stopped. Most children do not need to taper their dose off medication at discontinuation, unless they show signs of marked afternoon rebound.

A therapeutic plan may include other treatment components in addition to medication. New standards have been promulgated recommending multimodal therapy for the ADHD treatment. This was first reported by Satterfield et al. (1980) as successful in maintaining the short-term stimulant gains for periods of two or more years. Some combination treatments, such as behavior modification plus medication, have been shown to be somewhat more effective than medication treatment alone. However, the combination of medication and cognitive–behavioral therapy was not more effective than medication alone. More recent studies (Abikoff et al. 2004b, MTA cooperative group 1999) have evaluated a multimodal package variously including MTA given in multiple doses, parent training, educational supplementation, and social skills training for the child. This type of therapy is more costly, in time and money, than MedMgt accompanied by regular but infrequent counseling. Testing the relative efficacy of combination therapies is more challenging than assessing the stimulant efficacy, since more control groups are required to tease out the effects of each component and their combinations. Controlled studies of multimodal therapy have been confounded by the need to use a fixed package rather than tailoring the therapy to the child’s needs, thus generating high refusal rates and reluctance by families to accept the entire treatment package.

Treatment plans that center only on psychostimulant medication have flourished for a number of reasons. The effects of psychostimulants are rapid, dramatic, and normalizing. The risk of long-term side effects remains low, and no substantial impairments have emerged to lessen the remarkable therapeutic benefit–risk ratio of these medications. More expensive and demanding treatments, including behavior modification and cognitive–behavioral therapies, have, at best, merely equaled the treatment with psychostimulants. In a number of instances, the combination of behavioral and medication therapies have at best moderately surpassed treatment with psychostimulants alone (MTA cooperative group 1999). Current and future studies of multimodal therapies will test whether combined treatment results in better overall functioning in the long run and decreases appearance of comorbid conditions as compared to monomodal treatment with psychostimulants alone. It is essential to demonstrate that the continuation of stimulant medication during long-term maintenance benefits the patient with ADHD.

Treatment of Adult Depression

J. Craig Nelson

The use of stimulants for depression has a long history. Myerson (1936) first reported the use of amphetamine sulfate. Wilbur et al. (1937) also noted marked improvement of mood following administration of amphetamine, sometimes within 24 hrs, in depressed subjects. Wilbur also provided the first description of apparent habituation with time so that responding patients lost the initial effect. This remains one of the best descriptions of the principal limitations of this drug.

Acute Effects
The acute effects of stimulant drugs are well documented. Fawcett and Siomopoulos (1971) described the “stimulant challenge test” as a predictor of response to tricyclic antidepressants (TCAs). The usual test dose was dextroamphetamine 5 mg given orally three times a day. About 50% of severely depressed patients showed clinically meaningful change. Although the predictive value of this test for TCA response has been debated (Little 1988, Gwirtsman and Guze 1989), for a time many clinicians attempted this strategy. In contrast to the gradual effects of traditional antidepressants, the effects of dextroamphetamine were evident within 48 hrs.

Subsequent to the observation of Fawcett and Siomopoulos, several placebo-controlled studies or dextroamphetamine or methylphenidate confirmed the observation of acute response (Van Kammen and Murphy 1978, Brown et al. 1978, Van Kammen et al. 1981, Silberman et al. 1981, Ettigi et al. 1983, Sabelli et al. 1983). Changes in mood were commonly observed within 24–48 hrs although effects could be observed within 20 min after intravenous administration. The onset of effects was dependent on dose and route of administration. Clearly, amphetamine had rapid antidepressant effects.

Chronic Effects
Unfortunately, the dramatic acute effects of stimulants were not confirmed with chronic administration (3–12 week trials). In a previous review (Satel and Nelson 1989) we found 10 double-blind, random assignment, placebo-controlled trials of stimulant drugs in depressed subjects. Nine of the 10 studies were published between 1958 and 1972 with the 10th study published in 1985. Samples ranged in size from 20 to 204 and six samples were outpatients and four were primarily inpatients. Some studies excluded agitated or highly anxious patients. Half of the studies administered dextroamphetamine and half methylphenidate. Doses of amphetamine ranged from 10 to 40 mg/day. Methylphenidate doses were quite variable and ranged from 15 to 90 mg/day. In one 4-week comparison, methylphenidate was superior to placebo (Rickels et al. 1970). A second study found
methylenidate superior to placebo by patient report but no clinician rating. The other eight studies failed to find an advantage for the stimulant. Patients were responsive, but in some studies placebo response was as high as 72% (Wheatley 1969).

These studies are easy to criticize. Several were short 3–4 weeks trials but that might favor a drug with rapid effects. Several were crossover studies, which have limitations in depression. Most of these studies were conducted prior to the use of diagnostic criteria. Rating scales in the early studies were idiosyncratic. Nevertheless, during the same time period, 14 of 23 studies of imipramine using relatively similar methods demonstrated clear efficacy (Klerman and Cole 1965). It seems fair to conclude that the stimulants are not as effective as a standard TCA, imipramine in patients with depression.

Studies in Medically Ill and Geriatric Patients

Stimulants have been commonly used in medical settings. Murray and colleagues at Massachusetts General Hospital have been advocates of the use of stimulants on their consultation service. As Murray (Murray and Cassem 1998) noted, “We were looking for a faster acting antidepressant since most of the medical and surgical patients seen were not hospitalized for 2 or more weeks.” The MGH group published two large series of patients treated with stimulants on their consultation service. The first was a series of 66 patients treated between 1979 and 1983 (Woods et al. 1986). The second nonoverlapping series included 198 patients treated between 1983 and 1988 (Masand et al. 1991). In both series, almost all patients met Washington University criteria for “secondary depression,” meaning that medical illness preceded the depression (Feighner et al. 1972). Most of the patients were older; mean ages in the two series were 72 years and 65 years. In the first series, about half of the patients received dextroamphetamine and half methylenidate. In the second series three-quarters were treated with dextroamphetamine. Mean doses of dextroamphetamine were 12 and 8 mg/day. Mean doses of methylphenidate were 13.5 and 11 mg/day. On the Clinical Global Improvement scale 48% of patients in the first series and 70% in the second series had marked or moderate improvement. Peak response was seen within 2 days. Although all of these patients were hospitalized because of medical illness and some were seriously ill, side effects were relatively infrequent and transient. In the two series 7 and 10% discontinued treatment because of adverse effects. Most common side effects were central nervous system effects such as confusion, agitation, nervousness, hypomania, or delusions. In the larger series, six patients had cardiovascular symptoms—sinus tachycardia (3), elevated systolic blood pressure (2), and atrial fibrillation; however, in a medically ill, older population, these changes are not uncommon and it is not possible to attribute these changes to drug treatment without a placebo control group.

These two open series are presented in some detail because they are relatively large, they included “real-life” patients, and the findings are compelling. They are, however, uncontrolled. Two placebo-controlled studies in medically ill patients have been reported. Wallace et al. (1995) reported a double-blind crossover study of methylenidate in 16 older medically ill patients (mean age 72). Patients were randomized to methylenidate up to 10 mg twice a day or placebo for 4 days then crossed over to the other agent. During the first 4 days, patients in both groups improved. After the crossover only the patients on methylenidate continued to improve. Few side effects were noted and no changes in vital signs were observed. The small numbers, further reduced by dropouts in the placebo group, limit conclusions.

Wagner and Rabkin (2000) reported a second placebo-controlled study. This was a 2-week randomized trial in 23 patients (age range 18–65) who had various DSM-IV-TR depression diagnoses, fatigue, and advanced HIV illness. The mean baseline Hamilton score was 14.9. Patients were randomized to dextroamphetamine or placebo. Dextroamphetamine was started at 2.5 mg twice a day and increased 2.5 mg every 2 days up to 40 mg/day (mean 22.9 mg/day). All but one patient (a patient on placebo who became anxious) completed the 2-week trial. Eight of the 11 patients randomized to drug responded while 3 of 12 patients on placebo responded (Fisher exact test, p < 0.05). Of 15 patients who had either responded during the trial or were switched to drug after the trial, 10 maintained their response after 6 months. The authors noted that the value of stimulants appeared to be greater in less severely depressed patients. Side effects were infrequent and transient, and no serious side effects occurred.

Stimulants in Late Life Depression

Numerous case reports or small series have described the use of stimulants in older depressed patients and have been reviewed previously (Satel and Nelson 1989, Chiarello and Cole 1987, Nelson 2004). In many cases the older patients also had medical illness. There are no placebo-controlled studies of stimulants in late life patients with clear Major Depression. There are five placebo-controlled studies, previously reviewed (Satel and Nelson 1989), in institutionalized older patients and four of these studies noted some advantage for the stimulants. These studies, however, are difficult to interpret. Diagnoses were not clearly defined. Patients included had depressed mood, fatigue, and apathy and some were described as “senile.” While stimulants appeared to be useful, it was unclear what disorder was being treated.

Stimulant Augmentation in Depression

There are two types of stimulant augmentation studies. The early studies of stimulant augmentation added stimulants to patients who had not responded to an antidepressant. Subsequently stimulants were used to accelerate response. Five open label trials in 67 patients used stimulants to augment a TCA or monoamine oxidase inhibitor (MAOI) and have been previously reviewed (Ayd and Zohar 1987). In the largest of these, Fawcett et al. (1991) reported that 25 of 32 refractory patients responded to the addition of a stimulant and that response was maintained for several months. When used for augmentation the usual dose of dextroamphetamine was 10–15 mg/day and for methylenidate about 30 mg/day.

Stimulants have also been used to augment second-generation agents. Favorable results were reports in a single case (Gupta et al. 1992) and two small series of five and seven cases (Stoll et al. 1996, Masand et al. 1998). Recently,
a placebo-controlled study of 60 subjects was published (Patkar et al. 2006). An extended release formulation of methylphenidate was administered in patients who had failed or were partial responders to antidepressants. Subjects were randomized to a 4-week double-blind trial of methylphenidate (dose 18–54 mg/day, mean dose 34 mg/day) or placebo. The reduction on the HAMD was not significantly greater in the methylphenidate group and response rates in the drug and placebo groups, 40.0 and 23.3%, did not differ significantly, although the study may have been underpowered to detect a difference. Common side effects were loss of appetite, nausea, headache, and anxiety. There were no significant differences in weight, heart rate, or blood pressure.

**Acceleration of Response with Stimulants**

A particularly interesting question is whether the documented acute effects of a stimulant might be used to “jump start” treatment. This was first suggested by Gwirtsman et al. (1994), who added methylphenidate to TCAs. This idea was later taken up by Postolache et al. (1999), who began a randomized trial adding methylphenidate or placebo to sertraline at the beginning of treatment. The authors abandoned the trial, however, when no early effects were observed in any of the first nine patients. Alternatively, Lavretsky and Kumar (2001) reported that methylphenidate added to citalopram at the beginning of treatment appeared to hasten response during open label treatment of 10 elderly patients. Subsequently, Lavretsky et al. (2006) performed a randomized placebo-controlled trial in 16 elderly patients. Three of five subjects in the citalopram plus methylphenidate group met their criterion for rapid response while none in the placebo group met this criterion. Because of the age of the subjects, the dosing schedule for methylphenidate was rather cautious. To my knowledge, no one has attempted to combine the dextroamphetamine test dose of 5 mg three times a day while starting a second-generation antidepressant.

**Dextroamphetamine vs. Methylphenidate**

An obvious question is whether one stimulant is more effective or potent than the other. In large series, such as those reported by the MGH group (Woods et al. 1986, Masand et al. 1991), there were no significant differences between agents. Individual patients, however, may respond to one class but not the other. Little (1993) described a 1-day test dose strategy in 18 depressed inpatients (mean HAMD score = 22.8). Patients received dextroamphetamine 20 mg or methylphenidate 40 mg and were then crossed over to the other agent. Drugs were administered in a double-blind balanced order. Acute response was noted with both drugs in 5 of the 18 patients while 7 responded to dextroamphetamine only and 5 to methylphenidate only. One responded to neither. The authors noted that while both agents enhance catecholamine release, specific mechanisms differ and patient response can only be determined empirically.

Murray and Cassem (1998) state that the experience of the MGH group suggests that dextroamphetamine is somewhat more effective than methylphenidate, although the drugs did not show a significant difference in either of their case series. They also note that the apparent perception of greater safety of methylphenidate was not supported by their data. (Both were safe.) Alternatively in their review, Chiarelli and Cole (1987) suggested that dextroamphetamine might be associated with more side effects. A major problem in making these comparisons is determination of equivalent doses. On a mg-per-mg basis, dextroamphetamine appears to be more potent. Usual doses of methylphenidate were approximately double that of dextroamphetamine in the controlled depression trials cited above. Dosing of methylphenidate is complicated by its very short half-life, and absorption of methylphenidate may be dependent on the dosing schedule (Teicher et al. 2006). It is possible that the greater apparent efficacy of dextroamphetamine and the perception of greater safety of methylphenidate are the result of underdosing of methylphenidate.

**Side Effects and Safety**

In the MGH studies of medically ill patients, both dextroamphetamine and methylphenidate appeared safe with relativity low rates of discontinuation for adverse effects, 7 and 10% (Woods et al. 1986, Masand et al. 1991). In our previous review of depression studies (Satel and Nelson 1989), we also found little evidence of serious adverse effects. When stimulants are used at the usual oral doses, cardiovascular effects are uncommon. Two early reports examined the safety of stimulants in patients with cardiac disease and found little evidence of serious adverse effects (Dube et al. 1956, Ferguson and Funkerbunk 1956). In one of the recent controlled studies that systematically measured vital signs, no changes were noted (Wallace et al. 1995).

While these data suggest that stimulants can be used safely, it should be remembered that the database from systematic prospective controlled studies in depressed patients is quite limited. Nine of the 12 controlled studies in depression were performed prior to 1973. Electrocardiograms were not routinely performed. The three controlled studies after 1984 (Mates 1985, Wallace et al. 1995, Wagner and Rabkin 2000) had small samples of 20, 15, and 23 patients. Several studies were of brief duration. Sample size and trial duration are very important for detection of serious adverse events with low incidence rates. Stimulants have not been systematically studied in older patients who may be especially vulnerable to serious adverse events or in patients with heart disease. Thus while small controlled studies and anecdotal reports suggest that these drugs can be used safely, this suggestion cannot be confirmed.

The most common side effects are behavioral and include confusion, irritability, nervousness, or anxiety. Stimulants can induce hypomania and psychosis. “Amphetamine psychosis” was described early in the history of these agents (Young and Scoville 1938, Connell 1958).

The interaction of the stimulants with preexisting anxiety is interesting and not well understood. Early observations (Davidoff et al. 1957) of increased anxiety during open treatment led to the clinical impression that these agents should be avoided in anxious patients. Alternatively, some controlled studies (Overall et al. 1966, Rickels et al. 1972) found similar rates of emergent agitation in the drug and placebo groups. All of these data were collected prior to more recent observation of increased anxiety or restlessness during initial treatment with an SSRI. It is not clear that the stimulants are more likely to provoke anxiety or restlessness than current second-generation antidepressants.
Because the stimulant drugs have sometimes been used for weight reduction, clinicians may be concerned about the use of stimulants in older patients with weight loss. In fact, severe weight loss or cessation of eating is one of the acute problems encountered in older depressed patients that can require hospitalization or electroconvulsive therapy. In these patients stimulants can have a “paradoxical effect.” The acute beneficial effects of stimulants on mood can be associated with increased appetite and resumption of eating. Use of stimulants in this acute clinical situation can be dramatically effective. Alternatively during chronic treatment, loss of appetite has been observed with dextroamphetamine in patients with HIV illness (Wagner and Rabkin 2000).

**Abuse Potential**

Although the potential abuse of amphetamines is well recognized, increased abuse of these agents in depressed patients or patients with attention deficit hyperactivity disorder has not been established or observed (Nelson 1995). Recent evidence in ADHD suggests that successful treatment of the disorder may reduce the risk of substance abuse that is otherwise associated with ADHD (Wilens 2004, Wilens et al. 2003). Clinicians should remember, however, that diversion of prescribed stimulants might still be a problem.

**Modafinil for Depression**

Modafinil is a new agent approved by the FDA for promoting wakefulness. It is unclear if it should be classified as a stimulant. It does not have meaningful effects on dopamine release or reuptake as do amphetamine and methylphenidate and its mechanism of action is unclear. Nevertheless, modafinil has some stimulant-like properties.

Modafinil has been explored as a treatment for depression either as monotherapy or augmentation. Case series (Price and Taylor 2005) and case reports (Kaufman et al. 2006) have described the use of modafinil monotherapy in depression. Use of modafinil for atypical Major Depression was examined in a 12-week open trial in 66 subjects (Vaishnavi et al. 2006). Subjects significantly improved. Then 50 of the subjects who had at least minimal improvement were randomly assigned to modafinil or placebo for another 12 weeks. During this period there was no difference in relapse between the drug and placebo groups. This could suggest that the early effects of modafinil were maintained; however, the advantage of antidepressant treatment during relapse prevention is one of the best validated attributes of effective antidepressants (Geddes et al. 2003). It seems quite likely that the initial benefits were placebo-like effects and that is why no difference with placebo was observed during the controlled phase.

There are several reports of the use of modafinil for augmentation. Most of these reports are open label studies (Konuk et al. 2006, Rasmussen et al. 2005, Price and Taylor 2005, Nasr 2004, Schwartz et al. 2004, Markovitz and Wagner 2003, Menza et al. 2000). One of these open label studies added modafinil at the beginning of treatment to accelerate response (Ninan et al. 2004).

Fava et al. (2005) described the only placebo-controlled, double-blind, acute phase trial. In this study, 311 subjects with Major Depression, who had fatigue or excessive sleepiness, and were SSRI partial responders, were randomized to an 8-week trial of modafinil 200 mg or placebo.

At the final visit modafinil was significantly superior to placebo on the CGI scale but trend findings were noted on the Hamilton and MADRS scales. An open label 12-week extension of this study suggested that subjects continued to improve including those who failed the initial trial (Thase et al. 2006). In these reports the most common side effects were nausea, jitteriness, headache, and dizziness. Modafinil was also associated in some studies with weight loss, which was seen as an advantage.

**Conclusions**

Stimulants have been used to treat depression for over seven decades, yet their current use appears to be quite limited. Given the long history and the variable quality of research over this period, determination of the best available evidence for the stimulants is a challenge. The following conclusions seem warranted. The acute (24–48 hrs) effects of the stimulants on depressed mood are established in controlled studies and are consistent with clinical reports of 24–48 hrs response observed during the dextroamphetamine test and the MGH case series. Two small controlled trials indicate that stimulants accelerate response to TCAs and citalopram. Ten placebo-controlled studies of stimulants in primary or Major Depression indicate lack of efficacy of stimulants during sustained (4–6 week) treatment. Use of stimulants for augmentation of antidepressants is supported by open trials but controlled data are lacking. During oral administration and at usual doses, dextroamphetamine and methylphenidate appear to be safe, well tolerated, and without predictable effects on pulse and blood pressure; however, the data for stimulants in depression are not comparable to new antidepressants coming to market in terms of systematic collection of adverse events or vital sign data for 2,000–3,000 patients. Preliminary data for modafinil suggest that it may have a role for augmentation of antidepressants.

One controlled trial supports its use in partial responders with residual symptoms of fatigue and excessive sleepiness.

The clinical utility of stimulants for geriatric depression or depression secondary to medical illness is supported primarily by case series and two small controlled trials. Yet the case series from MGH are compelling. It could be argued that the short-term benefits in medically ill patients are mainly placebo effects and that the period of observation in the MGH series was too short to systematically document sustained improvement. Alternatively, Wittenborn (1982) has suggested that geriatric depression might be different from depression in younger individuals. Two emerging conceptual models support this view. One model suggests that some older patients with late onset depression have early degenerative disease, particularly vascular disease (Alexopoulos et al. 1997). These patients also tend to have cognitive disturbance in the form of executive dysfunction and appear to be less responsive to conventional treatments (Alexopoulos et al. 2005). Perhaps the stimulants are especially useful for both the mood disturbance and the cognitive disturbance these patients experience. The other model is based on the observation that some medically ill patients present with a depression-like syndrome described by Engel (1967) as a “giving up—given up complex” or more recently by Kissane et al. (2001) as a demoralization syndrome. Conventional antidepressants appear to be less useful for these patients. Perhaps the short-term effects of stimulants are
especially helpful in reducing the hopelessness of demoralized patients, and if prevention of relapse is less an issue for this syndrome (as opposed to recurrent depression), perhaps short-term effects of stimulants along with supportive care are sufficient. Both of the above hypotheses are untested.

Finally, the field of psychopharmacology has been interested in the bridge between the observed antidepressant effects of a compound, its known pharmacologic actions, and what this might suggest about the neurophysiology of depression and antidepressant mechanisms. Agents that have acute antidepressant effects are of particular interest. For example, a recent report of acute effects of ketamine on mood (Zarate et al. 2006) has received considerable attention. As we consider the neuropharmacologic implications of these clinical data, the acute effects of the stimulants ought to be kept in mind.

History and Background

Prior to the 1970’s, various medications were proposed for the treatment of dementia based on clinical experience or prevailing theories of dementia and aging. These included psychostimulants, vasodilators, ergoloids, and medication “cocktails.” In the US, the only one medication, ergoloid mesylates (dihydroergotoxin mesylate) was approved for an ill-defined condition, senile mental decline. By the late 1980’s, the advent and acceptance of research-based diagnostic criteria for the dementia of Alzheimer’s disease (AD), (McKhann et al. 1984) an initial understanding of its underlying pathology, and the development of mechanism-based pharmacological therapeutics provided the framework for clinical trials to exploit new treatment strategies that might positively impact the illness.

Since AD is defined by the presence of dementia, attempts have been made to identify a predementia state of cognitive impairment, likely to lead to AD. Criteria for “age-associated memory impairment” (AAMI), a construct for functionally significant, although mild and probably nonprogressive cognitive impairment has not been generally accepted as a diagnosis, although the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) includes a code for “age-related cognitive decline,” equivalent to AAMI. “Mild cognitive impairment” (MCI) has been the target of several clinical trials of medications previously used for AD. The evolving validity of MCI will rest mainly on its ability to predict the onset of the dementia of AD. In research clinics a diagnosis of MCI implies a conversion rate to AD of about 12–15% per year (Petersen et al. 2001). However, MCI is not necessarily a predementia stage of AD, since many people who fulfill criteria do not progress to dementia and some improve to not being cognitively impaired.

During the 1990’s, research- and consensus-based criteria emerged to address vascular dementia (Chui et al. 1992, Roman et al. 1993), dementia with Lewy bodies (McKeith et al. 1996), frontotemporal dementia syndrome, and Parkinson’s disease dementia. These latter criteria are still evolving and thus clinical trials including these populations have been limited.

Regulatory and Methodological Issues

The Food and Drug Administration (FDA) utilizes de facto guidelines for establishing that a drug has “antidementia efficacy” (Leber 2002). These require that: (1) clinical trials are double-blind and placebo-controlled, (2) patients fulfill criteria for a primary dementia such as AD (e.g., DSM-IV-TR or National Institute of Neurological and Communicative Disorders and Stroke–Alzheimer’s Disease and Related Disorders Association (NINCDS-ADRDA) Work Group Criteria) (McKhann et al. 1984), and (3) appropriate efficacy instruments are used. Further, a putative antidementia drug must show efficacy at improving memory or retarding its deterioration since memory impairment is one of the primary features of dementia. The drug also must have an effect, determined independently from neuropsychological assessment, using a global clinical measure or a measure of functional incapacity in order to address the concern that drug-related memory improvement may be observed with psychometric testing but not be clinically meaningful. Changes in behavior are considered to be of secondary importance for regulatory purposes.
Most clinical trials of antidementia drugs undertaken in the US to seek regulatory approval for mild-moderate AD have used the Alzheimer’s Disease Assessment Scale—Cognitive Subscale (ADASc) (Mohs et al. 1997) as the index of cognitive change and a version of a clinical global impression of change (CGIC) as the “global” clinical measure (Schneider et al. 1997). The ADASc includes the following measures: word recall, naming, commands, constructional and ideational praxis, orientation, word recognition, spoken language, comprehension of spoken language, word-finding, and recall of test instructions. The CGIC is usually rendered as a seven-point, ordinal scale upon which a clinician indicates his or her impression of clinical change from “no change” to “minimal,” “moderate,” or “marked” improvement or worsening. Trials conducted in people with moderate and severe dementia have used other cognitive measures, such as the Severe Impairment Battery (SIB) (Saxton et al. 1990), and/or the Alzheimer’s Disease Cooperative Study—Activities of Daily Living (ADCS-ADL) Scale to assess aspects of daily functioning (Galasko et al. 1997).

Limitations to the current guidelines include the lack of recognition of improvement in behavior as a legitimate therapeutic goal or indications in the prescribing information, despite the fact that behavioral symptoms occur in the majority of dementia patients. The FDA draft guidelines that patients fulfill established criteria for a primary dementia is an attempt to avoid the inclusion of ill-defined dementia syndromes in clinical trials, to obtain sample homogeneity, and to achieve consensus that the medication is effective in a specific group of patients with an illness such as AD accepted by a substantial number of experts.

This chapter focuses on the dementia of AD, because most work has been done in this area in recent years. Many of the issues raised will become relevant to other dementias or cognitive impairment syndromes as clinical investigators continue to study these syndromes.

**Typical Inclusion Criteria for AD Clinical Trials**

These include the presence of probable AD (NINCDS-ADRDA workshop criteria) (McKhann et al. 1984), a specified Mini Mental State Examination (MMSE) (Folstein et al. 1975) score (e.g., typically between 10 and 26 for “mild-moderate AD”); a score of less than 4 on the Modified Hachinski Scale (Rosen et al. 1980); a CT scan or MRI consistent with AD and showing no evidence of significant focal lesions; generally good physical health other than the dementia (confirmed by medical history, physical exam, neurological exam, ECG, and laboratory tests); normal blood pressure; English speaking; and having a reliable caregiver to participate in clinical evaluations.

Exclusion criteria typically consist of a history of other psychiatric or neurological disorders, of a stroke or CT/MRI evidence of a stroke, significant concurrent physical illness, or abnormal laboratory findings. Therefore, dementia populations studied in clinical trials consist mainly of mildly-to-moderately impaired outpatients living at home with their families, who are otherwise medically healthy and lack significant behavioral symptoms. Recently, some trials of disease modifying drugs have expanded inclusion criteria to allow the concurrent use of approved antidementia therapies.

**Etiopathology and Implications for Treatment**

This chapter offers a survey of treatments for AD ranging from approved therapies to those that have been or are in clinical trials. The survey is organized according to the etiopathologic basis of the therapy. This approach has merit because the field is changing rapidly, and a host of new approaches are being put to the test. Certain approaches of theoretical interest will be mentioned as well, since the field is changing so quickly. The review begins with a schematic summary of the pathobiology of AD, in order to provide a theoretical framework within which to present the surprisingly wide array of emerging therapies.

**Neuropathology of AD**

The definitive diagnosis of AD is based on the clinical dementia syndrome together with certain neuropathologic features first described by Alois Alzheimer in 1907. These include neuritic plaques and neurofibrillary tangles spread diffusely through the cerebral cortex and hippocampus (Khachaturian 1985, Mirra et al. 1991) (Figure 107–1). Plaques, found outside the neuron, are spherical structures possessing a central core of amyloid protein surrounded by distended abnormal neuronal dendrites and small axons. Tangles consist of bundles of filaments in cell bodies, axons, and dendrites. These histologic abnormalities are associated with loss of synaptic density and neuronal death. Much has been learned in recent years about the chain of events leading to these defining features of Alzheimer’s, knowledge that has lead to rational drug development and therapeutic candidates far different from the agents of the 1970s.

**Dominant theories of AD Pathobiology**

How do these pathological features come to pass? The “amyloid cascade” hypothesis posits that dysregulation in amyloid precursor protein (APP) occurs early in the illness and leads to increased production of Amyloid Beta Protein (Aβ 1-42) and other Aβ peptide fragments. This in
A Pathogenic Cascade Hypothesis

For purposes of organizing emerging treatment strategies, we offer an even broader schematic view of the evolution of Alzheimer’s Disease (AD) (Figure 107–2). We posit that the disease begins relatively early in life, and the times of onset of cognitive impairment and dementia are influenced by a variety of interacting factors such as aging; genetic susceptibility or resistance; environmental susceptibility factors such as toxin exposure, head injury, or smoking; possible exogenous protective factors such as exposure to certain medications; and endogenous susceptibility or protective factors such as menopause, diet, exercise, degree of educational attainment, depression and major depression, chronic psychological stress, or even social connectedness. The balance between stress and resilience tips at some point that varies tremendously from person to person, initiating a series of molecular events such as oxidative stress, excitotoxicity, altered APP processing, or early apoptosis. Compensatory mechanisms may protect against cell injury for some period of time, such as alterations in DNA repair, and enzyme upregulation. These stress responses eventually break down, leading to neuronal injury in common cellular signaling pathways and eventual loss of synapses, neurotransmitter failure, and cell death. The molecular phenotype may precede both the neuropathology and clinical phenotype by many years, perhaps decades; and the clinical manifestations may not emerge until there is significant cellular damage.

The neurodegenerative process is asynchronous, meaning that viable neurons coexist with damaged or dead cells, and highly variable both within an individual and among individuals over time. The fact that both inherited and sporadic forms of AD share many clinical and pathological features supports the hypothesis that there is a convergence of biochemical abnormalities downstream from the various initiating factors.

Each aspect of this cascade offers a potential therapeutic target. For instance, neurotransmitter-based therapies might afford symptomatic relief without altering the pathological outcome. Impaired signaling has been identified in cholinergic and glutamatergic pathways, and restorative therapies targeting cholinergic and glutamatergic neurotransmission have been approved. Interventions that decrease pathogenic Aβ production, fibrillization of Aβ, or decrease tau protein phosphorylation may prevent neuronal degeneration; and treatments with neuroprotective properties might result in enhanced cellular resistance and slower decline in clinical deterioration. This hope has yet to be realized.

Treatment Paradigms

Approaches to the treatment of AD can be grouped into several conceptual categories (Table 107–1). One approach attempts to treat the associated features of the illness such as sleep–wake cycle or appetite disruption, or behavioral disorders such as aggression, psychosis, agitation, depression, anxiety, or apathy. This approach, while valid, will not be the focus of our chapter. A second approach addresses the cognitive signs of the illness such as memory, language, praxis, attention, and orientation. Most neurotransmitter based therapies have this goal in mind. A third approach aims to slow the rate of progression of the illness, preserving patients’ quality of life or autonomy. A fourth conceptual treatment approach is primary prevention, delaying the time to onset of illness. Success at this approach could have considerable impact. For example, delaying the onset of AD by 5 years would halve its incidence (Brookmeyer et al. 1998, Jorm et al. 1987). We will not emphasize preventive therapies here, but bear in mind that interventions that can slow the progression of the disease once present might well have prevention potential, while it is also possible that treatments may be effective for prevention but not slowing disease progression.

### Etiologically Directed

**Targets:** β-Amyloid formation or hyperphosphorylated tau protein

**Examples:** Modulators of APP expression, β- and γ-secretase inhibitors, inhibitors of beta-amyloid protein aggregation or deposition, active or passive immunization with antibodies to beta-amyloid.

**Note:** The interventions listed above include some that are available and marketed, as well as some that have not been demonstrated effective or safe, and some conceptual treatments not yet developed.

Cholinergic Treatment Approaches

The primary implication of the cholinergic hypothesis is that potentiation of central cholinergic function should improve the cognitive and behavioral impairment associated with AD. This simple “neurotransmitter replacement” rationale has been validated by the consistent effects of cholinesterase inhibitors (ChIs) across trials (see Figure 107–4). Other cholinergic treatment approaches, including precursor loading, direct cholinergic receptor stimulation, and indirect cholinergic stimulation, have proven ineffective, effective but too toxic, or have not been completely developed.

Cholinergic therapies may have effects beyond the short-term symptomatic improvement of cognition and may modify the pathogenetic processes of the illness (Radebaugh et al. 1996, Thal et al. 1997). For example, activation of M1 muscarinic receptors can stimulate secretion of APPs via the α-secretase pathway such that there is a decrease in the production of toxic and insoluble β-amyloid peptides, thus theoretically decreasing the formation of amyloid plaques and promoting the normal processing of APP (Inestrosa et al. 1996, Muller et al. 1997, Nitsch et al. 1992). These effects have been reported with some cholinergic agonists and ChIs (Buxbaum et al. 1992, Haroutunian et al. 1997, Lahiri et al. 1992, Nitsch et al. 1992), but remain to be proven in clinical trials (Buxbaum et al. 1992, Haroutunian et al. 1997, Lahiri et al. 2000).

**Precursor Loading**

Early investigations focused on acetylcholine precursors, including choline and phosphatidyl choline (lecithin), in attempts to augment acetylcholine synthesis. Numerous trials of cholinergic precursors, most with small sample sizes, have generally failed to improve cognitive performance in patients with AD; only 10 of 43 such trials report any positive effect (Jorm 1986).

**Muscarinic Agonists and Antagonists**

The rationale for the use of direct cholinergic agonists rests on the fact that postsynaptic, M1, cholinergic receptors are relatively intact in AD and that presynaptic, M2, cholinergic receptors, which are decreased in AD, regulate...
In a transgenic mouse model, NGX267 improved cognitive deficits in a spatial task but not in contextual fear conditioning, and decreased Aβ and tau pathology. The decrease in Aβ was caused by selective activation of ADAM17, a protein with α-secretase properties and the reduction in tau pathology was due to a decrease in GSK3β activity decreasing tau protein kinase activity (Caccamo et al. 2006).

**Other Indirect Cholinergic Enhancing Strategies**

Various methods of indirect cholinergic enhancement included DuP 996 (linopirdine) that enhances the presynaptic, potassium-mediated release of acetylcholine, ondansetron, a 5-HT3 antagonist, may act as a cholinergic facilitator, enhancing acetylcholine release, and various partial nicotinic agonists. Despite interesting preclinical rationales these drugs have not shown clinical effectiveness (Rockwood et al. 1997, Dysken et al. 2002).

**Nicotinic Agonists**

Nicotinic acetylcholine receptors (nAChRs) are reduced in the hippocampus and the temporal and frontal cortex as an early phenomenon of patients with AD compared to age-matched controls (Nordberg 2001). Nicotine can improve memory, cognition, and attention in AD patients; and a nicotinic antagonist produces the opposite effect (Newhouse et al. 2001). Because nAChRs are found in both the CNS and PNS, nicotine usefulness is limited by the extent of its peripheral and parasympathetic effects. Therefore efforts have focused on development of a selective CNS nicotinic agonist, active at the α4β2 subtype of nAChRs, because of high densities of these receptors in brain regions involved in memory processes and AD (Nordberg 2001).

Ispironicine (TC-1734, AZ 3480) is a partial nAChR agonist with a high affinity and selectivity for the α4β2 subtype. A phase I study showed it to be tolerable, with dizziness and headache being reported as the most frequent adverse events (Dunbar et al. 2006). A Phase II study was completed in 2006, the results are currently unpublished. According to the manufacturer’s Web site, this study enrolled 193 subjects with age-associated memory impairment for 16 weeks in which there was significance in cognitive measures. The drug was reportedly well tolerated (www.targacept.com).

The α-7 nAChR subtype has also received particular attention (Mazurov et al. 2006). There are a number of α-7 nicotinic agonists in development including MEM 3454, SSR 180711C, PH-399733 and GTS-21 currently in phase II trials.

**ChIs**

Table 107–2 presents the aspects of ChIs. Modest, significant, and reliable improvement in memory was produced in early trials of the acetylcholinesterase (AChE) inhibitor, physostigmine (Christie et al. 1981, Davis and Mohs 1982, Mohs et al. 1985, Stern et al. 1987), but it caused adverse reactions and required frequent dosing. Early success with dosage-individualization (Jorm 1986) led to multicenter trials of the ChIs tacrine, velnacrine, and sustained-release physostigmine (Antuono 1995, Davis et al. 1992, Thal et al. 1996), and subsequently provided the rationale and justification for larger clinical trials, and eventual approval and marketing of several ChIs.

Tacrine was the first ChI approved for treatment of AD, but it is no longer actively marketed. The newer ChIs...
donepezil, rivastigmine, and galantamine are currently used in clinical practice. Other ChIs are under development including phenserine, huperzine A, ZT-1 (a pro-drug of huperzine A), ladostigil, bisnorcymserine. Phenserine is a long-acting ChI that additionally is thought to have properties that reduce Aβ levels (Haroutunian et al. 1997). In an unpublished, small sample size, 6-month trial (unpublished), this drug did not achieve statistical significance over placebo in cognitive measures. The positive isomer of phenserine has little ChI activity but may decrease the formation of Aβ. Huperzine A is an extract from club moss commonly used as a herbal remedy in Asia and available in the US as a dietary supplement. The optimal dose is unknown, and there have been no definitive trials of safety and efficacy. An NIH-funded trial involving over 200 participants will be completed by early 2006. Ladostigil is a combination ChIs and monoamine oxidase type-B (MAO-B) selective inhibitor, and bisnorcymserine. Phenserine is a long-acting ChI that additionally is thought to have properties that reduce Aβ levels (Haroutunian et al. 1997). In an unpublished, small sample size, 6-month trial (unpublished), this drug did not achieve statistical significance over placebo in cognitive measures. The positive isomer of phenserine has little ChI activity but may decrease the formation of Aβ. Huperzine A is an extract from club moss commonly used as a herbal remedy in Asia and available in the US as a dietary supplement. The optimal dose is unknown, and there have been no definitive trials of safety and efficacy. An NIH-funded trial involving over 200 participants will be completed by early 2006. Ladostigil is a combination ChIs and monoamine oxidase type-B (MAO-B) selective inhibitor, and bisnorcymserine is a selective butyrylcholinesterase inhibitor.

**Mechanisms of Cholinesterase Inhibition**

Acetylcholine is inactivated when it is hydrolyzed to choline and acetate by AChE. By inhibiting the actions of AChE, ChIs effectively increase the amount of ACh available for intrasynaptic cholinergic receptor stimulation. Butyrylcholinesterase (BuChE), another central enzyme that hydrolyzes ACh, is being targeted for AD therapy. AChE-positive neurons diffusely project to the cortex and are thought to modulate cortical processing and responses to new stimuli; BuChE-positive neurons project principally to the frontal cortex and might have a role in influencing attention, executive function, emotional memory, and behavior (Lane et al. 2006).

An AChE inhibitor can work at either of two sites on AChE, an ionic subsite or a catalytic esteratic subsite to prevent the interaction between ACh and AChE. Tacrine and donepezil act at the ionic subsite. Rivastigmine acts at the catalytic esteratic subsite (Enz and Floersheim 1997). Galantamine acts at both the ionic site and catalytic binding site (Lane et al. 2006). Donepezil and galantamine are relatively selective for AChE (Brufani and Filocamo 1997) whereas tacrine and rivastigmine inhibit both AChE and BuChE. Binding to the AChE sites may be either reversible or irreversible, and may be competitive or noncompetitive with acetylcholine. Galantamine is an example of a competitive ChI, competing with acetylcholine for AChE.

In addition, AChE is present in a few molecular forms containing one (monomeric G1), two (dimeric G2), or four (tetrameric G4) catalytic subunits. The G1 and G4 forms are present in the human brain, varying in proportion in different brain regions (Atack et al. 1986). The tetrameric G4 is located on the presynaptic membranes within the cholinergic synaptic cleft; the monomer G1 is found on postsynaptic membranes. While G4 is decreased along with the neuronal loss of presynaptic cholinergic neurons, postsynaptic cholinergic receptor neurons and G1 ACh are not decreased significantly with AD or aging (Enz and Floersheim 1997). Similar to AChE, BuChE exists in G1, G2, and G4 molecular forms, with a preponderance of the G4 isoform in the brain (Arendt et al. 1992). The BuChE monomeric G1 increases by 30−60% in the AD brain whereas the BuChE tetrameric G4 isoform decreases or remains the same. Thus, investigations of ChI should consider the molecular form-specific characteristics of AChE and BuChE inhibition. Rivastigmine is a ChEI that is highly selective for the postsynaptic G1 monomer form of AChE, while galantamine is less so, and donepezil is not.

A summary of pharmacokinetics and pharmacodynamics is in Table 107–3.

### Individual ChIs—Clinical Studies, Dosing, and Adverse Effects

Despite the slight variations in the mode of action of the three clinically available ChIs (Table 107–4) for treatment...
of AD, there is no evidence of meaningful difference among them with respect to efficacy (Birks, 2006).

**Tacrine**
Tacrine is a noncompetitive reversible inhibitor of ChE. It binds near the catalytically active site of the AChE molecule to inhibit enzyme activity, and has other actions as well (Adem et al. 1990). Two clinical trials resulted in FDA approval of tacrine in 1993 (Farlow et al. 1992, Knapp et al. 1994), demonstrating tacrine’s significant effect on the ADAS (Alzheimer’s Disease Assessment Scale) cognitive subscale assessment and on measures of daily function. Tacrine is no longer actively marketed due to a high incidence of hepatotoxicity and frequent dosing schedule.

**Dosing.** The recommended starting dose is 10 mg q.i.d. to be maintained for 6 weeks, while serum transaminase levels are monitored every other week. If the drug is tolerated and transaminase levels do not increase above three times the upper limit of normal, the dose is then increased to 20 mg q.i.d. After 6 weeks, dosage should be increased to 30 mg q.i.d., again with biweekly monitoring and then, if tolerated, to 40 mg q.i.d. for the next 6 weeks.

**Donepezil**
Donepezil is a long-acting piperidine-based highly selective and reversible AChE inhibitor. Two phase III clinical trials (Rogers et al. 1998a, 1998b) resulted in FDA approval for early to moderate stages of AD in late 1996. Subsequent randomized clinical trials have included a trial of 6 months duration (Burns et al. 1999), a Scandinavian study of 12 months (Winblad et al. 2001), a study of nursing home patients (Tariot et al. 2001), a trial assessing functional decline (Mohs et al. 2001) and a 6-month trial in which a large proportion were more severely impaired than in previous trials (Feldman et al. 2001).

Two 24-week clinical trials conducted in nursing home patients in Sweden (Winblad et al. 2006) and outpatients in Japan (Homma et al. 2000) with severe AD (MMSE 1-10) provided sufficient cognitive and global efficacy for the FDA to approve donepezil for this indication in 2006. Donepezil is the only ChI indicated for severe AD.

A trial sponsored by the UK’s Medical Research Council confirmed the modest benefits in cognition and activities of daily life over a 2-year period with a modal donepezil dose of 5 mg/day. However, it did not demonstrate that donepezil delayed time to nursing home placement or progression of disability (Courtney et al. 2004). Despite methodological limitations, the trial results undermined assumptions that such improvements in cognition and daily activities translated to cost-effectiveness of treatment or a meaningful delay in institutionalization.

Donepezil may decrease the rate of hippocampal atrophy in AD suggesting a neuroprotective mechanism (Hashimoto et al. 2005).

**Dosing/Formulation.** Donepezil is initiated at 5 mg/day and then increased to 10 mg/day after 4–6 weeks. Raising the dose earlier increases the risk for cholinergic adverse events. Five or 10 mg/day are effective doses; 10 mg tends to be somewhat more effective and to have more adverse effects than 5 mg when the various trials as a group are evaluated.

**Table 107–3 Pharmacodynamic and Pharmacokinetics of Marketed ChIs**

*Note: Pharmacodynamic effects of some ChIs are longer than their elimination half-lives. Drugs that inhibit or induce the cytochrome enzymes above might be expected to increase or decrease blood levels. For the most part, clinically however, drug interactions with donepezil, rivastigmine, and galantamine have not been clinical problems.*
Donepezil is also available as an oral disintegrating tablet avoiding the need to swallow tablets.

**Rivastigmine**

Rivastigmine is a pseudo-reversible, selective AChE subtype inhibitor. Although it inhibits butyrylcholinesterase as well, it is relatively selective for the postsynaptic G1 monomer form of AChE in areas of the cortex and hippocampus. After binding to AChE, the carbamate portion of rivastigmine is slowly hydrolyzed, cleaved, conjugated to a sulphate and excreted. Thus, its metabolism is essentially extra-hepatic and is unlikely to have significant pharmacokinetic interactions.

Four phase III randomized, placebo-controlled, 26-week-long clinical trials were completed of similar design, but differing mainly in dosing methods. Two have been published (Corey-Bloom et al. 1998, Rosler et al. 1999). Some results of the third have been included in secondary reports (Birks et al. 2000, Schneider 2002, Schneider et al. 1998, Spencer and Noble 1998).

In the two published trials, doses were titrated weekly during the first 7 weeks to one of two dosage ranges, 1–4 mg/day or 6–12 mg/day, and dose decreases were not permitted, possibly contributing to lesser tolerability and seemingly more side effects during these stages of treatment.

*All trials included only patients with probable AD (NINCDS-ADRDA criteria) or dementia of Alzheimer's type (DSM-IV-TR criteria), and generally with baseline MMSE scores between 10 and 26 inclusive, except for the galantamine trials that used narrower ranges of 10–22 and 11–24.

**Note:** Rounded to two figures. All trials had 58–64% female subjects except for tacrine (Knapp et al. 1994, 53%), and donepezil nursing home trial (Tariot et al. 2001, 82%). Dropouts are for all reasons to avoid bias; not just those attributed to side effects.

A 6-month, multicenter trial of transdermal rivastigmine showed that the patch provided similar benefits to oral rivastigmine at lower doses but with fewer side effects, with similar side effect burden at higher doses (Winblad et al. 2007).

**Dosing/Formulation.** The recommended starting dose of rivastigmine is 1.5 mg b.i.d., taken with meals, increasing to 3 mg b.i.d. after a minimum of 2 weeks of treatment if the initial dose is well tolerated. Subsequent increases to 4.5 mg and then 6 mg b.i.d. should be based on good tolerability with the previous, dose and may be considered after a minimum 2-week treatment interval. Higher daily doses, averaging about 9–10 mg were associated with better efficacy than lower doses. It is available as an oral solution. Transdermal rivastigmine is started with an initial 4.6 mg patch per day for at least 4 weeks before the dose is raised to a 9.5 mg patch per day maintenance dose, based on good tolerability with the previous dose.

**Galantamine**

Galantamine, an alkaloid originally extracted from Arum plant (Arum maculatum, the Roman arum), but now synthesized, is a reversible, competitive inhibitor of AChE with relatively little butyrylcholinesterase activity.
(Harvey 1995). Competitive inhibitors compete with ACh at AChE binding sites, so their inhibitions is, theoretically, dependent on intrasynaptic ACh. Another characteristic is its allosteric modulation of nicotinic receptor sites, thus possibly enhancing cholinergic transmission by presynaptic nicotinic stimulation (Maelicke et al. 2001).

Four multicenter trials, involving over 2,400 subjects (Raskind et al. 2000, Tariot et al. 2000, Wilcock et al. 2000, Rockwood et al. 2001), and a systematic review (Loy and Schneider 2006) have been published. The results of two trials indicated that treatment with either 24 or 32 mg/day galantamine improved cognition, clinician’s global assessment of change, and ADL scores, with lesser adverse effects at the lower dose. The results of the third showed that daily doses of 16 mg or 24 mg were effective, and 8 mg was not.

**Dosing/Formulation.** Initial dosing of the original formulation of galantamine is 4 mg b.i.d., and should be raised to 8 mg b.i.d. after 2–4 weeks. For patients who are tolerating medication but not responding the dose can be raised to 12 mg b.i.d. after another 4 weeks. The FDA approved galantamine in April 2001 under the trade name Reminyl™. Due to confusion with the diabetes medication glimepiride (Amaryl™), in 2005, the trade name Reminyl™ was changed to Razadyne™. An extended release formulation of galantamine (Razadyne ER™) was subsequently FDA approved for once daily use (Brodaty et al. 2005). The extended release formulation of galantamine is started at 8 mg/day and increased to 16 mg/day after 4 weeks. After 4 weeks, the dose can be further increased to 24 mg/day based upon clinical benefit and tolerability. The Cochrane Database of Systematic Reviews indicate that 16 mg/day showed statistically indistinguishable efficacy from higher doses (Loy and Schneider, 2006).

**Adverse Effects of ChIs**

Adverse events of the marketed ChIs are summarized in Table 107–5. Significant cholinergic side effects can occur in up to about 25% of patients receiving higher doses. Often they are related to the initial titration of medication. Patients tend to rapidly become tolerant to the adverse events when they occur. Nausea, diarrhea, vomiting, and weight loss are the most common side effects of the ChIs. Few trials have directly compared ChIs. One comparing donepezil and rivastigmine showed more frequent adverse events associated with rivastigmine during the titration phase but similar frequencies as donepezil in the maintenance phase (Bullock et al. 2005). Two clinical trials testing galantamine in MCI showed an increased mortality rate in the galantamine group (1.5%) compared to placebo (0.4%) leading to an FDA alert (http://www.fda.gov/cder/drug/InfoSheets/HCP/galantamineHCP.htm). However, two clinical trials testing donepezil and one with rivastigmine in MCI did not show an increase in mortality compared to placebo (Salloway et al. 2004, Petersen et al. 2005, Feldman et al. 2007). A donepezil trial in vascular dementia also showed an increased incidence of deaths in one trial (10 vs 0) but not in two others (Kavirajan and Schneider, 2007).

Because of the actions of ChIs, these drugs require caution when used in patients with significant asthma, significant chronic obstructive pulmonary disease, cardiac conduction defects, active peptic ulcers, or clinically significant bradycardia. Appropriate considerations are involved in general anesthesia as well since they may prolong the effects of succinylcholine-type muscle relaxants.

Adverse event estimates vary widely among the ChIs from study to study and thus relative adverse event rates among drugs are difficult to estimate. Cholinergic side effects generally occur early and are related to initiating or increasing medication. They tend to be mild and self-limited. Medications should be restarted at the lowest doses after temporarily stopping. See prescribing information referenced in Table 107–2.

**General precautions with ChIs** (as indicated in the prescribing information)

By increasing the central and peripheral cholinergic stimulation, ChIs may:

1. increase gastric acid secretion, increasing the risk for GI bleeding especially in patients with ulcer disease or those taking anti-inflammatories
2. produce bradycardia, especially in patients with sick sinus or other supraventricular conduction delay, leading to syncope, falls, and possible injury
3. exacerbate obstructive pulmonary disease
4. cause urinary outflow obstruction
5. increase risk for seizures
6. prolong the effects of succinylcholine-type muscle relaxants

**Drug interactions may include increased cholinergic effects with bethanacol; increased plasma tacrine levels with cimetidine or fluvoxamine. This may occur by inhibition of P450 1A2. The association of tacrine with haloperidol may increase parkinsonism and tacrine increases theophylline concentration.**

transaminases and then were rechallenged, were able to tolerate and continue medication (Watkins et al. 1994).

Common adverse effects related to cholinergic mechanisms are dose-related and include: nausea and/or vomiting in 28% of patients versus 8% in the placebo group, diarrhea in 16% versus 5%, anorexia in 9% versus 3%, myalgia in 9% versus 5%. Tacrine is not tolerated in about 10−20% of patients because of such peripheral cholinergic effects (Prescribing Information, October 2000). Due to the high side effect profile including hepatotoxicity, with the advent of newer ChIs for AD treatment, tacrine fell out of favor and is generally no longer used.

Donepezil
The most common gastrointestinal side effects of donepezil include nausea, vomiting, diarrhea, and anorexia. Some patients develop muscle cramps, headache, dizziness, syncope, flushing, insomnia, weakness, drowsiness, fatigue, and agitation. Weight loss of >7% of baseline occurred at twice the rate of placebo in the nursing home study, but not in outpatient trials. Adverse effects occur at higher rates when the titration from 5−10 mg was made in 1 week compared to 6 weeks.

Rivastigmine
Adverse effects are primarily gastrointestinal and occurred in the high-dose (6−12 mg/day) group. They occurred mainly during dose escalation and led to withdrawal in one study in 23% of the high-dose group, 7% of the low-dose group and 7% of the placebo group. Inclusion criteria for these clinical trials allowed for patients with a broad range of medical comorbidities to be entered into the studies, perhaps partially explaining the relatively high adverse event rate. Also, the protocols did not allow for the medication dose to be decreased in patients who developed adverse events during the titration period.

Adverse effects in the higher dose group were sweating, fatigue, asthenia, weight loss, malaise, dizziness, somnolence, nausea, vomiting, anorexia, and flatulence. In the maintenance phase, dizziness, nausea, vomiting, dyspepsia, and sinusitis occurred more in the 6−12 mg/day group than in the placebo group. The FDA approval letter requested that the manufacturer do further analyses to better characterize these effects, especially weight loss and anorexia.

Galantamine
Principal adverse effects are nausea, vomiting, diarrhea, anorexia, weight loss, abdominal pain, dizziness, and tremor. Again, adverse events were more frequent earlier in the course of treatment and during the dosage titration from 16−24 mg/day and higher. In one trial the effective dosage of 16 mg/day was not associated with overall greater adverse events than the placebo-treated group. According to the Cochrane Database of Systematic Reviews, doses of 16 mg/day when titrated over a 4-week period were best tolerated. (Loy and Schneider, 2006)

Particular Adverse Events with Chls
An increased but modest incidence of anorexia appears to be a consistent finding across clinical trials and appears to be dose related. The absolute reported incidence varies across trials from approximately 8−25% at the highest dose of Chl compared to 3−10% in comparable placebo patients. Similarly, there is an increased rate of significant weight loss with higher doses of Chls compared to placebo patients. The proportion of patients losing greater than 7% of their baseline weight varies from approximately 10−24% in the higher doses and from 2−10% of the placebo-treated patients in those trials reporting the statistic. Anorexia and weight loss are significant clinical problems for many elderly patients independent of medication effects, and whether or not demented.

Cholinergic side effects such as diarrhea, nausea, and vomiting, tend to occur at initiation of treatment and when titrating to higher doses. They may be transient or self-limited and can often be managed with encouragement and maintenance of the present dose level, by omitting one or more doses, or by temporarily decreasing dosage. However, anorexia and weight loss may be clinically significant problems over the longer term, especially in older, more medically ill, and nursing home patients, so these parameters should be monitored.

Uncommonly, the vagotonic effects of Chls may cause significant bradycardia, and this can be a particular concern to patients with supraventricular conduction impairments or sick sinus syndrome.

Because gastric acid secretion may be increased with ChIs, there may be an increased risk for developing ulcers or gastrointestinal bleeding. Uncommonly, Chls may cause bladder outflow obstruction, seizures, and exacerbate asthma or obstructive pulmonary disease, and interfere with succinylcholine-like anesthetics.

Glutamatergic Therapies
The N-methyl-d-aspartate (NMDA) receptor, a glutamate receptor subtype, has important effects in learning and memory. Stimulation by the excitatory amino acid glutamate results in long-term potentiation of neuronal activity basic to memory formation (Cotman et al. 1988). There appears to be a decrease in cerebral cortical and hippocampal NMDA receptors in AD. Glycine, acting as an adjoining glycine-B receptor, modulates the effects of glutamate. Milacemide, a produg that readily crosses the blood–brain barrier where it is converted to glycineamide and glycine, although effective at facilitating various aspects of memory in animal models, did not significantly improve any efficacy parameter in a multicenter trial in 228 AD patients (Dysken et al. 1992).

Memantine
Memantine is an uncompetitive NMDA antagonist that binds to the NMDA receptor-operated cation channels and may act by inhibiting calcium ion influx thus modulating the excitotoxicity. Memantine also acts as an uncompetitive antagonist at the 5HT1 receptor but the clinical significance of this is unknown (Rammes et al. 2001). The FDA approved memantine for moderate to severe AD in 2003. Three randomized placebo controlled trials have shown benefits over placebo in moderate or severe AD on several measures. Two studies, one of which evaluated participants who were being treated with donepezil, showed significant improvements on the SIB, the modified ADCS-ADL Scale, and the Clinician's Interview-Based Impression of Change Plus Caregiver Input (CIBIC-Plus) global score (Reisberg et al. 2003 and Tariot et al. 2004). A fourth 6-month trial...
in moderate to severe AD did not show significant effects in favor of memantine. (The SIB assesses attention, orientation, language, memory, and social interactions)

The third study, conducted in nursing homes in Latvia showed a significant advantage of memantine over placebo in the Behavioral Rating Scale for Geriatric patients (BGP), which assessed day-to-day functioning and a global impression of change (Winblad and Poritis, 1999). Another 6-month-long placebo-controlled trial in moderate to severe AD outpatients did not show advantages for memantine (Van Dyck et al. 2007).

Three trials evaluated memantine in mild to moderate AD. Two of the three failed to show advantages for memantine on cognitive, global, functional or behavioral outcomes (www.forestclinicaltrials.com; unpublished data, 99679, data on file, H. Lundbeck A/S, 2004; unpublished data, Peskind et al. 2006). According to the Cochrane Database of Systemic Reviews, pooled data on memantine in mild to moderate AD show a marginal beneficial effect at 6 months that was clinically insignificant with no effect on data or ADLs (McShane et al. 2006) and the drug is not FDA approved for mild AD.

There is no evidence that memantine prevents or slows neurodegeneration in AD, although preclinical evidence suggests that this may be a possibility. Second generation NMDA receptor antagonists are currently in development including delucemine, which is currently in a phase I study, and neramexane which is in phase II clinical trials.

**Dosing**

Memantine is available in tablet and oral solution form. Treatment is initiated with 5 mg/daily for one week and increased by 5 mg/daily in divided doses to a maintenance dose of 10 mg twice a day. The nursing home trial in Latvia showed efficacy with 10 mg/day doses.

**Adverse Effects**

Significant side effects can include dizziness, constipation, headache, and confusion. Generally, memantine is well tolerated, and is thought to have low potential for drug interactions.

**AMPA Receptor Modulators**

The α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptor is a non-NMDA-type ionotropic transmembrane receptor for glutamate found in many parts of the brain. These receptors are thought to be integral to encoding memory. A class of drugs called ampakines has been developed which augments the AMPA receptor ionic current flow, enhancing fast, excitatory synaptic responses. Several animal studies have shown improved encoding of memory in rats in many paradigms including spatial cues, odor discrimination, and cue matching (Ingvar et al. 1997). The ampakine CX516 appears to have a possible positive affect on delayed recall of nonsense syllables (Lynch et al. 1996). In another study in normal healthy adults, this drug showed some improvement in some aspects of memory including visual associations, recognition of odors, and acquisition of a visuospatial maze (Ingvar et al. 1997). CX516 is currently under investigation for AD and is also being tested for treatment of schizophrenia, fragile X syndrome and autism.

LY450108 and LY451395 are biarylsulfonamides, a new class of centrally acting AMPA receptor potentiatators. Doses of 1 mg and 5 mg have crossed the blood brain barrier and appeared well tolerated in healthy subjects (Jhee et al. 2006). The biarylsulfonamides are currently in early phase clinical trials.

**Treatment Approach with Approved Compounds**

Optimal duration of treatment with approved compounds is unknown but overall efficacy extends at least 9−12 months based on the clinical trials and open-label extension phases. Maintenance treatment can be continued as long as a therapeutic benefit for the patient seems apparent. The potential clinical benefit should be reassessed on a regular basis. Discontinuation should be considered when evidence of a therapeutic effect is no longer present. It is difficult to assess individual patient response because of the variability of the deteriorating course of AD, and because most of the effect of medication is due to a stabilization or lack of worsening of symptoms or cognitive function while placebo-treated patients continue to decline. Therefore, the clinical observations of minimal or no clinical worsening may be sufficient reasons to continue medication treatment if patients are tolerating therapy.

**Effect on Behavior**

The evidence that ChIs may improve behavior is based on case series and secondary analyses of efficacy trials (Kauf er et al. 1996, Raskind et al. 1997). Patients enrolled into ChI trials were selected largely on the basis of their ability to cooperate; they are not generally agitated, psychotic, or depressed. There is little consistency in the subscales of the behavioral rating instruments that might improve from study to study. For example, in two trials each there was a significant effect on the hallucination or aberrant motor behavior items and in one trial each on agitation or apathy. One prospective clinical trial with donepezil in patients with AD and significant psychopathology was designed as a withdrawal trial (Holmes et al. 2004) in which patients received open label donepezil for 3 months and were then randomized to either placebo or donepezil. The placebo group showed relative worsening of behavior.

Clinical experience suggests that they may be effective at least for mildly disturbed behavior, and in delaying the onset of troublesome behaviors, perhaps by maintaining cognitive function or perhaps through enhancing attentional processes and activation. However, there was no effect on behavior in any of the three donepezil trials in severe AD; and a trial targeting patients with severe AD and significant behavioral disorder also found no significant effect with donepezil on behavioral symptoms (Howard et al. 2007).

Memantine showed beneficial effects on behavior in one (Tariot et al. 2004) of three trials in moderate-severe AD (Reisberg et al. 2003), and inconsistent and nonrobust effects in patients with mild-moderate AD (McShane et al. 2006).

**Other Neurotransmitter Based Approaches**

Structural and functional disturbances of central cat echolaminergic systems in AD and their important role in brain-related functions provide the rationale for
pharmacological enhancement of these systems. The general strategies employed are analogous to those used with cholinergic agents: precursor loading, inhibition of degradative enzymes, and use of agonists. Studies of dopamine precursors (e.g., with tyrosine, L-dopa) and agonists (e.g., clonidine, guanfacine, amantadine, bromocriptine) have largely been negative (Schneider and Tariot 1997).

At a dose of up to 10 mg/day, selegiline relatively selectively inhibits MAO-B. The overall effect of selegiline at this dose may be to increase CNS levels of dopamine and some trace neurotransmitters such as phenylethylamine without affecting norepinephrine levels. Selegiline is currently marketed for the treatment of Parkinson’s disease for which it has demonstrated effects in maintaining motor function (Parkinson Study Group 1993). Selegiline also may have potential to preserve surviving neurons (Tatton 1993). Elevated levels of MAO-B, found in the brains of patients with AD, might lead to elevated levels of neurotoxins such as 6-hydroxydopamine, quinones, and free radicals, or even environmental toxins. In either case, inhibition of monoamine oxidase (MAO) on a chronic basis could theoretically retard progression of the illness based on antitoxic mechanisms. Finally, selegiline may have neuronal “rescue” effects, based on neurotrophic-like properties not involving MAO inhibition. It is notable that rodents and dogs treated with selegiline have increased survival (Knoll 1988, Milgram et al. 1990, Ruehl et al. 1997).

Numerous clinical trials with selegiline have been performed, with variable results and insufficient evidence to justify routine clinical use in AD (Burks and Flicker, 2003). One multicenter trial found that selegiline, 5 mg b.i.d., both alone and combined with vitamin E, 1,000 IU b.i.d., was associated with maintenance of ADLs and survival in the community compared to placebo in moderately to severely impaired AD patients but with no improvement in cognition (Sano et al. 1997).

Other MAO-B inhibitors under development include rasagiline and safinamide. Ladostigil combines MAO-B inhibition with cholinesterase inhibition in a single molecule, is in phase II trials, and is neuroprotective in neuronal cell cultures, possibly due to the S-isomer (Youdim et al. 2006).

Histamine

The H3 histamine receptor is thought to play a role in control of arousal and cognition. Cortical histamine levels are significantly reduced in brains of patients with AD (Panula et al. 1998). Mounting evidence suggests that H3 receptor antagonists may improve cognition in AD. Preclinical tests have shown increased performance in attention and memory tasks whereas H3 receptor agonists have produced a decline in cognitive function (Witkin and Nelson 2004). At least two drugs that affect CNS histamine are currently in clinical trials.

One of these is dimebon, which had been approved in Russia as an antihistamine since the early 1980s but is not currently available. It is under investigation as a therapy for AD and Huntington’s disease. Dimebon was thought to block the histamine binding site of the NMDA receptor, thus modulating activity of the NMDA receptors (Grigoren et al. 2003), and also inhibits AChE, but these effects occur at concentrations outside the human therapeutic range. Animal studies (Lermontova et al. 2000), and an in vitro study suggested improved survival of cerebellar granule cells during long-term incubation with Aβ (Lermontova et al. 2001). Thus, its mechanism of action must be considered unknown at present. According to the manufacturer’s website, a 6-month, randomized, double-blind, placebo-controlled trial, conducted in Russia, that included 183 patients with mild to moderate AD, showed significant improvement on cognition, global assessment, ADL, and behavior compared to placebo.

Somatostatin

Somatostatin is a neuropeptide that is believed to play a role in learning and memory (Schettini, 1991 and Matsuoka et al. 1995). Some studies have shown a correlation between an impairment in somatostatin-mediated neurotransmission in the brain and AD (Davies et al. 1980 and Bissette and Myers, 1992). FK960 is a synthetic compound that enhances somatostatin release and has been shown to improve memory in animal models of amnesia (Yamazaki et al. 1996 and Matsuoka and Aigner, 1997). FK962 was developed to further optimize the pharmacological action and pharmacokinetic properties of FK960, and was shown to be beneficial in animals (Tokita et al. 2005). This compound completed phase I and II testing, but showed no efficacy in AD.

Neurotrophic Factors

Nerve Growth Factor (NGF)

NGF, a trophic factor for cholinergic neurons, may target forebrain cholinergic neurons that release the majority of acetylcholine in the cortex and hippocampus. Profound degeneration of these cells is thought to contribute to cognitive decline in AD. Because NGF does not cross the blood-brain barrier, it was directly infused into brain ventricles in a study that was terminated prematurely due to significant adverse events including weight loss and pain. Additionally, animal studies of intraventricular NGF showed abnormal axonal sprouting of sympathetic nerves and migration of Schwann cells into the subpial space surrounding the brainstem and spinal cord forming a dense sheath (Tuszynski 2002).

Subsequently, a trial introducing the actual NGF gene was performed (Tuszynski et al. 2005) by engineering patient’s own fibroblasts to produce human NGF, and then to stereotactically inject the cells into the nucleus basalis. The first two patients had serious brain hemorrhages resulting in death in one patient due to movement during the injection procedure. These patients were alert but sedated for the procedure. There were no surgical complications in the following 6 patients, as the surgery was performed under general anesthesia. Patients were followed for 18–24 months. One patient developed two syncopal events, possibly related to the procedure. Two of six subjects showed improved MMSE scores, one showed no decline, two showed minor decline, and one had a large decline. Compared to historical controls, rates of decline in the ADAS-Cog also showed improvement. PET scans in four patients showed significant increases in FDG uptake rather than the usual decline observed in AD. Increases were observed in most cortical regions receiving cholinergic input from the nucleus basalis. Brain autopsy in one patient who died showed...
survival of the implanted autologous fibroblasts with little evidence of inflammation. In situ hybridization for messenger RNA encoded NGF showed robust NGF expression by the transplanted fibroblasts. Immunocytochemistry showed sprouting of cholinergic axons in and around the transplant site. The absence of controls and the small number of patients preclude conclusive evidence; however, this trial serves as an impetus for future studies in gene therapy. A new gene delivery method using adeno-associated virus (AAV) is currently completing a phase I trial, and a phase II trial is in the planning stages.

Other Trophic Factors

Cerebrolysin

Cerebrolysin is a synthetic compound comprised of neurotrophic peptides from the porcine brain that has been found to reduce amyloid burden and improve synaptic plasticity in transgenic mice (Rockenstein et al. 2003). It is thought to regulate APP maturation and transport to sites where Aβ protein is generated (Rockenstein et al. 2006). In an initial placebo-controlled trial, small improvements in ADAS-cog scores and global assessments of severity were seen (Reuther et al. 2001). A second randomized trial of 192 patients did not find significant effects on the severity of the ADAS-Cog but did on global assessment (Panisset et al. 2002); a third observed improvements on ADLs (Muresanu et al. 2002).

Leteprinim

Leteprinim (AIT-082) is a derivative of the purine hypoxanthine that is thought to stimulate the production of several neurotrophic factors (Glasky et al. 1994, 2001). A one-week phase I randomized, double-blind, placebo-controlled, dose escalation trial randomized 36 patients to one of three different dose groups. It was safe and well tolerated, but there were no improvements in cognitive testing (Grundman et al. 2003). A phase II trial was completed but no results were reported.

Xaliproden

The compound xaliproden (SR57746A) mimics the neurotrophic effect of NGF in cell cultures (Fournier et al. 1992). In rats with a vincristine-induced septohippocampal lesion, which is thought to serve as a model forebrain cholinergic neuron and memory deficits, xaliproden reversed the reduction in hippocampal ChAT. There was a significant improvement in the behavioral impairments observed (Fournier et al. 1993). Two phase III clinical trials of 18 months duration were recently completed but results have not been reported.

Paliroden

Paliroden (SR57667B) has been found to be neuroprotective and neurotrophic in both in vitro and in vivo models. In the intra-septal vincristine lesion model in rats, this compound was found to activate migration of neural stem cells from the lateral ventricle with increased numbers of these cells reaching the lesioned site and differentiating into neurons (Labie et al. 2006). This compound is currently in a phase II clinical trial, and is also being tested for Parkinson’s disease.

MK-0677

MK-0677 is a compound that induces secretion of insulin-like growth factor-1 (IGF-1). In a 1-year study (unpublished), 563 AD patients were randomized to MK-0677 or placebo daily. Although MK-0677 increased IGF-1 serum levels by 60%, the primary endpoints of the CIBIC-plus and ADAS-Cog scales showed little change. Secondary endpoints were also did not show significance.

Estrogens

Estrogens may have cholinergic neurotrophic and neuroprotective effects and may enhance cognitive function (Simpkins et al. 1994). In ovariectomized rats, estradiol replacement enhanced learning; reversed the decrease in neuronal choline uptake and ChAT caused by ovariectomy; prevented the ovariectomy-associated decline in NGF and in brain-derived neurotrophic factor mRNA.

Clinical trials of conjugated equine estrogens (CEE) to improve cognition in both hysterectomized and nonhysterectomized women with AD have not led to success, and indeed women treated with CEE somewhat worse both in cognition and safety including 5% developing deep vein thrombosis (Henderson et al. 2000, Mulnard et al. 2000).

The Women’s Health Initiative Memory Study (WHIMS), a randomized, double-blind, placebo-controlled clinical trial, examined whether postmenopausal CEE supplementation (both CEE alone and estrogen plus progesterin) reduces the risk of all-cause dementia (primary outcome) and subclinical (mild) cognitive impairment (secondary outcome) in healthy women aged 65 years or older (Shumaker et al. 2003). (CEE plus progesterin was associated with increased risk for heart disease, stroke, pulmonary embolism, and breast cancer). CEE alone and CEE plus progesterin therapy increased the risk for probable dementia in postmenopausal women aged 65 years or older and did not prevent MCI. These outcomes do not preclude the possibility for a beneficial effect of estrogens for younger women.

Glucocorticoid Antagonists

Mifepristone, a glucocorticoid II receptor antagonist also known as RU-486, has received wide media attention because it is used to terminate intrauterine pregnancies and as an emergency contraceptive. Abnormalities in the hypothalamic pituitary adrenal axis have been implicated in the pathophysiology of AD, and a correlation has been shown between increased plasma cortisol with cognitive decline and hippocampal atrophy (Lupien et al. 1998). It was thus hypothesized that mifepristone, a long-acting antagonist of progesterrone and glucocorticoid receptors, may be useful for treatment of AD by countering any effects of exposure to glucocorticoids.

One pilot study randomized nine mild-to-moderate AD patients for a 6-week trial to mifepristone 200 mg or placebo.
but was too small to show effects (Pomara et al. 2002). A larger trial was reported by Corcept, the manufacturers of mifepristone, to not have shown significance but details were not provided.

Prospective neurotrophic proteins thought to promote neurite outgrowth under study include activity-dependent neuroprotective protein (ADNP) and activity-dependent neurotrophic factor (ADNF) as well as short peptide derivatives of these proteins such as ADNF-9 and NAP (Gozes and Spivak-Pohis 2006). AL-108 is an eight amino acid peptide based on NAP tested in a Phase Ia study for AD, and will be tested in Parkinson’s disease as well.

**Metabolic Enhancement**

In view of regional decreases in glucose utilization and abnormal oxidative metabolism, drugs have been employed with the aim of correcting these abnormalities, including ergot alkaloids and nootropics. A discussion of the ergot alkaloids can be found in the previous edition of this book and in a Cochrane systematic review (Olin et al. 2001). Although it was, once, one of the most frequently prescribed medications in the world, it is rarely prescribed now. Numerous clinical trials in various elderly patient groups have not clarified its efficacy or clinical role. Another ergot derivative available in Europe, nicergoline, was associated with significant improvement on some areas such as orientation and attention and has been undergoing clinical testing (Fioravanti and Flicker 2001). Nicergoline, dihydroergotamine, and other ergolines can induce chronic pleural thickening, fibrosis and effusion, however.

**Nootropics**

Piracetam, oxiracetam, pramiracetam, aniracetam, CI 933, and BMY 21502 are pyrrolidone derivatives of γ-aminobutyric acid (GABA). Although they do not appear to have GABA-like effects, they are postulated to have neuroprotective properties. These drugs may also enhance the CNS microcirculation by reducing platelet activity, by reducing adherence of red blood cells to vessel walls, and may stimulate central cholinergic activity. These diverse effects are termed nootropic to indicate the class of drugs that are structurally related to piracetam and may improve learning and memory (Nicholson 1990). Double-blind, multicenter, controlled studies have shown mixed results with piracetam in the treatment of dementia in the elderly (Flicker and Evans 2001, Vernon and Sorkin 1991). Pramiracetam and oxiracetam have been evaluated in large scale multicenter studies with no sufficiently significant clinical effects in dementia. Piracetam is undergoing a clinical trial for MCI.

**Amyloid-Based Interventions**

Significant progress has been made toward developing disease-modifying anti-amyloid therapies producing several promising agents that are now in clinical trials.

**Immunotherapy**

**Active Immunotherapy**

Active immunotherapy introduces an antigen that triggers an immune response. Investigations with AN 1792 in transgenic mice exhibiting CNS pathology similar to AD showed reduced development of amyloid plaques and decreased cognitive decline (Janus et al. 2000). The phase II trial of AN 1792 in humans was terminated early due to the development of a T-cell immune mediated aseptic meningoencephalitis in 18 of 300 (6%) subjects who were randomized to the study drug. A total of 59 subjects (19.7%) developed an antibody response. No significant differences were found between antibody responder and placebo groups for ADAS–Cog, Disability Assessment for Dementia, Clinical Dementia Rating, MMSE, or CGIC.

A subset (n = 11) of antibody responders had CSF analysis showing no change in Aβ levels, but a decrease in tau (Gilman et al. 2005), suggesting the possibility of a reduced rate of cellular degeneration in antibody responders. A series of autopsies of antibody responders showed a markedly reduced number of amyloid plaques compared to patients treated with placebo or active vaccine who did not show high antibody titers (Nicoll et al. 2003; Orgogozo 2006), thus suggesting the possibility that Aβ immunotherapy may reduce plaque burden. Paired MRI scans of antibody responders showed a greater decrease in brain volume and greater ventricular enlargement as compared to placebo with no correlation to cognitive decline. The reasons for these findings are unclear but the authors postulate the role of amyloid removal and fluid shifts.

A second active vaccine, ACC-001, has been developed to induce a highly specific antibody response to Aβ that will hopefully avoid the adverse effects associated with AN 1792, and is in phase II testing. CAD106 is another active vaccine that has recently entered clinical testing. This vaccine is based on the first six N-terminal amino acids of Aβ which is believed to stimulate human B cells without a T-cell response thereby possibly avoiding the adverse effects seen with AN 1792.

**Passive Immunotherapy**

Antibodies are delivered directly, averting the need to mount an immune response; however antibodies have to be given frequently and have a relatively short life span (less than 1 month) as compared to active immunization.

Several different formulations are being studied. The anti-Aβ antibody m266 has been found to restore hippocampal cholinergic dysfunction and impaired learning in APP transgenic mice (Bales et al. 2006). LY206430 is a humanized version of the m266 monoclonal antibody that binds to the Aβ16-23 amino acid region. Data from early human studies are not published yet. Although no significant improvement was measured on the ADAS-Cog, a 150–600-fold increase in plasma Aβ1-40 levels was demonstrated this antibody will be further tested.

AAB-001 (bapineuzumab) is a monoclonal antibody to Aβ currently entering an 18-month-long phase III trials while a phase II trial assessing safety and tolerability with approximately 200 AD patients is ongoing.

Human intravenous immunoglobulin (IVIg), polyclonal antibodies which contain antibodies against Aβ, is currently being studied for therapeutic benefit in AD. In a small pilot study, IVIg was administered monthly for 6 months to 5 patients with AD. The total Aβ levels in the CSF decreased by 30.1%, serum Aβ increased by 233%, and ADAS-cog and MMSE scores essentially stabilized (Dodel et al. 2004). A second open-label pilot study reported similar findings (Relkin et al. 2005) and a placebo-controlled trial is underway.
Secretase Inhibitors

Both β-secretase (β-site APP cleavage enzyme; BACE) and γ-secretase abnormally cleave APP, an early action in the cascade of pathological events. Both enzymes have been targeted for therapeutics as anti-amyloid disease modifying treatments, however, development of this class of compounds has been challenging. BACE inhibitors have yet to be studied clinically as they are large molecules that have difficulty penetrating the blood-brain barrier and the receptor site is difficult to bind (Walker et al. 2005).

The current γ-secretase inhibitors also block the Notch signaling protein, a physiologically essential substrate that acts as an important intermediate in many cellular functions, most notably, the regulation and differentiation of cells in the gastrointestinal tract and immune system. Interference with Notch can result in untoward biological consequences, gastrointestinal adverse events, and is of concern in the development of some γ-secretase inhibitors.

The first γ-secretase to be studied in clinical trials is LY450139. In a phase I trial, 37 healthy adults were randomiz​ed to LY450139 at doses ranging from 5–50 mg. Plasma Aβ concentrations decreased in a dose-dependent manner over a 6-hour interval following drug administration, but transiently increased thereafter. CSF Aβ levels were unchanged (Siemers et al. 2005). A phase II trial randomized 70 patients with mild-to-moderate AD who were on stable doses of Chls. Subjects were given 30 mg of LY450139 for 1 week followed by 40 mg for 5 weeks. There were no changes in CSF concentrations of Aβ during treatment, but a similar pattern of a decrease in plasma Aβ with rebound were found in the serum. No changes in cognitive function were found. Moderate gastrointestinal adverse side effects were reported (Siemers et al. 2006). A follow-up Phase II study has been completed.

Another γ-secretase inhibitor, MK-0752 showed a dose-dependent Aβ40 reduction and was adequately tolerated which has led to the way during an ongoing phase I trial.

Selective Aβ42-Lowering Agents

A subset of nonsteroidal anti-inflammatory drugs (NSAIDs) may have direct Aβ42 lowering properties. In contrast to γ-secretase inhibitors, selective Aβ42-lowering agents (SALAs) do not interfere with physiologically essential substrates such as Notch because they do not bind to the active site. The SALAs allosterically modulate γ-secretase that alter the enzymatic site of action on APP to produce shorter, less toxic Aβ fragments (Beher et al. 2004).

The R-enantiomer of flurbiprofen (R-flurbiprofen, tarenflurbil) has no significant cyclo-oxygenase inhibitory, which is a target of S-flurbiprofen and other NSAIDs. Preclinical animal studies showing improved spatial memory led to a phase I trial in normal volunteers (Gialasko et al. 2004). A 12-month phase II trial of 207 participants with mild-to-moderate AD evaluated two different doses, 400 mg b.i.d. and 800 mg b.i.d. Although there was no overall treatment effect, a post hoc analysis of the patients with mild AD (MMSE 20-26) taking the higher dose showed a statistically significant improvement in cognition and function, and the few patients taking the higher dose and continuing throughout a 1-year open-label extension seemed to have worsened cognitively a little less than expected (Wilcock et al. 2006).

Two phase III 18-month placebo-controlled trials of R-flurbiprofen 800 mg b.i.d. in patients with mild AD are underway with the first to be completed in March, 2008.

Two nitric oxide (NO) releasing derivatives of flurbiprofen, HCT 1026 and NCX 2216, possess anti-amyloidogenic activity in AD models (Gasparini et al. 2005). These drugs consist of a NO-donating moiety coupled to flurbiprofen. When in the presence of cells or tissues, NO is slowly released, mimicking the physiological levels of NO. This NO release is thought to improve the tolerability of the parent drug flurbiprofen (Wallace et al. 2004). In AD transgenic mice models, HCT 1026 and NCX 2216 both reduced cerebral amyloid, and the latter drug was associated with persistent activation of microglia in the peri-plaque areas (Van Groen and Kadish, 2005).

Anti-Aggregation Agents

After APP is cleaved into Aβ fragments, glycosaminoglycans (GAG) bind to the Aβ protein which enables polymerization into amyloid plaques. Agents that interfere with this aggregation process may be therapeutic.

Tramiprosate is a GAG mimetic that binds to Aβ at GAG binding sites, thus reducing Aβ aggregation by thwarting GAG binding (Gervais et al. 2001). A transgenic mouse model of AD showed a dose-dependent reduction of both soluble and insoluble Aβ1-40 and Aβ1-42 levels in the brain and plasma. A phase II study of 58 patients with mild-to-moderate AD demonstrated tolerability over a 3-month period at 3 different doses, and 42 subjects entered an open-label phase for 17 months. The most frequent adverse events were nausea, vomiting, and diarrhea. A dose-dependent reduction in CSF Aβ1-42 levels, but not Aβ1-40 was observed after 3 months; suggesting that the drug is affecting brain amyloid. There were no significant differences in cognition after 3 months (Aisen et al. 2006). A multicenter phase III trial involving two doses and over 1050 patients failed to show efficacy. A second phase III trial is ongoing in Europe.

A second anti-aggregation agent, scyllo-cyclohexanehexol (AZD-103) also shows salutary effects in preclinical studies (McLaurin et al. 2006). Fibril formation due to aggregated Aβ is strongly facilitated by phosphatidylinositolipds. Scyllo-cyclohexanehexol is a phosphatidylinositolipd derivative that competes with the phosphatidylinositolipds for binding to Aβ and interferes with Aβ fibril assembly. An initial phase I study in 12 healthy volunteers suggested the drug was well tolerated, and a second phase I study with higher doses is currently underway.

Metal Chelators

The fibrillation of Aβ is influenced by heavy metal ions, leading to the hypothesis that heavy metal chelators can reduce polymerization. Clioquinol was used for parasitic gastrointestinal disease but removed from the market because it was linked to a rare form of optic nerve damage called subacute myelo-optico-neuropathy (SMON) (Tateishi 2000). It has copper and zinc chelation properties, and reduced brain amyloid in transgenic mice (Cherny et al. 2001). A small phase II study in 36 patients with moderately severe AD did not show evidence of cognitive benefit but did show a decline in plasma Aβ levels (Ritchie et al. 2003). Further development of this drug for AD has been halted due to
concerns regarding toxicity and impurities in the clinical formulation. PBT-2 is another chelator with similar properties as clioquinol is under development.

Colostrinin
Colostrinin, a proline-rich polypeptide found in sheep colostrum inhibits Aβ aggregation in cellular assays through an unknown mechanism (Bilikiewicz and Gaus 2004). A randomized placebo controlled study followed 105 patients for 30 weeks. The first 15 weeks patients were randomized into a double-blind place phase followed by 15 weeks of an open-labeled phase where all patients received colostrinin. There were significant improvements on cognition and daily function measures. It is currently under investigation.

Statins
Epidemiological studies have suggested an association between cholesterol-lowering therapy with the HMG-CoA reductase inhibitors and a lower risk of AD (Jick et al. 2000 and Wolozin et al. 2000). The mechanism underlying this possible relationship is uncertain, but could be related to cholesterol reduction and mediation of inflammatory effects. Another proposed method of action suggests that statins may activate the α-secretase pathway, shifting Aβ processing away from the β-secretase and γ-secretase. The result of increased α-secretase activity translates to increased levels of a less toxic form of Aβ and lower levels of Aβ42.

Simvastatin did not significantly alter CSF levels of Aβ overall although Aβ40 levels were decreased in a post hoc subgroup with mild AD, in a randomized, placebo-controlled, double-blind trial of 44 patients over 26 weeks (Simons et al. 2002). Also a randomized, placebo-controlled trial of atorvastatin in mild-to-moderate AD in 67 patients over 12 months was not statistically significant (Sparks et al. 2005). There are two ongoing placebo-controlled studies of statins that are currently underway, one sponsored by NIA with simvastatin and one by Pfizer with atorvastatin.

Curcumin
This curry spice is a potent antioxidant and has been investigated for possible protective roles in AD inflammatory processes. Curcumin inhibits Aβ40 aggregation in a dose-dependent manner in vitro (Ono et al. 2004); and reduces plaque burden in mice by disaggregating Aβ and preventing fibril and oligomer formation (Yang et al. 2005). Curcumin is currently in clinical trials.

Docosahexaenoic Acid (DHA)
Epidemiological studies suggest a reduced risk of AD associated with fish consumption (Kalmijn et al. 1997 and Barberger-Gateau et al. 2002). DHA is one of the major omega-3 fatty acids found in fish oil, an integral component of neural membrane phospholipids, and the major polyunsaturated fatty acid in the brain (Lauritzen et al. 2001). Data from several animal studies support the use of DHA by means of anti-amyloid, antioxidant, and neuroprotective mechanisms. Safety and tolerability studies (Arterburn et al. 2006) have led the way to a multicenter phase III randomized placebo-controlled study being conducted by the ADCS.

Peroxisome Proliferator-Activated Receptor-γ Agonists
Attention has been placed on insulin modifying therapy in view of the association between AD with elevated plasma insulin levels and reduced insulin sensitivity. Several theories of how insulin may influence AD pathophysiology have been proposed. In animals, insulin was found to facilitate Aβ release from intraneuronal compartments and interfere with degradation of Aβ (Leissring et al. 2003). Insulin may also contribute to cerebral inflammation as increased plasma insulin levels in response to a glucose challenge are associated with elevated inflammatory markers (Hak et al. 2001). Peroxisome proliferator-activated receptor-γ (PPAR-γ) agonists improve insulin sensitivity, and thus is it has been hypothesized that PPAR-γ agonists may protect neurons from the presumed harmful effects of insulin resistance.

Rosiglitazone is a PPAR-γ agonist currently being tested in clinical trials. A pilot study suggested improvement in delayed recall (Watson et al. 2005). A trial of 511 nondiabetic AD patients over 6 months did not show significant effects. A post hoc analysis of APOE status, however, found that subjects lacking an APOE ε4 allele showed improvements (Risner et al. 2006) compared to placebo, and led to three ongoing large-scale placebo-controlled multicenter trials assessing rosiglitazone in AD patients stratified by APOE status.

Tangle-Based Therapies
Some studies suggest that lithium and valproic acid have anti-amyloid and neuroprotective properties (Tariot et al. 2002). Valproic acid protects cultured rat hippocampal neurons against Aβ and glutamate induced injury, possibly due to stabilization of intracellular calcium levels (Mark et al. 1995). Endoplasmic reticulum (ER) stress-induced intracellular lipid accumulation and cell death may play a role in the pathogenesis of AD. Glycogen synthase kinases (GSK)-3alpha/beta also play an important role in signaling downstream effects of ER stress including the phosphorylation of tau. Valproic acid also inhibits GSK-3, and may protect against cell damage due to ER stress (Kim et al. 2005). A multicenter phase III clinical trial is currently underway assessing the potential neuroprotective effects of valproate in AD patients (Tariot et al. 2002). Lithium also inhibits GSK-3, but in one small placebo-controlled trial showed a nonsignificant effect on cognitive scores. A phase III trial will soon be implemented.

Inflammatory Processes
 Emerging evidence indicates overactivity of aspects of immune function in AD (Aisen and Davis 1994). Immune/inflammatory reactions may be established by reactive microglia surrounding senile plaques and astrocyte proliferation; and inflammatory cytokines are produced such as tumor necrosis factor alpha, interleukin-1 (IL-1), α-2-macroglobulin, and α-1-antichymotrypsin. IL-1 and IL-6 promote the synthesis of β-APP.

Anti-inflammatory Medications
Epidemiological evidence supports the use of nonsteroidal anti-inflammatories as preventative of AD. However, clinical trials data are discouraging. The potential role for
anti-inflammatory agents is supported by a small 44-patient placebo-controlled trial of indomethacin (Rogers et al. 1993). Low-dose prednisone (10 mg) did not prove effective in a 1-year-long, placebo-controlled trial by the ADCS (Aisen et al. 2000). There have been clinical trials failures with cyclo-oxygenase-2 inhibitors, celecoxib and rofecoxib, as well as with the nonspecific cyclo-oxygenase inhibitor naproxen (Aisen et al. 2002). Thus, overall efficacy of anti-inflammatory agents in AD has yet to be demonstrated.

**Antioxidants**

Many studies report evidence of increased level of oxidative or free radical damage to neurons in Alzheimer’s disease as well as normal aging, and there are some empirical findings supporting this.

**Vitamin E and Selegiline**

In a trial comparing vitamin E, 1,000 IU b.i.d. and selegiline, 5 mg b.i.d. in outpatients with moderate-to-severe dementia (Sano et al. 1997), overall, both drugs were effective in maintaining patients’ ADLs and prolonging survival in the community by about 5−7 months. There was no effect on cognition, however. A subsequent trial in MCI comparing vitamin E with donepezil and placebo did not find efficacy with vitamin E (Petersen et al. 2005).

**Ginkgo Biloba**

**Ginkgo biloba** extract (GbE) may exert neuroprotective effects under conditions of hypoxia, ischemia preventing neuronal cell death (Spinnewyn 1992), inhibit the toxic effects of β-amyloid (Bastianetto et al. 2000), and act as a free radical scavenger (Dorman et al. 1992, Dumont et al. 1992, Pietschmann et al. 1992). In aged animals, oral GbE treatment leads to increases in the densities of hippocampal muscarinic acetylcholine receptors and cortical 5-HT_{1A} receptors (Huguet et al. 1994, Taylor 1985) and enhances high affinity choline uptake into hippocampal synaptosomes (Kristofikova et al. 1992).

A GbE preparation (EGb761) is approved in Germany and other countries for the treatment of disturbances of cerebral function related to dementia syndromes. Several clinical trials have been conducted in patients with dementia, including AD (Le Bars et al. 1997, Maurer et al. 1997, Weitbrecht and Jansen 1986, Hofferberth 1994) and mixed populations with patients suffering from either vascular dementia or dementia of the Alzheimer type (Haase et al. 1996, Kanowski et al. 1996). Doses used in these trials are either 120 or 240 mg/day. Results have varied with some earlier trials showing outcomes in favor of EGB 761. However, a recent, 6-month-long placebo controlled trial involving over 500 patients with mild to moderate AD showed no differences between 240 mg/day, 120 mg/day and placebo in cognitive or global outcomes (Schneider et al. 2005). A long-term prevention trial involving over 2,500 patients followed over 3 years for the development of dementia is ongoing.

**Anti-Excitotoxic Therapies**

**Calcium Channel Blockers**

The process of neuronal death in aging and in AD may be mediated by an increase in intracellular free calcium, which activates various destructive enzymes (such as proteases, endonucleases, and phospholipases) and disrupts intracellular processes. Neuronal calcium levels are regulated by specific proteins known as t-type calcium channels. Abnormal regulation of these channels is believed to be an early step in the AD process. In principle, blocking the increase in intracellular free calcium may retard these mechanisms and thus slow progression of disease.

Three calcium channel blockers that have been tested in AD patients are nimodipine, a Bristol-Myers Squibb investigational compound, and MEM 1003. In one trial, the low-dose nimodipine group (30 mg t.i.d.) showed less deterioration on several memory tests over a 10−12-week treatment period than the placebo or high-dose nimodipine (60 mg t.i.d.) group (Tollefson 1990). Another trial showed significant cognitive effects for nimodipine compared with dihydroergotoxin mesylates (“Hydergine”) and placebo (Kanowski et al. 1988). It is not clear, however, whether study subjects fulfilled criteria for possible AD.

Although nimodipine has shown some benefits in AD clinical trials (Fritze and Walden, 1995), a meta-analysis of dementia trials concluded that although there may be evidence for short-term benefits, there was no justification for its use as a long-term anti-dementia agent (Lopez-Arrieta and Birks 2002). Nimodipine is used for cognitive impairment and dementia in several continental European countries, but has not been approved by the FDA for dementia.

MEM 1003 has a longer elimination half-life than nimodipine may have little or no effect on blood pressure at highest dose tested (180 mg b.i.d.), and also may have cerebral selectivity in that it may improve cerebral blood flow (Lowe et al. 2006). In late 2005, a phase II study in patients with mild to moderate AD was initiated.

**Idebenone**

Idebenone is a benzoquinone derivative that is hypothesized to improve brain metabolism and protect cell membranes against lipid peroxidation. A placebo-controlled trial that randomized 300 patients for a period of 6 months, found a mild improvement in cognitive function (Weyer et al. 1997). A second trial that randomized 450 patients for a 2-year period, showed an improvement during the first year of treatment with some decline in effect in the second year (Gutzmann and Hadler 1998). However, a third large trial which randomized 536 subjects over one year showed no improvements in cognition, global assessments, or ADL (Thal et al. 2003). It was concluded that this drug failed to slow cognitive decline in AD.

**Propentofylline**

Propentofylline blocks the uptake of adenosine and inhibits phosphodiesterase which appears to inhibit the production of free radicals and reduce the activation of microglial cells.

A Cochrane review analyzing results from several clinical trials concluded that there is limited evidence that propentofylline might benefit cognition, global function and ADL of people in AD.

**Combined Therapies**

The combination of drugs with different mechanisms of action may be more effective than individual medications
alone. As a past example, choline precursors were combined with ChIs but with no evident augmenting effect. One clinical trial addressed the effect of adding memantine or placebo to ongoing donepezil therapy in people with moderate-severe AD, showing significant benefit of memantine vs placebo but cannot be interpreted as an additive effect (Tariot et al. 2004). There has not been a direct comparison of memantine with a AChI and the combination. Most practicing clinicians would take a dim view of combining two ChIs since their actions are additive. Physicians should be skeptical also of combining available anti-inflammatories or hormones with ChIs: first because of the lack of demonstrated efficacy of these drugs, and second because of the additive adverse events, especially gastrointestinal events. Clinical experience suggests that the combination of ChIs with vitamin E or ginkgo biloba does not appear to worsen adverse effects, but there is no efficacy evidence for this practice either, nor of the clear efficacy of the latter drugs. Selegeline has been combined with ChIs in small pilot studies suggesting an additive effect but this remains to be unequivocally demonstrated. Additional strategies employing combination therapies in AD are likely to emerge.

**Summary**

There is an explosion of clinical trials for treatment and prevention of AD, many addressing new mechanisms of action based on recent research. It is too soon to predict which, if any, of these approaches will bear fruit. The prospects for cognitive enhancement in elderly patients are encouraging. As we await results from these trials, currently approved therapies remain part of the therapeutic portfolio for the foreseeable future. ChIs are the best proven efficacious symptomatic treatments for AD. They provide consistent effects in many patients with mild-to-moderate dementia, and have become the current pharmacological standard of treatment. Memantine is effective in moderate to severe AD and is associated with very mild adverse events. Vitamin E, selegiline, and ginkgo biloba are all available for use, but there is little evidence for efficacy.

Consumer interest in complementary and alternative medicine (CAM) has been driven by concerns about medication side effects, nonresponse to standard medications, and the high cost of prescription medications. The scientific community is beginning to realize that CAM approaches can influence many of the regulatory systems involved in the pathogenesis of psychiatric disorders, providing new avenues for treatment. The Sequential Treatment Alternatives to Relieve Depression (STAR*D) trial highlighted the benefits and limitations of combining or switching antidepressants (Rush et al. 2006). Treatment resistance is an indication of our incomplete understanding of the neurobiological basis of mood disorders. Paradigms for treating affective disorders are expanding beyond monoamine neurotransmission models to incorporate other regulatory systems. The exploration of information about the effects of immune function, autonomic nervous system balance, neuroendocrine systems, antioxidants (cellular defense and repair), the arachidonic acid cascade, second messengers, and gene activation opens the way for new therapeutic approaches including CAM treatments.

Many of the medicines used today derive from botanicals known to herbalists for centuries. In addition to herbal medicines, nutrients, and nootropics, CAM encompasses prevention, optimal nutrition, exercise, mind–body practices, and balancing of work and play (Muskin 2000). CAM treatments are particularly useful for patients who have incomplete responses or undesirable side effects with prescription medications. Misunderstanding leading to misuse of natural medicines and the potential for contaminants in unregulated herbal preparations can cause serious health hazards and herb–drug interactions (Ko 1998, Schaumburg and Berger 1992, De Smet 2002). To optimize the benefits and minimize the risks of CAM physicians need a working knowledge of herbs and other nutritional supplements (Brown and Gerbarg 2000).

This chapter focuses on CAM treatments supported by scientific evidence for mechanisms of action, clinical trials demonstrating safety and efficacy, and observations of benefit from the authors’ clinical experience. In some cases, the data are limited but this should not deter physicians interested in exploring the widest range of therapeutic possibilities from considering these substances for appropriate patients. Rigorous controlled studies have been completed for many agents. Potentially worthwhile compounds have not attracted the large research investments necessary to obtain FDA approval. As more clinicians discover the benefits of CAM, interest in supporting larger controlled studies will develop. Although CAM may include any treatment that is not used by the majority of allopathic physicians, this discussion will selectively cover treatments that have practical uses in psychiatry: herbs, nutrients, vitamins, nootropics, neurotherapy, and mind–body practices such as yoga and meditation. The first section of this chapter explores mood disorders, depression and bipolar. The second section covers anxiety and stress-related disorders: generalized anxiety disorder (GAD), panic disorder, insomnia, post-traumatic stress disorder (PTSD), and obsessive–compulsive disorder (OCD). The third section reviews disorders of attention, memory, and cognition: age-associated memory impairment.
Mood Disorders

St. John’s Wort (SJW) (*Hypericum perforatum*)

In the US, SJW became popular after publication of a 1996 meta-analysis of 23 randomized depression trials (Linde et al. 1996) in which 55% of patients on SJW improved compared to 22% on placebo, with a side effect rate similar to placebo. This meta-analysis noted that the studies were limited by vague definitions of depression, less rigorous methodology, unclear outcome measures, low doses of the comparison antidepressants, and short length of trials. A 1999 meta-analysis using more stringent criteria concluded that SJW was similar in efficacy to low dose TCAs in treatment of mild to moderate major depression (Kim et al. 1999). Another review found evidence that SJW yielded higher rates of improvement than placebo but lower rates than TCAs, even at suboptimal starting doses (Gaster and Holroyd 2000).

SJW 500 mg/day was comparable to fluoxetine 20 mg/day in mild/moderate depression (*N* = 240) in a double-blind randomized control trial (DBRCT) (Schrader 2000). In a 6-week double-blind, randomized, multicenter (DBRMC) trial, 209 hospitalized patients with severe major depression given either hypericum LI 160 (Kira) (a standardized preparation of SJW) 600 mg thrice a day (*ter in die* (t.i.d.)) or imipramine 150 mg/day. Hamilton Rating Scale for Depression (Ham-D) scores at the end of the trial were similar for both groups. There were fewer side effects with SJW. The study indicated that treatment with SJW requires higher doses (1800 mg/day) and takes longer to achieve response (6–12 weeks) than with imipramine (3–6 weeks) (Vorbach et al. 1997). The *Journal of the American Medical Association* (JAMA) published a double-blind randomized multi-center

PMS, premenstrual syndrome; PMDD, premenstrual dysphoric disorder; BPH, benign prostatic hypertrophy; GI, gastrointestinal side effects; BP, blood pressure; HT, hyper-tension; sx, symptoms.
placebo-control trial (DBRM CPC) study of 20 patients with major depression using 900 mg/day Kira (low dose). At 4 weeks nonresponders got 4 weeks of Kira at 1,200 mg. The study concluded that Kira was no better than placebo (Shelton et al. 2001). However, placebo response rate of 19% raises the question that the patients were more severely depressed or treatment resistant. This study showed no separation from placebo for SJW (900–1,500 mg/day) or sertraline (50–100 mg/day) possibly due to subtherapeutic dosing in severely depressed patients (Davidson and the Hypericum Depression Trial Study Group 2002). In a 6-week DBRCT, 300 mg t.i.d. hypericum extract WS®5570 was as effective as paroxetine 20 mg/day in a study of 251 adult outpatients with severe depression (17-item HAM-D ≥ 22 at baseline). Those who did not show at least 20% improvement after 2 weeks were increased to 600 mg t.i.d. WS®5570 or 40 mg paroxetine with improved response. Hypericum extract was better tolerated than paroxetine (Szegedi et al. 2005). A randomized clinical trials (RCT) of 135 patients with major depression (mean HAM-D = 19.7± 3.2) compared SJW 900 mg/day with fluoxetine 20 mg/day and placebo. A greater numerical reduction occurred in mean HAM-D scores in the SJW group than in the fluoxetine and placebo groups, however, these were not statistically significant differences (Fava et al. 2005). A 6-week DBRM CPC trial of 332 outpatients with HAM-D ≥ 18 compared hypericum extract WS®5570 600 mg/day (p < 0.0001), WS®5570 600 mg twice in a day (bis in die (b.i.d.)) (p < 0.0001), and placebo. Response rates (> 50% reduction in HAM-D) were 69.8% for 600 mg/day, 61.3% for 600 mg b.i.d., and 31.1% for placebo. Remission rates (HAM-D ≤ 7) were 32.8% for 600 mg/day (p < 0.004), 40.3% for 600 mg b.i.d. (p < 0.001), and 14.8% for placebo (Kasper et al. 2006).

The “side-effect profile” of SJW at higher doses is similar to selective serotonin reuptake inhibitors (SSRIs). Common side effects with SJW are nausea, heartburn, loose bowels, jitteriness, insomnia, and fatigue. High doses may cause sexual dysfunction and bruxism. Phototoxic rash occurs in less than 1% of people taking the usual dose (900 mg/day) but may be more frequent at higher doses. Nierenberg et al. (1999) reported four possible cases of SJW-induced mania in bipolars. SJW causes slight reuptake inhibition of serotonin (5-HT), norepinephrine (NE), and dopamine (DA) (Muller et al. 1998), and a change in monocyte cytokine production of interleukin 6 (leading to decreased corticotrophin-releasing hormone) (Thiele et al. 1994). There have been six cases of serotonin syndrome reported with SJW in combination with both SSRIs and nefazodone (Anonymous 2000, Gelenberg 2000). Whether this is due to the weak serotonin effect of SJW or other factors is not yet clear (DeMott 1998).

Some authors have suggested that SJW is effective in 50–70% of patients with mild depression, particularly in wintertime seasonal affective disorder (SAD) is present (Cott and Fugh-Berman 1998, Hansgen et al. 1994, Wheatley 1999).
SJW has serious potential medication interactions. Digoxin levels decreased by 28% in healthy volunteers given SJW versus a 9% drop in the placebo group (Jonte et al. 1999). Researchers hypothesize that SJW induces cytochrome P450 3A4 and 1A2 intestinal wall P-glycoprotein (resulting in gut loss of digoxin). SJW can lower levels of warfarin, HIV protease inhibitors, and reverse transcriptase inhibitors (Piscitelli et al. 2000, Ruschitzka et al. 2000). SJW’s ability to induce hepatic enzymes can result in lower levels of cyclosporine (which has caused transplant rejection), theophylline, and other drugs. Breakthrough bleeding has been reported in women on birth control pills who take SJW. Anesthesiologists anecdotally report changes in heart rate and blood pressure, particularly in patients taking SJW, ginkgo, and ginseng. These herbs should be discontinued 2–3 weeks before surgery (Voelker 1999). A review of adverse effects of SJW from 35 DBRCTs found that the reported rates of side SJW effects were similar to placebo and lower than those of comparison antidepressants (Knüppel and Linde 2004). Evidence suggests that Hypericum extracts are well tolerated and safe if taken under the guidance of a physician who is aware of the potential risks, clearly informs the patient, and monitors the patient for changes in medications.

Most independent analyses of SJW brands report the amount of hypericin and/or hyperforin, but do not test for quality or activity. Although a concentration of hypericin 0.3% of the extract is the usual standard, the measurement of hypericin 0.3–0.5% may be more relevant. Two double-blind randomized placebo-control trial (DBRPC) studies suggest that clinical response rates and changes in brain waves are related to the concentration of “hyperforin”, not “hypericin” (Muller et al. 1998, Schellenberg et al. 1998). Independent testing of SJW brands by ConsumerLab.com found that 14 out of 21 met their requirements for having the amount of active compound claimed on product labels and a minimal amount of cadmium (a carcinogenic contaminant) (ConsumerLab.com 2001). Another independent study by www.vitacost.com found that only two out of eight brands contained adequate hyperforin (Schrardt 2000). Double-Blind Placebo-Controlled (DBPC) clinical trials and studies showing activity in vitro for particular products provide more compelling evidence of efficacy. In 2000, the Boston Globe sent brands of SJW to two labs for testing. Two of the brands, Quanterra and Nature Made, showed significant ability to block serotonin re-uptake in animal cells in vitro. Research trials have shown Kira (LI 160), Remotiv (ZE 117), STW3, and WS5570 to be effective. In the authors’ clinical experience Natures Way Standardized Extract (Perika), Kira, Quanterra, and Nature Made are reliable brands.

S-Adenosyl-L-Methionine, (SAMe), Adometionine, AdoMet
SAMe has been widely used in Europe for over 20 years, primarily for treatment of depression, arthritis, and liver disease. Tested in more than 80 clinical trials involving over 24,000 people, it was approved as a nutraceutical by the FDA in 1998. SAMe is a prescription medication in some countries and is sold over-the-counter in others. Knowledge of the biochemistry of SAMe is necessary to understand its multiple therapeutic effects. The US Department of Health and Human Services Agency for Healthcare Research and Quality (2002) based on a search of 25 biomedical databases, concluded that treatment with SAMe was equivalent to standard pharacotherapy for depression and osteoarthritis. It was not possible to pool the data on liver disease because the studies were too diverse. However, SAMe was found to be more effective than placebo in reducing bilirubin and pruritis in intrahepatic cholestasis and cholestasis of pregnancy.

SAMe is a physiologically essential molecule in all living cells. The human diet supplies only part of the body’s needs for SAMe, generated by de novo synthesis from methionine and adenosine triphosphate (ATP); the liver is the largest producer (3 g/day). Oral SAMe supplementation is the easiest way to boost SAMe levels. Though most concentrated in brain and liver, SAMe is an active metabolite in all tissues of the body and is crucial for three central metabolic pathways involving more than 200 different biochemical reactions (Figure 108–1): transsulfuration (donation of methyl groups, CH3), transulfuration (donation of sulfur), and transaminopropylation (donation of amino- propyl moieties). Transmethylation increases 5-HT, DA, and NE levels (Otero-Losada and Rubio 1989a, 1989b), probably contributing to antidepressant activity (Czyrak et al. 1992, Fava et al. 1990). Donation of methyl groups protects catecholamine neurons. SAMe improves nerve cell membrane uptake of phospholipids for a more fluid lipid bilayer, enabling the coupling of protein receptors to second messengers and enhancing transmission of impulses by neurons (Bottiglieri 1997). Methyl groups protect DNA from attack by carcinogens and reduce homocysteine (Finkelstein 1998), a major risk factor for heart attack and stroke. SAMe is necessary for synthesis of the most important antioxidant, glutathione, as well as secondary antioxidants, cysteine and taurine (Colell et al. 1997, Evans et al. 1997). Through the transsulfuration pathway, SAMe stimulates proteoglycan synthesis for cartilage regeneration in arthritis (Barcelo et al. 1987). Transsulfuration and aminopropylation (generation of polyamines) contribute to analgesic properties, antiinflammatory action, and protection of gastrointestinal mucosa. SAMe methylation pathways require B12 and folate as cofactors (see Figure 108–1) (Crellin et al. 1993). B12 (1,000 μg/day), folate (800–1,000 μg/day), and B6 (50–100 mg/day) may enhance the antidepressant effect of SAMe. Low levels of SAMe in cerebral spinal fluid, red cell folate deficiency, high homocysteine, and low monoamine metabolites (5-HT, NE, DA) were found in 24 out of 46 patients hospitalized for severe depression (Bottiglieri et al. 2000).

When SAMe was discovered in 1952 (Cantoni 1952), there was no stable oral preparation (Stramentinoli 1987). Early studies, therefore, used intravenous (i.v.) and intramuscular (i.m.) formulations. Agnoli et al. (1976) published the first clinical study demonstrating antidepressant effects. Over the past 40 years more stable preparations, resistant to oxidation and gastric enzyme degradation (enteric coated, with demonstrated bioavailability and clinical efficacy) have been developed. Lower than normal levels of SAMe are found in cerebral spinal fluid in some patients with depression, AD, dementia, Parkinson’s disease treated with levodopa, disorders of folate metabolism, and other illnesses (Bottiglieri et al. 1990, Bottiglieri and Hyland 1994). SAMe was found to be a safe and effective treatment
for depression in 16 uncontrolled trials (660 patients), 13 DBRPC trials (535 patients), and 19 controlled DB trials, comparing it to other antidepressants including imipramine, amitriptyline, clomipramine, nomifensine, minaprine, and desipramine (1,134 patients) (Bressa 1994, Delle Chiale and Boissard 1997, Brown et al. 2000), and three trials using SAMe to augment response to imipramine (Berlanga et al. 1992). In two well-designed, DBRPC studies, SAMe was rapidly effective in “postpartum depression” (Cerutti et al. 1993) and “postmenopausal depression” (Salmaggi et al. 1993). In a 4-week open study, 48 patients medically hospitalized showed a 50% decrease in depression ratings and tolerated SAMe well (Criconia et al. 1994). Some reports describe dramatic responses to SAMe even after patients have failed or been unable to tolerate prescription antidepressants (Bell et al. 1994, Criconia et al. 1994, Kagan et al. 1990, Rosenbaum et al. 1990).

SAMe was successfully combined with psychoactive medications in a 6-month study that included 350 patients on tricyclic antidepressants (TCAs), 500 on benzodiazepines, 60 on monoamine oxidase inhibitors (MAOIs), 445 on anticonvulsants, and 18 alcoholic patients on antidepressants or anticonvulsants. No adverse effects were reported. Patients on SAMe/TCA combination responded in 7–10 days as compared to the 10–15-day period for TCA-only group. Forty-eight of the SAMe/imipramine patients improved on 30% lower doses of imipramine. In all cases, SAMe reversed or prevented the elevation of gamma-glutamyl-transpeptidase (GGT), an indicator of liver toxicity, that occurred in the patients taking MAOIs or anticonvulsants and in the alcoholic group (Torta et al. 1988). In a DBRPC study of 63 outpatients with moderate to severe major depression, the imipramine/SAMe group improved more rapidly and reduced their benzodiazepine use in comparison to the imipramine/placebo group. By Day 14, the groups were comparable (Berlanga et al. 1992). In two well-designed, DBRPC studies, SAMe was rapidly effective in “postpartum depression” (Cerutti et al. 1993) and “postmenopausal depression” (Salmaggi et al. 1993). In a 4-week open study, 48 patients with depression secondary to physical illnesses (40 were medically hospitalized) showed a 50% decrease in depression ratings and tolerated SAMe well (Criconia et al. 1994). Some reports describe dramatic responses to SAMe even after patients have failed or been unable to tolerate prescription antidepressants (Bell et al. 1994, Criconia et al. 1994, Kagan et al. 1990, Rosenbaum et al. 1990).

Studies show that SAMe improves liver function, reverses physical symptoms and biochemical markers (abnormal liver function tests) of alcoholic and infectious hepatitis and cirrhosis. It has also been used to dissolve gallstones (Frezza et al. 1990, Friedel et al. 1989, Lieber 1999, Milkiewicz et al. 1999, Osman et al. 1993). Mato et al. (1999) reported a 2-year, DBRPC study of 123 patients with alcohol-induced liver cirrhosis. In Child's Class A and B cases, SAMe 1,200 mg/day p.o. increased the rate of survival and delayed liver transplantation. Preliminary studies support the use of SAMe for depression complicating alcohol and opiate withdrawal (Agricola et al. 1994). Methamphetamine depletes SAMe and DA levels in rat brain (Cooney et al. 1998). SAMe may be useful to relieve post methamphetamine depression and drug craving.

In general, SAMe side effects are mild and usually transient: headaches, anxiety, agitation, insomnia, loose bowels, upset stomach and, occasionally, palpitations. SAMe does not cause weight gain or sexual dysfunction. SAMe is
contraindicated in patients with a personal or family history of bipolar disorder because SAMe can induce mania (Cryan et al. 1987, 1989, Kagan et al. 1990). There is no evidence that SAMe interacts with other drugs, affects cytochrome P450 metabolism, or displaces other drugs from protein binding. There are no clear cases of serotonin syndrome even when SAMe is combined with prescription antidepressants, including SSRIs and MAOIs. Nevertheless, until more information is available, SAMe and MAOIs should only be combined under close medical supervision. No teratogenic (Cozens et al. 1988) or mutagenic activity has been found in vitro or in animals (Pezzoli et al. 1987). The amount of SAMe passed to infants through breastfeeding is unknown. Infants normally have SAMe levels three to seven times higher than adult levels (Surtees and Hyland 1989). Therefore, an infant would probably not be harmed by the amount of SAMe in breast milk. Nevertheless (as with prescription antidepressants), no definitive prospective studies are available to rule out the possibility of adverse effects in infants.

The usual dosage of SAMe is 400 mg/day for minor depression and 800–1,600 mg/day for major depression. Higher doses may be needed for severe treatment-resistant depression and in neurological disorders such as Parkinson’s disease. SAMe is best absorbed on an empty stomach. Starting with 200 mg 30 min before breakfast and 30 min before lunch minimizes the stimulation, which some patients report in the first few weeks of treatment. This can be switched to 400 mg before breakfast after a few days. The dose can be raised by 200–400 mg every 3–7 days. Patients notice an improvement in their energy level within 2 weeks. Starting with low doses and increasing more gradually in geriatric, medically ill, and anxious patients minimizes the risk of side effects. It is sometimes possible to treat a bipolar II patient whose mania is under good control with a mood stabilizer such as lithium or valproate by using lower starting doses (e.g., 100 mg four times a day (quater in die (q.d.)) or b.i.d.), smaller increases, and careful monitoring.

SAMe tends to oxidize rapidly when exposed to air. The manufacturing and packaging of SAMe tablets is critical to assure full potency. Unfortunately, few companies test their products for self-life. Bargain brands may lose 50–100% potency before use. Tablets are best preserved in individual blister packs and should not be refrigerated. The table at the end of this chapter lists several brands of good quality. It is useful to consult ConsumerLab.com periodically for updated information on SAMe brands. Nonresponse to an appropriate dose of SAMe or the occurrence of excessive side effects are usually due to the use of a poor quality brand. Changing to a better brand and adding folate and B-vitamins may improve response. Physicians should become knowledgeable about SAMe in order to advise patients on its use to augment antidepressant treatment or as an alternative to traditional pharmacotherapy. Further research is needed to clarify SAMe’s role as a first-line treatment in affective disorders (Brown et al. 2000).

**Rhodiola Rosea**

The Section “Cognitive Enhancement” contains a complete discussion of the adaptogenic herb, *Rhodiola rosea.* *R. rosea* increases 5-HT, increases transport of tryptophan and 5-HT into the brain (Saratikov and Krasnov 1987b), and may reduce the breakdown of 5-HT by carboxy-O-methyl transferase (COMT) inhibition. One hundred and twenty-eight depressed patients were given 150 mg t.i.d. *R. rosea* or placebo. Two-thirds of those on *R. rosea* improved significantly (Brichenko and Skorokhova 1987, Saratikov and Krasnov 1987a, 1987b).

A DBRPC study of *R. rosea* as a mono-therapy for 89 adults who met Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Revised (DSM-IV-TR) criteria for mild to moderate depression (baseline HAM-D ranging from 12–31) found that those given a standardized extract of *R. rosea* produced by the Swedish Herbal Institute named SHR-5® 340 mg/day or SHR-5® 680 mg/day for 6 weeks showed significantly greater improvements in mean HAM-D compared to a group given placebo (Darbinyan et al. 2007). *R. rosea* is a useful activating agent to augment the treatment of depression, particularly for target symptoms of fatigue, apathy, psymchomotor retardation, anhedonia, memory impairment, poor concentration, and loss of libido. Its use as a mono-therapy for mild to moderate depression warrants further study.

**Other Herbs for Mood Disorders**

Lavendar (*Lavandula angustifolia*) significantly enhanced accelerated antidepressant effect of 100 mg/day imipramine (*p < 0.0001*) in a 4-week DBRBP study of 45 outpatients with major depression (DSM IV-TR) mean baseline HAM-D ≤ 18 (Akhondzadeh et al. 2003).

Saffron (*Crocus sativa*) has been used for depression in traditional Persian medicine. An extract of the petal 15 mg b.i.d. was compared to fluoxetine in an 8-week pilot DBRCT of 40 outpatients with major depression (DSM-IV-TR) baseline HAM-D ≥ 18. *C. sativa* was equally as effective as fluoxetine in treating mild-to-moderate depression. Remission rate was 25% for both treatments (Akhondzadeh et al. 2006). Comparison of petal of *Crocus sativus* and fluoxetine in the treatment of depressed outpatients; a pilot double-blind randomized trial. Previous studies had shown that the stamen of *C. sativa* had antidepressant effects in mild-to-moderate depression greater than placebo and comparable to imipramine and fluoxetine (Akhondzadeh et al. 2004, 2005, Noorbala et al. 2005). This study focused on the petal as a more practical source of material because the stamen is used as one of the most expensive spices in the world. More long-term RCTs, are needed to validate the benefits of *C. sativa* petal as a treatment for depression.

A Chinese herbal compound, Jai-Wei-Xiao-Yao-San or Jia-Wey Shiau-Yai San (Free and Easy Wanderer Plus (FEWP)) or Kami-Shoyo-San in Japanese has been used in traditional medicine to relieve mood swings, PMS, and menopausal symptoms. It contains extracts of 11 medicinal herbs: *Bupleurum chinense*, *Scutellaria baicalensis*, *Zingiber officinale*, *Angelica sinensis*, *Gardenia jasminoides*, *Paonia suffruticosa*, *Paonia lactiflora*, *Atractylodes macrocephala*, *Poriae Cocos*, *Mentha haplocalyx*, and *Glycrrhiza uralensis.* FEWP has been studied as an adjunctive treatment with carbamazepine in bipolar disorder and as a monotherapy. In a 12-week DBRPC study of 87 unipolar and 62 bipolar depressed patients, those given FEWP showed significantly greater improvements on HAM-D. Montgomery–Åsberg Depression Rating Scale (MADRS), and Clinical Global Impression of Severity (CGI-S) compared to those on placebo (Zhang et al. 2006).
**Effects of Vitamins and Nutrients on Mood**

Low levels of B12 (cyanocobalamin) and folate have been associated with disorders of mood, memory, and cognition, particularly in depressed patients and the elderly (Bottiglieri 1996, 1997, Crellin et al. 1993). Studies have demonstrated that B-vitamins can improve mood and cognitive functions (Benton et al. 1995, 1997, Riggs et al. 1996). In a DBRPC study of 14 depressed geriatric inpatients on TCAs, 10 mg each of vitamins B1, B6, and B12 improved depression and cognitive function (Bell et al. 1992). A study of 129 healthy adults given Vitamin C, Vitamin E, and seven B-vitamins at 10 times the US FDA recommended daily allowance for 1 year, resulted in significantly greater improvement in mood than in a placebo group. Higher serum levels of riboflavin (B2) and pyridoxine (B6) correlated with improved mood in men, while higher levels of thiamine (B1) correlated with better mood in women. Improved mood correlated with levels of Vitamin E and biotin (B-vitamin associated with skin, nail and hair growth) regardless of gender (Benton et al. 1995). B12 deficiency (associated with high methylmalonic acid) more than doubled the risk of severe depression in 700 disabled women over the age of 65 (Penninx et al. 2000). In a study of dietary folate and B vitamins, 121 out of 865 Japanese women developed postpartum depression. Consumption of riboflavin (B2) in the third quartile decreased risk of postpartum depression (Miyake et al. 2006).

Low levels of folate have been associated with nonresponse to antidepressants (Fava et al. 1997, Lerner et al. 2006). In a DBRPC study, 127 women on fluoxetine 20 mg/day were given either folate 500 μg/day or placebo. In the fluoxetine/folate group, 94% of the women had a good response versus 61% in the fluoxetine/placebo group. In women treated with fluoxetine/folate, plasma folate increased and homocysteine decreased (Coppen and Bailey 2000). Low folate levels were associated with delayed response to fluoxetine in a study of 110 patients with major depressive disorder (MDD) (Papakostas 2006). Although further studies of antidepressant supplementation with folic acid would be useful, at this time it is reasonable to give folate 2 mg/day during acute treatment (Abou-Saleh and Coppen 2006) and 1 mg/day for maintenance.

Inositol (a vitamin in the B6 complex) boosts cyclic adenosine monophosphate (AMP), a second messenger in neurons. Inositol 12−20 g/day has been superior to placebo in a series of randomized trials for depression (Benjamin et al. 1995a), panic (Benjamin et al. 1995b), and OCD (Fux et al. 1996) (see for review: Bender 2000). A study from the National Institute of Mental Health (NIMH) Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BP) compared the effects of antidepressant augmentation with lamotrigine, inositol, and risperidone for refractory depression in 66 bipolar patients. Differences in recovery rates with lamotrigine (24%), inositol (17%), and risperidone (5%) did not reach statistical significance (Nierenberg et al. 2006). This suggests a possible role for inositol augmentation in bipolar depressed patients who do not respond to lamotrigine, who develop side effects (allergic rash or photosensitivity), or who cannot afford the high cost of lamotrigine. Gastrointestinal side effects include gas and loose bowel movements. A therapeutic dose requires at least six large inositol 650 mg pills t.i.d., compliance is a problem. In one case, mania was induced by 3 g/day.

Choline (a B-complex vitamin) reduced mania in a number of case reports and case series. A small case study of treatment-refractory, rapid-cycling bipolars who were taking lithium found that four out of six responded to the addition of 2,000–7,200 mg/day of free choline. The two nonresponders were also taking hypermetabolic doses of thyroid medication. Clinical improvement correlated with increased intensity of the basal ganglia choline signal as measured on proton magnetic resonance imaging (MRI). The effect of choline on depressive symptoms was variable (Stoll et al. 1996).

Acetyl-l-Carnitine ALCAR 500 mg b.i.d. was compared to amisulpride 50 mg t.i.d in a 12-week DBRPC study of 204 patients with pure dysthymia (DSM-IV-TR). Both groups showed improvement on HAM-D21 with no significant difference between groups. Improvements on Clinical Dementia Rating (CDR5), MADRS, and CGI were also similar between groups. ALCAR cause fewer side effects (Zanardi and Smeraldi 2006).

Essential polyunsaturated fatty acids (PUFAs) interact with biochemical pathways involved in mood regulation (Sublette et al. 2004). Some functions of PUFAs include: (1) membrane fluidity essential for neuronal responsiveness, (2) functioning of ion channels, receptors (including monoamine pathways), and enzyme systems, (3) gene expression, (4) second messengers, and (5) precursors to eicosanoids and prostaglandins. Arachidonic acid (AA) and docosahexanoic acid (DHA) account for 90% of PUFAs in brain tissue. Dietary supplementation with fish or soy oil increased heart rate variability (HRV) (indicator of increase vagal activity) in elderly patients. The effect was greater and more rapid with 2 g/day fish oil (Holguin et al. 2005). Eicosapentenoic acid, an omega-3 fatty acid, was added to ongoing antidepressant treatment in a DBPC 4-week study. Twenty patients with “breakthrough depression” given 2,000 mg/day eicosapentanoic acid showed significant improvement on HAM-D compared to placebo (Nemets et al. 2002). A DBRPC pilot study by Stoll et al. (1999) explored the possibility that omega-3 fatty acids (omega-3FAs) could improve bipolar disorder by inhibiting neuronal transduction pathways in a mechanism similar to that of lithium carbonate and valproate. Thirty bipolar patients, most of whom were on mood stabilizers, were randomized to placebo or omega-3FAs (6.2 g eicosapentanoic acid plus 3.4 mg DHA per day). Those given omega-3FAs showed significant reduction in symptoms and relapse rates. In another study, eight out of ten bipolar patients showed 50% or more decrease in depression scores when given 1.5–2.0 g eicosapentenoic acid (EPA) (Osher et al. 2005). The addition of 1–3 g/day ethyl-EPA to standard treatment in a DBRCT of 75 bipolar patients significantly reduced depression (Frangou et al. 2006).

Studies of omega-3FAs for depression have been reviewed (Parker et al. 2006, Sontrop and Campbell 2006). Treatment with 2 g/day eicosapentanocic acid significantly improved depression in four out of seven DBRCTs. Variable findings may be due to the use of different doses, proportions and preparations of EPA and DHA. To what extent clinical improvement depends upon co-administration of antidepressants or pretreatment levels of omega-3FAs remains to be determined. Although larger studies are needed to confirm the findings, overall evidence is adequate for the use of omega-3FAs to augment treatment.
of depression and bipolar disorder. Omega-3FAs are one of the few interventions known to be safe and potentially beneficial to neural development during pregnancy and breast-feeding (Bourre 2006). Although doses of 1−2 g/day omega-3FAs have been shown to reduce depression ratings in bipolar patients, the authors (R.B. and P.G.) find that higher doses of 8−10 g/day are more effective for mixed symptoms of mania and depression and for rapid cyclers. High doses may cause gastrointestinal distress.

**Yoga for Depression and Bipolar Disorder**

Stress and sympathetic activation are associated with an increase in proinflammatory cytokines. Evidence suggests that vagal activity (parasympathetic activation) inhibits inflammation via cholinergic signaling (Pavlov and Tracey 2005, Saeed et al. 2005). The cholinergic antiinflammatory pathway inhibits local cytokine release by the release of acetylcholine from vagus nerve endings that binds to δ7 receptors on macrophages and other cells in the reticuloendothelial system, preventing damage from excess cytokine production (Tracey 2005). The role of inflammatory response in the pathophysiology of depression has been reviewed (Raison et al. 2006). Central acting cytokines alter monoamine metabolism in emotion regulatory circuits, reward systems, and the hypothalamic-pituitary-adrenal axis (HPA) axis. Interventions that reduce stress, decrease sympathetic nervous system (SNS) activity, and increase parasympathetic nervous system (PNS) activity may be beneficial in treating depression. The proposed neurophysiological model for rapid activation of the PNS by yoga breathing leading to widespread effects on peripheral and central nervous system (CNS) is presented in the section on anxiety disorders below. Literature on yoga for depression is of mixed quality and often difficult to interpret. In part of this is due to the reluctance of some schools of yoga to divulge details of their practices outside of their training settings. Reluctance may stem from a sense of sacredness attached to the practices, the tradition that the yoga teacher must impart wisdom, and concern that without proper training some practices may cause harm. While this protectiveness toward sacred practices is understandable, it can impede research that would provide evidence of efficacy (see for reviews of yoga and depression: Brown and Gerbarg 2005a, 2005b). Yoga is a comprehensive program that integrates yoga knowledge with physical and mental practices in the context of an individual relating to a teacher and a group. Studies of isolated components may not capture the combined effect. “Yoga for Depression” by Weintraub (2004) is an instructive example of the clinical integration of yoga practices for depressed clients.

**Sudarshan Kriya Yoga (SKY) Breathing**

An open study of 46 patients with dysthymia (mean illness duration 3.15 years) showed significant improvement on Beck Depression Inventory (BDI) and Clinical Global Impression scales 1 and 3 months after SKY breath training. Among the 37 patients who completed the program, 67.5% achieved remission (Janakiramaiah et al. 1998). In a randomized, controlled study, 45 hospitalized patients with severe melancholic depression received either SKY, imipramine 150 mg/day, or electroconvulsive therapy (ECT) three times a week. SKY was as effective as imipramine and almost as effective as ECT in significantly reducing scores on BDI and HAM-D. Significant prolactin elevations were noted after Sudarshan Kriya (SK) cyclical breathing (Janakiramaiah et al. 2000).**

**Iyengar Yoga**

Twenty-eight healthy volunteers (not being treated for depression), ages 18−29, with mild depression (BDI = 10−15) were randomly assigned to two 1-hr Iyengar yoga classes for 5 weeks or wait-list control. Postures believed to alleviate depression (back bends, standing poses and inversions) were emphasized with breath practices. The yoga group showed significantly greater decreases in scores for depression and anxiety on BDI, State-Trait Anxiety Inventory, and Profile of Moods States compared to the control group (Woolery et al. 2004). Another wait-list RCT of 24 women with perceived stress found that those assigned to a 3-month Iyengar yoga class experienced significant improvement in depression (Michalsen et al. 2005). While these small studies did not select patients with a diagnosis of depression, they suggest a positive impact on depressed mood that warrants further study.

**Kundalini Yoga**

Kundalini Yoga breathing meditation techniques recommended for depression include establishing a meditative state of mind, imagery, chanting, and several yoga breath techniques and postures (Shannahoff-Khalsa 2004). However, these have yet to be studied in controlled trials for depression.

**Anxiety Disorders**

**GAD, Panic Disorder, Social Phobia, Posttraumatic Stress Disorder (PTSD), OCD, Insomnia, and Stress-related disorders**

Estimates of the use of CAM by people with anxiety disorders range from 40−50% (Eisenberg et al. 1998) and is highest among those with panic attacks (Unutzer et al. 2000). Individuals with anxiety disorders are vulnerable to substances abuse and dependence on prescription anxiolytics. Mind–body practices provide significant relief without the risk of drug dependence and are used more frequently than herbs for anxiety (Bandelow et al. 1995). This section begins with mind–body practices that address the pathophysiological mechanisms that underlie anxiety.

**Mind–Body Approaches for Anxiety Disorders and Insomnia**

Meditative and yogic practices are being integrated into Mindfulness Based Stress Reduction (MBSR) and Cognitive Behavioral Therapy (CBT) (Stratynper 2006). As these programs become more sophisticated in their approaches to affect regulation and awareness of internal experience, they are embracing Eastern psychology, Zen and Buddhist philosophy, and Hindu yoga. Mindfulness Based Cognitive Behavioral Therapy (MBCBT) researchers have expanded their scope of behavioral practices to include yoga.

Research on mind–body practices faces the challenges of any emerging field. Early studies were mainly either descriptive or open pilots. Recent work has greater methodological rigor. Nevertheless, there is much to learn from
the evidence, clinical observations, and the long history of traditional healing practices. Criteria for evaluating research on mind–body practices must take into account the impossibility providing double blinding (done easily with placebo tablets in medication studies). Studies using blinded raters and control groups such as psychocoeucation, other stress reduction interventions or wait-list controls are preferable to uncontrolled trials. While it has been argued that just the provision of attention may account for clinical improvement, this is unlikely in serious anxiety disorders, which are often resistant to standard psychotherapy and medication. Another problem is the difficulty of funding large-scale studies. For the present, studies should not be disregarded because of small sample size, particularly when a large effect size may indicate statistical significance. Literature reviews may not represent the available data because tight exclusion criteria may eliminate studies of medical illnesses in which anxiety may have improved if it was not the primary focus.

**Autonomic Balance, Brain waves, Neuroplasticity**

Anxiety and PTSD are associated with over activity or erratic activity of the SNS and underactivity of the PNS (Berntson et al. 1998, Thayer and Brosschat 2005). Low respiratory sinus arrhythmia (RSA) and low HRV, reflecting decreased vagal tone, are associated with negative states of mind in adults, fear and depression in infants, aggression and antisocial behavior in adolescent boys, anxiety disorder and panic disorder (Beauchaine 2001, Carney and Ellis 1988, Carney et al. 1995, Mezzacappa et al. 1996, 1997). Certain mind–body practices shift autonomic balance in favor of PNS dominance.

Mediation has been shown to reduce SNS activity and to increase PNS activity. However, the process of meditation requires mental focus and the ability to quiet the mind. Many people with anxiety disorders cannot focus or quiet their mind enough to achieve a meditative state. Most meditation practices include breath-centered work such as slow breathing, focused attention on the breath, or deep abdominal breathing. Yoga breathing normalizes SNS activity and increases PNS tone. For treating anxiety disorders, it is important to enhance PNS activity and to increase the flexibility of the stress response system. Voluntarily changing the pattern of breath influences emotional states (Philipot 2002). Even simple slow breathing can stimulate the PNS and that effect is enhanced by more advanced breath techniques (Brown and Gerbarg 2005a).

Afferent autonomic and somatosensory feedbacks from the body are central to peripheral models of emotion and their extension into self-awareness (Bechara et al. 1997, Damasio 1999). Interoception, the perception of “feelings” (e.g., visceral sensations and pain) that reflect the physiological state of the body may have primary representation in the dorsal posterior insula and meta-representation in the right anterior insula, a possible substrate for emotional awareness (Craig 2003). This converges with Damasio’s “somatic marker” hypothesis that brain regions involved in mapping and regulation of internal states contribute to representational images of body states, a basis for awareness of feelings states (Critchley 2005).

The PNS calms the stress response system through cholinergic pathways and neuroendocrine activity. It not only slows the heart and respiratory rates, but also quiets the mind and restores energy supplies. A few tracts of the PNS run through the spinal cord, but its main pathways are the right and left vagus nerves that innervate the organs and tissues of the throat, chest, abdomen and periphery. Approximately 20% of the vagal fibers (efferents) carry messages from the brain to the body, whereas 80% (afferents) carry information from the body up to the brainstem nuclei and from there to the limbic system, hypothalamus, thalamus, and broad areas of the cerebral cortex. This influences how we experience our bodies, our emotions, and our state of consciousness. Thayer and Brosschat (2005) propose that the medial prefrontal cortex (mPFC) inhibits lower centers such as the amygdala. Disturbances in the dynamics between prefrontal cortex (PFC), amygdala and thalamus may contribute to depression and fear-related symptoms as in PTSD (Das et al. 2005, LeDoux 2000). Low PNS activity and hypooactivity of the PFC are associated with poor affective processing. Therapeutic implications of these concepts have been demonstrated in the use of Vagal Nerve Stimulation (VNS) (Figure 108–2) of the right vagus nerve for epilepsy and treatment-resistant depression (Sackeim et al. 2001). However, the use of electrical devices to stimulate part of the vagus nerve is a crude method compared to the intricate network of afferent sensory vagal fibers that constantly dialogue with the brain. The lungs and airways contain pressure receptors and mechanoreceptors, stretch sensors (Yu 2005) that fire in response to lung inflation and deflation, sending signals to vagal afferents. The authors propose that voluntarily changing the pattern of breath alters the firing of lung sensors and the visceral somatosensory (including pharynx, larynx, chest wall, diaphragm, baroreceptors, and chemoreceptors) information carried by vagal afferents leading to changes in emotional and cognitive processing by shifting the balance of input to the prefrontal cortex, insula and related areas involved in emotion regulation and the representation of bodily feeling states.

Enhancement of alpha and theta activity and phase synchrony (Hebert et al. 2005, Lehmann et al. 2001, Satyanarayana et al. 1992), interhemispheric asymmetry in alpha and beta activity, and high voltage gamma synchrony (Benson et al. 1990, Davidson et al. 2003, Lutz et al. 2004) occur with meditation and yoga breathing. Data from electroencephalogram (EEG), positron emission tomography (PET), and functional magnetic resonance imaging (fMRI) studies are being used to study the effects of mind–body practices on emotional and cognitive processing, neuroplasticity, and brain aging (Lazar et al. 2000, Lazar et al. 2005). The long-term practice of meditation and yoga breathing has been associated with sustained changes in resting EEG, which may reflect changes in brain structures in areas being exercised during those practices. Repeated experience may lead to neuroplastic development in specific cortical regions. The right insula has been associated with interoception and breath awareness. Lazar et al. (2005) found that this area showed the largest changes between meditators and controls. Awareness of breathing is fundamental to the practice of meditation and yoga. Most practitioners learn to focus on the breath as the first interoception. Attending to the breath leads to slowing of the respiratory rate. In the Lazar study respiratory rate correlated with cortical thickness in the inferior occipitotemporal visual cortex and the right anterior insula.
Review of Research

Mindfulness Meditation

In Kabat-Zinn’s et al. (1992) open pilot study of mindfulness meditation for GAD and panic disorder 24 participants were carefully screened using the Structured Clinical Interview for Diagnostic and Statistical Manual of Mental Disorders, Third Edition, Revised (DSM-III-R) (SCID), Beck Anxiety Inventory (BAI), BDI, Hamilton Rating Scale for Anxiety (HAM-A), HAM-D, and ratings of panic attacks. The intervention included an 8-week course in meditation, followed by a weekly 2-hr class of daily meditation up to 45 min, and a 7.5 hr silent retreat two weeks before the program ended. Meditation included body scan, sitting meditation, and mindful hatha yoga (postures with breath control). Significant declines were found in scores on HAM-D, HAM-A, BAI, and frequency of panic attacks over the course of the intervention and 3-month follow-up. A follow-up study of 18 of the original subjects showed that most subjects continued mindfulness practices and maintained improvements on HAM-A and BAI (Miller et al. 1995). This study supports the short- and long-term benefits of the intervention, but requires validation by larger RCTs.

A review of meditation for anxiety disorders identified 50 relevant studies of which 48 failed to meet inclusion criteria (Krisanaprakornkit et al. 2006). Studies in which anxiety was not the primary focus were excluded. The review defined two types of mind training based on the attentional strategies: concentrative meditation and mindfulness meditation. Meditation therapies may include one or both approaches. Two well-known forms of concentrative meditation, Transcendental Meditation™ (TM) and the relaxation response (Benson 1975), focus attention on an object until the mind becomes still. Meditations intended to open up awareness rather than focus on one-pointed attention include Mindfulness meditation, pranayama (Hindu breathing), Sahaj Samadhi Meditation, Anapasati (Buddhist breathing meditation), Qigong, and “Open Focus” (Fehmi and McKnight 2001). With open awareness, the practitioner cultivates detached observation of any conscious mental contents with a nonreactive, accepting attitude. In the first of the two RCTs considered of “moderate quality” by the Cochrane review, TM was compared to muscle biofeedback and relaxation training in an 18-week program for 31 subjects with Anxiety Neurosis (Diagnostic and Statistical Manual of Mental Disorders, Second Edition (DSM-II)) who were symptomatic for one year or more (Raskin et al. 1980). All three interventions were equally effective in reducing anxiety as measured on the Taylor Manifest Anxiety Scale, Current Mood Checklist, and Social Rating Scale. Sleep disturbance did not improve. The total dropout rate was 44%. The second RCT was a 12-month randomized comparison of Kundalini Yoga (eight practices including slow (1 cpm) left-nostril breathing with breath holds, mantra meditation, and postures) versus relaxation and mindfulness meditation in OCD. The Yoga group showed significant mean reduction (~38.4%) on the Yale-Brown Obsessive-Compulsive Scale (Y-BOCS) versus the control group (~13.9%). No adverse events were reported. Improved ratings of OCD were noted in a previous 12-month pilot study (Shannahoff-Khalsa et al. 1999). Both groups merged for an additional year of the Kundalini program. The 11 completers had a mean improvement of 70.1% on Y-BOCS compared to baseline (Shannahoff-Khalsa 2003). In a 4-month RCT of 35 Swedish employees comparing a stress management program based on CBT with a Kundalini Yoga program, both groups attained significant improvement on self-rated measures of stress, behavior, anger, exhaustion, and quality of life. Most variables showed medium-to-high effect sizes. There were no significant differences between the groups suggesting that both are promising stress management interventions. Physiological measures approached but did not reach statistical significance except for a significant decline in mean noradrenaline levels: $t(14) = 3.15$, $p < 0.007$ in the yoga groups (Granath et al. 2006). culture, involves physical postures and breath practices. It can include meditation, chanting, and Eastern philosophy. Weak evidence supports benefits of Hatha yoga for well-being. Iyengar Yoga, a form of Hatha Yoga, stresses structural alignment of the body through postures aided by props such as blocks, straps, and sand bags. In a nonrandomized wait-list control study of self-referred women who perceived themselves as “emotionally distressed,” those who participated in 90-min; bi-weekly; 3-month Iyengar Hatha Yoga classes demonstrated significant improvements in Cohen Perceived Stress Scale, State-Trait Anxiety Inventory, Profile of mood States, CESD-Depression Scale, and ratings of physical well-being compared to controls. Salivary cortisol decreased significantly in the yoga group (Michalsen et al. 2005). A 6-month RCT compared Hatha yoga (90-min weekly class, 18 postures, relaxation, visualization, meditation, and daily practice) with aerobic exercise (1-hr weekly class of walking and daily exercise), and wait-list control. 135 relatively healthy seniors (aged 65–85 years) showed no improvements in attention, alertness or mood (Profiles of Mood States (POMS)). However, the Hatha yoga group had significantly greater improvement in quality of life, particularly vitality, energy, and fatigue (SF-36, \( p = 0.006 \)), bodily pain (\( p = 0.006 \)), social functioning (\( p = 0.015 \)) and physical composite scale (\( p = 0.005 \)) compared to the other groups. The authors cautioned that improvement in social function could be due to greater opportunities for social interaction in the Hatha yoga class (Oken et al. 2006).

Qi is an ancient Taoist and Chinese system of yoga used for health and longevity. Internal Qi is used primarily in treatment with inhalation, exhalation and breath holds to stimulate the circulation of blood and the vital life energy. Qi is the vital life energy, Qi. External Qi is used on physical movements with internal quiescence. Most studies of Qi are of limited value because of methodological limitations and small sample sizes. The effects of Qi on HRV were assessed in several studies comparing healthy sedentary adults with healthy Qi-trainees. During controlled respiration Qi training increased high frequency (HF) power and decreased low frequency/high frequency (LF/HF) power ratio of HRV, indicating increased cardiac parasympathetic tone. Moreover, experienced Qi-trainees had higher HRV than age-matched sedentary controls (Lee et al. 2002, Lee et al. 2005a, 2005b). Tai Chi Chuan (a form of meditation in smooth movements) was found to reduce psychological and physical indicators of stress and anxiety in a nonrandomized comparison study of 33 experienced and 33 beginning practitioners before, during and after the practice (Jin 1989). Compared to baseline POMS, ratings of tension, depression, anger, fatigue, and confusion were significantly lower during and after Tai Chi. State anxiety was significantly lower before than during Tai Chi \( f(1.60), 0 < 0.001 \). Larger RCTs are needed to confirm these observations. A 3-month study of medical students compared a program of yoga postures and breathing, prayer, visualization and meditation with a control reading group. The yoga group had significant mean reduction on state-trait anxiety inventory the day of examinations (−34%) vs. control (−3.4%) \( (p < 0.001) \) (Malathi and Damodaran 1999). Kirkwood et al. (2005) reviewed eight studies of yoga for anxiety disorders reporting positive findings, but only the Shannahoff-Khalsa et al. (1999) OCD study documented adequate randomization procedures. Methodological flaws precluded general conclusions other than that results are promising and further research is needed.

A systematic review of studies of the effects of yoga on indices of cardiovascular disease (CVD) risk and insulin resistance syndrome (IRS) included 26 uncontrolled trials, 21 nonrandomized controlled trials, and 22 RCTs. These studies suggest that yoga may decrease many IRS-related risk factors for CVD. However, methodological limitations in most studies point to the need for better quality studies to confirm these positive findings (Innes et al. 2005). A 16-week RCT compared the effects of TM on metabolic syndrome to a control intervention of health education. The study included 103 people with stable coronary artery disease. At the end of 16 weeks, the TM group showed modest improvements in measures of mean blood pressure (−3.4 ± 2.0), insulin resistance, and HRV (high frequency) compared with the control group (Paul-Labrador et al. 2006). Additional studies are needed to validate the benefits of TM in modulating stress response and risk factors for coronary artery disease (CHD). Twenty-five adolescents with irritable bowel syndrome in a RCT were assigned to either 1 hr of yoga instruction followed by four weeks of daily home practice or a wait list control. Those in the yoga group showed significantly lower scores on gastrointestinal symptoms and emotion-focused avoidance (Kutner et al. 2006). Musicians were offered a yoga and meditation program in a nonrandomized, self-selected study. Those who did not choose yoga served as controls. Musicians in the yoga program \( (N = 10) \) reported improvement in performance anxiety compared with control \( (N = 8) \) (Khalsa and Cope 2006).

**Yoga Breathing**

Hundred of yoga breath practices have been used to maintain health, treat illness, and promote self-development. Identifying common elements among diverse practices, Brown and Gerbarg developed a neurophysiological theory for the effects of yoga breathing, providing a framework for further study (Brown and Gerbarg 2005a, 2005b).

Slow yoga breathing usually begins with focusing attention on the breath and increasing awareness of the breath. Most forms of slow deep breathing will produce some calming effects. Slow yoga breathing (including Ujjayi) increases RSA, HRV, and PNS activity (Cappo and Holmes 1984, Lehrer et al. 1999), arterial baroreflex sensitivity, and oxygenation. Reducing respiratory rate to 5–6 bpm enhances synchronization between the respiratory and cardiovascular (CV) systems and optimizes oxygen exchange (Bernardi et al. 2005, Vaschillo et al. 2004). Using CDs or DVDs enhances compliance (see for a CD with paced breathing at 5–6 bpm: www.coherence.com). The mental and physical calming of slow yoga breathing is substantially enhanced by resistance breathing, prolonged expiration, breath holds, alternate nostril breathing and left nostril breathing. Ujjayi (Victorious Breath or Ocean Breath) is an effective form of resistance breathing. Contraction of laryngeal muscles with partial closure of the glottis (creating a sound like the ocean) increases airway resistance, intrathoracic pressure, baroreceptor stimulation, HRV, RSA (Calabrese et al. 2000), and stimulation of somatosensory. Airway resistance
enhances breath control. Ujjayi can first be done slowly with inspiration equal to expiration. Lengthening the expiration phase and adding breath holds further increases PNS activation and effectiveness (Telles and Desiraju 1992). The “Ha” breath used by ancient priests (Kahunas) of Hawaii for storing energy and healing has similarities to Ujjayi in that the whispered sounds of “Ha” on exhalation and “Ho” on inhalation create airway resistance. Although there have been no formal studies of these practices, they are used during meditative contemplation and to overcome physical and emotional stress (Kahn 2004). During slow chanting, such as “AUM” or “Om,” the contraction of the vocal cords creating the sound also creates airway resistance. Chanting may increase PNS and decrease SNS activity, contributing to calmness and well-being that many people experience singing hymns. Alternate nostril breathing, slow paced expiration and inspiration through one nostril alternating with expiration and inspiration through the other nostril for 10–20 min, is easy to master and calming in most clinical disorders, with no adverse side effects. Bhastrika (Bellows Breath), a forceful rapid breathing (30 cpm) activates the SNS inducing CNS excitation followed by emotional calmness with alertness. Cyclical breathing at different rates produces a variety of effects. For example, breathing at 8–12 bpm decreases PNS withdrawal in response to threat and reduces anxiety (Sakakibara and Hayano 1996). High frequency breathing stimulates the SNS. While the possibility that this could benefit anxiety disorders may seem counterintuitive, when done in short bursts for short periods of time and balanced by slow breath forms, these techniques can increase the range and flexibility of the stress response system. In many traditions the sounds So Ham or Ham So (So’Hum, Su-Hum) are used to pace cyclical breathing. Some teachers chant in monotone at a fixed rate (http://www.swamij.com/cd-soham.htm), while others deliver So Ham as a melodic chant with varying rates as in SK. Ham So translates from Sanskrit as “I Am That I Am,” the name God gave for himself to Moses in the Bible (Exodus 3:14). It is considered to be the natural mantra of the true self.

SKY is a unique system of four breath techniques that require 20–30 min daily practice and that have the potential to relieve symptoms of stress, anxiety, panic, OCD, and PTSD. It is hypothesized that SKY affects emotional and cognitive processing via shifts in autonomic activity, CNS electrical patterns, and neuroplasticity. SKY begins with a technique combining arm postures with Ujjayi breathing (2–6 cpm) using expiration longer than inspiration and breath holds, intensifying PNS activation such that even highly anxious individuals often experience complete mental and physical relaxation within minutes. This is followed by the “om” chant, Bhastrika (rapid forceful breathing) for about 90 s, and SK, a highly advanced technique using So Ham to pace rounds of cyclical breathing at varying rates. High frequency breathing activates the SNS and may prepare the brain for more rapid information processing. SKY cyclical breathing may disrupt fixed patterns within neural networks, the the legacy of stress and trauma-related emotional schemas (Gerberg 2007, Bucci 2003). We postulate that the physiological challenge of SKY temporarily disrupts established brain wave patterns and neuronal connections in areas containing stress- and trauma-related schemas, creating opportunities for new input (perceptions, experiences, cognitions, emotions, etc.) with positive affective valence to access previously closed areas (containing trauma schemas) and form new linkages leading to structural change and recovery (Gerberg 2007).

A study comparing EEGs of 19 regular SKY practitioners at rest with 15 healthy age-matched controls found significant increase in β-1 and β-2 activity in left frontal, midline and occipital regions of the SKY group (Bhatia et al. 2003). Another EEG study of 12 volunteers during SKY and meditation showed increased spectral power of α-rhythm in the middle band (10−10.5 cps) in O1 and O2 montages (p < 0.005), interpreted as heightened alertness. Significant inter-hemispherical asymmetry disappeared. The highest α-activity appeared at the end of SK in centrencephalic mediobasal structures and occipital cortex (p < 0.05), suggesting enhancement of inter-hemispheric communication and integrative function (p < 0.05) (Snayder et al. 2006). Electrophysiological studies of SKY practitioners show that daily practice of SKY over time is associated with increased coherence and high amplitude synchrony (Larsen et al. 2006). Increased high amplitude gamma synchrony was found in long-term meditating Tibetan Buddhist monks (Lutz et al. 2004). Coherence and synchrony are associated with improved perception, cognition (Mizuhrara et al. 2005), memory (Guderian and Duzel 2005), and neuroplasticity.

PTSD

In severe anxiety disorders and PTSD, slow, deep, or abdominal breathing is insufficient, as the following study illustrates. An RCT comparing relaxation (simple instructions to relax in a reclining chair), relaxation with deep breathing (gradual filling of the lungs and slow complete exhalation), and relaxation with deep breathing and thermal biofeedback in 90 Vietnam veterans with PTSD found all interventions to be mildly therapeutic. Addition of deep breathing and thermal biofeedback did not produce further improvements on PTSD scales (Watson et al. 1997).

In an open trial, 139 war-traumatized high school students in Kosovo were given an 8-week mind−body skills program including meditation, biofeedback, movement, guided imagery, breathing techniques, autogenic training, drawing, family genograms, psychoeducation about stress, and group discussions of their experiences (Gordon et al. 2004). Scores on an Albanian version of the PTSD Reaction Index (16 dichotomous questions derived from DSM-III-R) were significantly reduced after the mind−body skill program and remained reduced at 9- and 15-month follow-up. This study lacked a control and had other methodological limitations. It is difficult to evaluate which of the many components were essential for the therapeutic effect. Nevertheless, it suggests that a multimodal program of mind−body practices may reduce symptoms of PTSD.

SKY breath practices have been used to relieve psychological suffering among masses of civilians and military personnel in the wake of natural and man-made disasters such as floods, earthquakes, industrial accidents, wars, and terrorist attacks (Gerberg and Brown 2005). In a wait-list comparison controlled study, 180 village survivors of the 2004 Asian Tsunami who had been living for nine months in refugee camps in Nagapattinam and who scored above 50 on the Post Traumatic Stress Disorder
Yoga techniques could be developed as adjunctive treatment when they awoke at night or when they felt “road rage.” Veterans using yoga breathing to calm themselves in the wait-list group (Carter and Byrne 2006, Brown et al., in press). Veterans using yoga breathing to calm themselves when they awoke at night or when they felt “road rage.” Yoga techniques could be developed as adjunctive treatment for the full range of PTSD symptoms in veterans, providing an alternative for those who do not accept psychiatric treatment.

Patients with PTSD due to sexual abuse benefit when SKY breathing is combined with traditional psychiatric and psychological therapies (Sageman 2002, 2004, Sageman and Brown 2006a). Yoga breathing reduces arousal, anxiety, and overreactivity, enabling the patient to recall and discuss traumatic material without feeling overwhelmed. Other beneficial components of SKY course includes cognitive-behavioral teaching and psychoeducation in human values of acceptance, social responsibility, and community service (Sageman 2002). In a 4-day RCT, 40 women who had been abused by an intimate partner were randomly assigned to three groups. The first was given Breath Water Sound (BWS), a short (8-hr) group program of SKY breath techniques. The second group was received the same 8-hr BWS program followed one week later by Trauma Incident Reduction (TIR) in which a trained listener encourages the subject to repeatedly describe the trauma over one to four sessions until the subject achieves emotional relief. The third group served as a wait-list control for five weeks and then received BWS. In four days BWS dramatically reduced symptoms of PTSD and depression on standardized measures (PCL-C and BDI) and the benefits were sustained at 6-week, 3-month, and 6-month follow-ups. Scores on PCL-C fell below 50 for all subjects. The addition of TIR showed no further impact on PCL-C scores, possibly due to a floor effect, the scores having dropped too low after BWS (Descilo et al. 2006).

A 6-week Iyengar Yoga program was given to disabled Australian veterans of the Vietnam War with PTSD in four small open studies. Although the Iyengar Yoga postures (Iyengar 2001) improved symptoms of depression, the addition of yoga breathing (particularly Ujjayi) and Ham Su meditation significantly reduced symptoms of PTSD, including anxiety, insomnia, flashbacks, and anger outbursts (Carter and Byrne 2004). In a wait-list controlled study of 30 disabled Australian Vietnam veterans with PTSD, those given SKY showed significantly greater reductions on the Clinician Administered PTSD Scale (CAPS) and the self-administered PTSD Checklist-Military (PCL-M) than those in the wait-list group (Carter and Byrne 2006, Brown et al., in press). Veterans using yoga breathing to calm themselves when they awoke at night or when they felt “road rage.” Yoga techniques could be developed as adjunctive treatment for the full range of PTSD symptoms in veterans, providing an alternative for those who do not accept psychiatric treatment.

In a 4-day RCT, 40 women who had been abused by an intimate partner were randomly assigned to tell about the abuse (two 45-min sessions of testimony with a trained listener over two consecutive days), participate in yoga breathing (two 45-min sessions of yoga breathing including slow deep breathing with some breath holds, sound, and yoga postures), a combined testimony/yoga breathing intervention (45-min testimony immediately followed by 45 min of yoga breathing), or serve as wait-list controls (Franzblau et al. 2006). Those who received both testimony and yoga breathing showed the greatest improvement on scores for self-efficacy on the Franzblau Self Efficacy Scale (FSES) 20, particularly in feelings of control, security, and confidence. This study is limited by small sample size, brief duration, and the use of only one measure, the FSES 20. Nevertheless, it highlights the potential for developing integrative treatments for psychological trauma.

### Insomnia: Evidence for Mind–Body Techniques

Pharmacotherapy for insomnia in geriatric populations is associated with problematic side effects including confusion, motor incoordination, intellectual and memory impairment, syncope, daytime sleepiness, and dysphoria. In an RCT, 69 residents in a home for the elderly (over the age of 60) were randomly assigned to three groups: a 6-week yoga program (postures, relaxation, breath practice, and lectures on yoga philosophy; an herbal Ayurveda preparation, Rasyana Kalpa, composed of Withania somnifera root 2 g, Emblica officinalis 1 g, Sida cordifolia 0.25 g, and Piper longum 0.5 g); or a wait-list control (no intervention) (Manjunath and Telles 2005). On a self-rating sleep questionnaire, the yoga group showed significant decrease in the time to fall asleep (average decrease of 10 min, \( p < 0.05 \)), increase in the number of hours slept (average increase 60 min, \( p < 0.05 \)), and improved feelings of being rested \( (p < 0.05) \) compared to no change in the Ayurveda or wait-list control groups. Findings from subjective self-assessments suggest that yoga programs may be a safe and effective for sleep disorders in the elderly. However, they should be confirmed using more objective measures such as polysomnography.

### Clinical Issues: Referrals and Precautions

In recommending yoga practices to patients, one must look for programs that can achieve significant results with a relatively small amount of practice. It is difficult to motivate most patients to do more than 20 min of any daily practice. Some techniques must be learned in courses with certified instructors. However, there are beginning techniques that therapists can learn to teach patients. Most people are able to experience yoga breathing and meditation courses without difficulty. However, clinicians should be aware of the following precautions: Pregnant women and patients with uncontrolled hypertension, migraine headaches, severe COPD, acute asthma symptoms, recent injuries of the neck, shoulders, or chest, or recent myocardial infarction should not do breath holds, Bhashrika or any rapid or forceful yoga breathing. Gentle basic Ujjayi (without breath-holds), alternate nostril breathing, and meditation are safe and soothing. Yoga breathing is generally contraindicated in seizure disorders. Bipolar patients may be triggered to become manic, particularly from Bhashrika and rapid cycle breathing. Bipolar II patients whose mood swings are under good control on medication may do yoga breathing under supervision if they avoid Bhashrika and rapid cycle breath forms. However, if they become agitated or anxious, the yoga breathing should be discontinued. Yoga breathing can increase excretion of lithium causing a drop in serum lithium levels. Bipolar patients being treated on lithium alone should not undertake yoga breath training. Patients on lithium in combination with other mood stabilizers who begin yoga practices should have lithium levels monitored. A review of Qigong-induced mental disorders (Ng 1999) concluded that incorrect or excessive practice of Qigong could induce abnormal psychosomatic responses and mental disorders. Most cases occurred in individuals with underlying bipolar or psychotic disorders in whom Qigong may have served as a trigger. Individuals with PTSD primarily due to recent trauma or trauma during adulthood usually do well with SKY. Patients with chronic PTSD from childhood abuse can benefit from SKY if they...
do not have significant dissociative symptoms. In such cases, the therapist could contact the teacher, prepare the patient, and help process trauma-related material that may emerge. Severe character disordered patients may not be suitable for the group setting. Psychosis is a contraindication for yoga breathing. However, schizophrenic patients have been shown to benefit from gentle basic Ujjayi, alternate nostril breathing, and gentle yoga postures (Descilo et al. 2006).

**How and When to introduce Yoga as a Complementary Treatment**

Factors to consider in suggesting yoga during psychotherapy include the patient’s readiness to engage in mind-body practice, availability of yoga programs, and the quality of yoga instructors. Clinicians who learn about mind-body practices by taking classes themselves, are better equipped to make appropriate referrals, prepare patients, and help overcome obstacles to daily practice. Although there are immediate gains, long-term benefits may not appear for 6−12 months (a time course similar to VNS and biofeedback). Practitioners who become proficient in yoga breathing can learn how to teach the simpler practices to their patients providing a nonaddicting, inexpensive method to control anxiety, insomnia, and other symptoms of hyperarousal. Slow gentle Ujjayi and alternate nostril breathing are the two techniques that have the broadest clinical applications with virtually no side effects when practiced properly.

Many psychiatric patients are unable or unwilling to undertake yoga classes because of social anxiety, distress in the benefits, bias against Eastern practices, time constraints, or financial limitations. In such cases, it can be very helpful to teach the patient one or two basic yoga breathing techniques in the office. For example, alternate nostril breathing or simple Ujjayi will usually give the patient an immediate experience of calmness, relaxation, quieting of the mind, and relief from distress. This becomes a potent motivator for daily practice with encouragement by the therapist. After one to three months of such practice, many patients are ready to learn more by taking classes. CDs that guide the breath practices can be useful, but the quality is variable. It is advisable for the therapist to evaluate CDs before recommending them to patients.

**Hormones for Anxiety Disorders and Insomnia**

Melatonin, the primary hormone secreted by the pineal gland, affects sleep circadian rhythms by interacting with melatonin receptors. Unlike most hypnotics, melatonin does not disturb sleep architecture. In patients with insomnia, DBRPC trials show that melatonin improves sleep, reduces sleep onset latency (Kayumov et al. 2001), and restores sleep efficiency (Zhdanova et al. 2001). Melatonin has a direct action on sleep and on circadian effects on sleep; this dual activity makes it particularly useful in treating delayed sleep phase syndrome (DSPS), insomnia in dementia and jet lag (Pandi-Perumal et al. 2005). A DBRPC study in elderly melatonin-deficient insomniacs found that 1 week of 2 mg sustained-release melatonin effectively maintained sleep, while 1 week of 2 mg fast-release melatonin improved sleep initiation. 1 mg/day sustained-release melatonin for 2 months improved sleep initiation and maintenance with no adverse effects (Haimov et al. 1995). In a 4-week, open pilot study, melatonin 3 mg at the hour of sleep (hora somni (h.s.)) reduced sun downing (agitated behaviors) and daytime drowsiness in 11 elderly nursing home residents with dementia (Cohen-Mansfield et al. 2000). Numerous other short- and long-term studies of melatonin for insomnia in Alzheimer patients show improvements in sleep, mood, memory, reduced sundowning, and delay in cognitive deterioration (see for review: Pandi-Perumal et al. 2005, 2006). A recent DBRPC crossover trial of 40 patients with Parkinson’s disease revealed significant improvements in sleep using melatonin 50 mg and 5 mg versus placebo (Dowling et al. 2005). Melatonin is a powerful antioxidant for the DA system. This promising treatment for insomnia in Parkinson’s patients warrants further study. In a DBRPC trial, 24 patients being treated with fluoxetine 20 mg for major depression and insomnia, sleep quality and continuity improved in the group given up to 10 mg h.s. melatonin. Melatonin caused no more side effects than placebo (Dolberg et al. 1998). Melatonin significantly improved sleep in a DBRPC cross-over trial in schizophrenics (Shamir et al. 2000) and in a pilot study of 11 patients with bipolar disorder, mania type (Bersani and Garavini 2000).

Rapid eye movement (REM) sleep behavior disorder (RBD), a chronic progressive parasomnia, is characterized by loss of paralysis during REM sleep. Patients physically act out their dreams causing injury to themselves or their partner. Many cases occur in neurodegenerative disorders and in Parkinson’s patients treated with DA agonists and levodopa. In neurologically vulnerable patients, stimulants, TCAs, and SSRIs may trigger RBD (Schenck et al. 1986). Traditional treatments for RBD, clonazepam (0.5–2 mg h.s.) or carbamazepine (100 mg t.i.d.) may worsen cognitive function or cause ataxia (increasing the risk of falling). Carbamazepine can cause hepatitis, blood cell dyscrasias, and hyponatremia. Melatonin rarely has side effects even at 9−12 mg h.s., the doses necessary to treat RBD (Kunz and Bes 1997, Paparrigopoulos 2005).

A DBRPC trial in 15 children with pervasive developmental disorders or autism with severe insomnia found that all children given melatonin had significant improvement in insomnia, irritability, alertness, and social ability (Jan et al. 1994). Eight out of 10 epileptic children with severe sleep waking rhythm pathology ages 6 months to 10 years responded to melatonin 5−10 mg h.s. with improved sleep and daytime alertness. Six of the responders gained better seizure control (Fauteck et al. 1999). A study of 20 developmentally disabled children with sleep problems showed benefit from melatonin (Dodge and Wilson 2001). Two DPRPC trials in 40 and 62 children with chronic sleep onset insomnia found that melatonin 5 mg was better than placebo (Smits et al. 2001, 2003).

The heterogeneity of melatonin studies has been attributed to variability in product quality and onset of action (slow vs. fast release), diagnostic differences, comorbid conditions, and timing of administration. A review of 14 RCTs found that melatonin reduced sleep onset latency more in people with DSPS than in those diagnosed with insomnia (Buscemi et al. 2005). Distinguishing between DSPS and insomnia accounted for much of the heterogeneity in study results. Ten of the studies reviewed for safety indicated a low incidence of adverse events (headaches, drowsiness, dizziness, and nausea) with no difference between melatonin...
and placebo in any study. No study ran more than 3 months, limiting conclusions about long-term safety.

Jet Lag: In a DBRPC study of 320 people followed for four days after a long plane trip, the group given 5 mg fast-release melatonin slept better, fell asleep faster, and were more awake and energetic during the day than groups given 5 mg slow-release, 0.5 mg fast release, or placebo (Suhner et al. 1998). Another small DB study found that airline crews were more rested using 10 mg fast-release melatonin compared to placebo. The benefits of melatonin were equivalent to ropi- clone, without next day impairment in cognition (Paul et al. 2001). People who travel across five or more time zones benefit most from melatonin (Arendt et al. 1997). The brain can more easily delay than advance the sleep cycle. It is difficult to advance more than 1 hr at a time. Melatonin given in the evening helps the biological clock advance more by enhancing homeostatic sleep mechanisms. For example, flying from the East coast of the US to Europe requires a sleep phase advance of six or more hours. Taking 5 mg fast-release melatonin to sleep on an evening flight accelerates adaptation to European time and reduces Jet Lag. If this dose causes excess sedation, a smaller dose may be sufficient. Prescription sedative/hypnotics may impair the ability to function in an emergency or the next day. By reducing the tendency to move and walk during long flights, sedating medications increase the risk of deep vein thrombosis (Herxheimer and Petrie 2001).

Benzodiazepine Withdrawal: Many patients start benzodiazepines for sleep during a period of stress, but are unable to discontinue it due to recurrence of insomnia. Melatonin may be useful in helping patients discontinue the benzodiazepine while maintaining sleep quality. For those unable to completely discontinue BZD, it was possible to significantly reduce the dose of BZD by using melatonin concurrently (Pandi-Perumal et al. 2005).

Clinical Guidelines, Safety and Side Effects. One report indicated that four out of six brands of melatonin had ill-defined impurities (Anonymous 1995). Consumers should choose supplements from mainstream companies with pharmaceutical grade melatonin. Side effects, cramps, fatigue, dizziness, headache, and irritability, are infrequent and usually mild. Melatonin is a safe short-term alternative to prescription hypnotics for insomnia. In therapeutic doses, 1.0−3.0 mg h.s. (with increases up to maximum 9 mg h.s. prn), it has few side effects. Elderly patients who are susceptible to cognitive/memory impairment and daytime drowsiness from benzodiazepines, may benefit from melatonin without risk of these adverse effects. Melatonin is best given about 30 min before bedtime. Patients should be instructed to turn lights out for at least 30 min before bedtime to achieve the best effect. Taking melatonin during the daytime bright light may sensitize the eyes to light damage. The safety of high-dose melatonin has not been established. The possibility exists that very high doses (above 50 mg/day) might have long-term effects on testosterone or prolactin levels. Clinicians who prescribe chronic melatonin or danemelon should monitor patients for adverse effects (Bellon 2006).

7-Keto Dehydroepiandrosterone (DHEA) for Post Traumatic Stress Disorder and Bipolar Disorder

There is a limited literature on the treatment of patients with comorbid PTSD and Bipolar Disorder. Retrospective studies show that in adults with Bipolar disorder, about half have a history of severe trauma and about 35% have comorbid PTSD. These patients tend to have more frequent and severe mood swings, a high incidence of comorbid substance abuse, more frequent hospitalizations, and poorer response to standard treatments (Goldberg and Garno 2005, Leverich and Post 2006). A small case series (5 women) with severe chronic PTSD due to severe early abuse, reported rapid and substantial improvement in dissociative symptoms, emotional numbing, avoidance, irri-
tability, energy, mood, memory, concentration, cognitive function, libido, anxiety, and insomnia when treated with 3-acetyl-7-oxo-dehydroepiandrosterone (7-keto DHEA), a metabolite of DHEA (Sageman and Brown 2006b). These patients were symptomatic despite years of psychotherapy and pharmacotherapy. Levels of DHEAS prior to treatment were below normal or in the lower quartile of normal. Doses of 7-keto DHEA ranged from 50−75 mg/day. None of the 5 patients reported any adverse side effects. A previous study of 13 women with chronic PTSD had found that those with a higher level of DHEA in response to adrenal activation by adrenocorticotropic hormone had less severe PTSD symptomatology (Rasmussen et al. 2004). Cortisol-lowering treatments have been found to reduce the kinds of symptoms associated with PTSD. DHEA has been shown to counteract effects of circulating glucocorticoids and to improve memory, mood, and cognition. Unlike DHEA, 7-keto DHEA is not aromatized to testo-
steron or estrogen and therefore is unlikely to increase the risks of acne, baldness, hirsuitism, prostatic changes, or increased estrogenicity (risk of uterine or breast cancer). Further trials are needed to explore the benefits of 7-keto DHEA in treating PTSD. For patients with chronic PTSD who show poor or limited response to standard treatments, 7-keto DHEA should be considered. Serum DHEA and DHEAS levels should be obtained on patients with refractory PTSD or depression. Those with levels below normal or in the lower 50% of normal may benefit from a trial of 7-keto DHEA. The range of normal on laboratory tests of DHEA/DHEAS may not reflect the values seen in healthy age- and gender-matched controls (see for guidelines, the values listed under, Treatment and Disease Prevention Protocols: www.lef.org)

Herbs and Nutrients for Anxiety Disorders and Insomnia

Kava

Kava (extracted from Piper methysticum), a social and ceremonial drink in the Pacific Islands, has intoxicant, sedative, anxiolytic, anticonvulsant, and analgesic properties. These effects are mediated by alpha-pyrones (kavalactones) which have sodium and calcium channel blocking activity as well as some serotonin blocking action. In reviewing seven DBRPC studies of kava for anxiety, Pittler and Ernst (2000) concluded that it was relatively safe and superior to placebo. In the three studies that met criteria for meta-
1800s describe kava intoxication in natives and seamen left behind by Captain Cook (see for review: Singh and Blu-menthal 1996). After kava was introduced to the Maori in northern Australia, long-term users suffered facial swelling, scaly rash, increased patellar reflexes, and dyspnea. Low levels of albumin, increased GGT, abnormal CBCs with decreased white cell and platelet counts, and hematuria were found. Tall P waves on ECGs were consistent with pulmo-nary hypertension (Mathews et al. 1988). A report on 62 indigenous Kava users showed increased liver enzymes which reversed after several weeks abstinence. (Clough et al. 2003). Two postmarketing studies of over 3,000 patients found a 1.5% and 2.3% incidence of side effects, mostly gastroin-testinal, allergic reactions, headache, and light sensitivity. Less commonly, restlessness, drowsiness, lack of energy, and tremor were reported. In four cases, kava induced dystonic reactions, oral/lingual dyskinesias, and worsening parkin-sonian symptoms in a woman on levodopa. These effects are consistent with DA blocking. In one case, a 45 year-old woman developed severe parkinsonism after kava treatment (Messeguer et al. 2002). No studies of long-term safety, teratogenicity, or mutagenicity beyond 6 months have been reported. Combining kava with alcohol or other sedatives such as alprazolam or muscle relaxants has resulted in coma (Almeida and Grimsley 1996).

Since 1998, serious liver toxicities including liver failure requiring transplantation have been associate with kava extracted with acetone or alcohol. Aqueous kava extracts did not affect liver function in a rat study (Singh and Devkota 2003). The U.S. Food and Drug Administration (FDA) issued a Letter to Health Care Professionals and a Consumer Advisory about the potential risk of liver injury (FDA 2002, Kraft et al. 2001). Kava extract and kava lactones inhibit P450 enzymes involved in the metabolism of most pharmaceuticals (CYP1A2, 2C9, 2C19, 2D6, 3A4, and 4A9/11) (Mathews et al. 2002). Considering the minor benefits of kava versus the potential for rare serious side effects, intoxication, abuse, and dependency, there seems lit-tle reason to recommend kava unless more compelling data on safety and efficacy become available.

Valerian
Valerian (Valeriana officinalis) is thought to bind to GABA-A receptors. One review of DBRPC trials of valerian for sleep found the evidence to be encouraging but not compelling (Stevinson and Ernst 2000). Another review found subjective improvement in sleep in six out of seven DBRPC trials with no side effects other than minimal hangover in doses of 600–900 mg (Krystal and Ressler. 2002). One DBRPC cross-over study of 16 mild insomniacs using polysomnography reported a significant decrease in slow wave sleep (SWS) onset latency and an increase in the percent of SWS time (Donath et al. 2000). The effect of valerian improves over time and maximal benefit may take 2 weeks.

A small study of 36 patients compared valerian (mean daily dose 81.3 mg valepotriates), diazepam (mean daily dose 6.5 mg), and placebo (Andreatini et al. 2002). There were no significant differences in this 4-week RCT among the three groups on either baseline or the change from baseline scores on HAM-A. All three groups had significant reduc-tion in HAM-D scores. However, only the diazepam and valepotriates groups showed significant reductions on the HAM-A psychic factor. In a MCRPC parallel-group study of 184 adults with mild insomnia (Morin et al. 2005), the groups given valerian-hops or diphenhydramine showed modest improvements in subjective sleep parameters, most of which did not reach statistical significance. The valerian-hops produced greater, but not statistically significant, reductions in sleep latency than diphenhydramine and placebo. Quality of life improved significantly in the valerian-hops group compared to placebo, suggesting that valerian-hops may be a useful adjunct for mild insomnia. No serious adverse events occurred and there were no residual symptoms. Reports of dystonia and hepatitis from preparations containing a mixture of ingredients (including valerian) are difficult to interpret. Valerian tea and tablets have an unpleasant taste and odor. One advantage of valerian over other sedative/hypnotics is that there have been no cases of habituation or abuse and only one case of possible withdrawal symptoms. Valerian should be avoided in pregnancy. A review and meta-analysis of 16 Valerian studies concluded that it might improve sleep without causing side effects and that further studies were needed (Bent et al. 2006).

Lemon Balm
Lemon Balm (Melissa officinalis): In a DBRPC cross-over study of Melissa officinalis using a 20-min laboratory-induced psychological stressor, the Defined Intensity Stressor Simulation (DISS) battery in 20 healthy volunteers, subjects were given single doses of 600 mg, 1000 mg, and 1600 mg, or placebo (Kennedy et al. 2003). The 600 mg dose significantly improved self-ratings of “calmness” Bond-Lader scales. A combination of Melissa officinalis and Valerian officinalis in three doses (600 mg 1200 mg, and 1800 mg) was given to 24 healthy volunteers in a DBRPC cross-over trial using a 20-min laboratory-induced psychological stressor, the DISS battery (Kennedy et al. 2004). Mood and anxiety were evaluated at baseline and 1, 3, and 6 hr. The 600 mg dose sig-nificantly reduced anxiety ratings, while the 1800 mg dose somewhat increased anxiety ratings. Within a therapeutic window, the combination of M. officinalis and V. officinalis may reduce anxiety under stress. A DBRPC internet-based study of kava and valerian reported no significant differences between kava and placebo for anxiety or between vale-rian and placebo for sleep disturbance (Jacobs et al. 2005). Subject selection was based on State-Trait Anxiety Inven-tory subtest (Stai-State) and on self report of “a problem going to sleep or staying asleep over the past 2 weeks” rather than on standard diagnostic criteria. The negative results may have been due to selection of a heterogeneous population, comorbid conditions, inadequate doses of herbs, or other limitations of internet surveys. A large uncontrolled MC study of a combination valerian/lemon balm product was tested in 918 children under the age of 12 years with restless-sness and dyssomnias (Muller and Klement 2006). Substantial improvement occurred in 80.9% of the children with dyssomnia and 70.4% of those with restlessness. Controlled trials would be useful in assessing safety efficacy of herbs for children

Passionflower
Passionflower (Passiflora incarnata) has been approved by the Kommission E for treatment of nervous restlessness.
Passionflower contains a dihydroflavone, chrysin, which binds to benzodiazepine receptors. In a DBRPC comparison trial, 36 patients with a DSM-IV-TR GAD (HAM-A ≥ 14) were given Passiflora extract 45 drops/day plus a placebo tablet, or oxazepam 30 mg/day plus placebo drops for 4 weeks. Although the oxazepam effect was more rapid, Passiflora was as effective in reducing anxiety and caused less impairment in job performance (Akhondzadeh et al. 2001). Larger studies are needed to validate these findings.

Chamomile
Chamomile (Matricaria recutita). There is little scientific evidence to support the use of, chamomile for sleep or as a sedative. Apigenin, a component of chamomile, has high affinity for benzodiazepine receptors, but minimal sedative or muscle-relaxant effects (Brown 1996). People who have ragweed allergy should not use chamomile.

Clinical Considerations in Using Herbs for Anxiety and Insomnia
Herbs are most useful in patients with mild-to-moderate anxiety/insomnia who:

1. are at risk for addiction or abuse; may be sensitive to prescription medication side effects (e.g., children and geriatric patients);
2. require maximal alertness the next day; show adverse effects from medications (e.g., night eating syndrome with Ambien or amnesia from BZDs); and
3. have not responded to or complied with mind–body practices or who need more time to learn them.

Patients with recurrent major depression and anxiety/insomnia usually need more sedating medications (e.g., BZDs, TCAs, mirtazepine, or atypical neuroleptics). Psychotherapy or CBT, lifestyle changes, mind–body practices, and daily exercise over a period of months or years are usually needed to gradually discontinue such medications.

Cognitive Enhancement

Cognitive Enhancement in AAMI, AD, Dementia, Poststroke, TBI, ADHD, and Dyslexia
Cognitive enhancement should begin in utero and continue throughout the life cycle by providing (1) nutrients for the developing brain, (2) neuroprotective supplements for the aging brain, and (3) treatments for organic brain diseases. After age 20 years, memory decreases by 1–2% per year and usually memory loss becomes significant by age 45 (Crook et al. 1991). Age-associated memory impairment (AAMI) and age-related cognitive decline (ARCD) can be ameliorated by cognitive enhancers. Many neuropsychiatric conditions such as dyslexia, ADHD, AAMI, AD, dementias, ischemia, stroke, and TBI are affected by similar or overlapping pathophysiological processes. For example, TBI is often complicated by secondary ischemia. This section explores the emerging role of alternative treatments based upon the probable mechanisms by which they affect neurophysiological processes, cellular metabolism and repair, and neuronal electrical activity. Recent reviews of herbal medicines in AD found evidence for good therapeutic effectiveness with Melissa officinalis, Salvia officinalis, Yin-Gan, San, Ba Wei Di Huang Wan and Ginkgo biloba. However, limitations in the studies, such as small size and variations in preparatins leave us with a need for larger studies using protocols such as the Consolidated Standards of Reporting Trials (CONSORT) to improve the standardization and reporting of the contents of the herbal preparations (Dos Santos-Neto et al. 2006).

For more detailed discussions of these processes, refer to the following:

1. Neurotransmitter theories: the cholinergic hypothesis (acetylcholine) (Arciniegas 2003, Arciniegas and Silver 2006); catecholamines (DA, NE, and 5-HT); and N-methyl-D-aspartate (NMDA)-glutamate receptor systems (Bell et al. 1998).
2. Biochemical and metabolic derangements: decreases in cellular energy (mitochondrial) production; free radicals (Long et al. 1996); hypoxia; secondary ischemia; nerve membrane alterations and the membrane hypothesis of aging (Zs-Nagy 1994); decreased calcium channel conductance; nitric oxide (McCann et al. 2005); blood–brain barrier damage (Hayes and Dixon 1994).
3. Anatomic areas sensitive to injury and age-related deterioration include the hippocampus, ventro–medial cortex, ventro–basal forebrain, cingulate gyrus, and reticular system (Murdoch et al. 1998, Schmidt and Grady 1995). The decline of hippocampal cells in the CA3 region during aging has been associated with decreased neuronal firing, increased lipid peroxidation, and increased lipofuscin (membrane fragments that accumulate). Stimulation of hippocampal CA3 fibers induces long-term potentiation (LTP) of synaptic transmission, a critical process for memory and learning. Information transfer across the corpus callosum is also important in learning and memory.

Vitamins
The Cache County study of 4,740 elderly subjects followed over 3 years showed that combined use of Vitamin C plus E supplements (neither alone nor B-complex) reduced prevalence and incidence of AD (Zandi et al. 2004). Other data support this finding (see for a review of earlier data: Sano 2003).

B-Vitamins, Folate, Bio-Strath, and Homocysteine
The methylation pathways that maintain cellular proteins, membranes, and antioxidants depend on B-vitamins and folate as cofactors. B-vitamin and folate deficiencies are associated with abnormalities of mood, memory, and cognitive function (Bottiglieri 1996, Hassing et al. 1999). Higher folate, B6, and B12 concentrations have been associated with better cognitive performance. The fasting concentration of Homocysteine (tHcy) and its cofactors, folate, B6, and B12 were analyzed in 812 adults (mean age 61) from the
Maine-Syracuse study who had no evidence of dementia or stroke. Hcy levels were inversely related to cognitive performance, with adjustment for age, gender and CVD. Folate, B₉, and B₁₂ levels were positively related to cognitive performance, but after adjustment for CVD, and CV risk factors, the relationship persisted for B₁₂ only (Elias et al. 2006). Supplementation with B-vitamins improves mood and cognitive function in healthy subjects (Benton et al. 1997). Bio-Strath, a B-vitamin supplement was given at double the usual adult dose to 75 patients, 55–85 years of age, with mild dementia in a 3-month DBRPC trial. The placebo group deteriorated. In contrast, the Bio-Strath group showed improvement in short-term memory as well as physical and emotional benefits. It took 3 months for the differences to appear (Pelka and Leuchtgens 1995). Given the relationship between B-vitamins and cognitive function and the probable role of antioxidants, it is important to treat geriatric and brain-injured patients with B-vitamins.

Nutrients

Omega-3FAs

Omega-3FAs, especially docosahexanoic acid (DHA), are important in neuronal development (Bourre 2005, Bourre 2006, Crawford et al. 1993) and in infant formula supplementation. Research on the benefits of essential fatty acid (EFA) supplementation of formula for normal infants has yielded mixed results. DBPC studies have shown that infants given omega-3 enriched formula have improved brain and eye development (Jensen et al. 1996), better problem solving at 10 months (Willatts et al. 1998), and an increase in scores on the mental development index (Birch et al. 2000). Long-term, large-scale studies with measures of development are needed. EFAs play a role in the synthesis of the PUFAs (necessary to maintain membrane fluidity), membrane enzyme activities, and production of prostaglandins, leukotrienes, and thromboxanes. Increasing free radical damage with loss of membrane PUFAs (lipid peroxidation) occurs with age and is associated with neurodegenerative disorders such as Parkinson’s disease and AD. Abnormally low levels of omega-3FAs have been found in patients with depression and aggression (Hibbeln et al. 1997, Maes 1998, Peet et al. 1998), a subset of ADHD (Stevens et al. 1995), dementia, and AD (Conquer et al. 2000). A prospective study of 1,200 elderly subjects found that after 8 years, those with low DHA serum levels had a 67% greater chance of developing AD than those with high DHA levels (Kyle et al. 1998). Neurological symptoms improved in AD patients given DHA (Nidecker 1997, Soderberg et al. 1991). In a recent DBRPC study, 174 AD patients, 600 mg EPA slowed cognitive decline in very mildly impaired patients over a 6-month period (Freund-Levi et al. 2006). Although much work needs to be done in this area, supplementation with antioxidants and omega-3FAs may protect against neurodegenerative processes (Youdim et al. 2000). In many countries the average diet is deficient in omega-3FAs. Cold water fish, nuts, flax, and dark green vegetables are good sources. Fish or flax oil capsules are convenient for patients unwilling to change their diets. Although there is evidence that omega-3FAs may enhance cognitive development and protect against neurological decline, additional research is needed. High intake of unsaturated, nonhydrogenated fats may lower risk of AD, whereas high consumption of saturated or trans fats may increase risk (M Bryon et al. 2003). A recent epidemiologic study found reduced AD risk with increasing adherence to a Mediterranean style diet (Scarmeas et al. 2006).

SAMe

SAMe is formed by the condensation of the amino acid methionine and ATP (see Figure 108–1). As a methyl donor, SAMe helps maintain neuronal membrane integrity and fluidity, neurotransmitter synthesis, and energy metabolism. The authors have reviewed the data on SAMe (Brown et al. 2000). In primate studies, SAMe reduced impairments and facilitated recovery from ischemic lesions in the motor cortex and dorsolateral prefrontal cortex and from reserpine. Microscopic data suggested that SAMe enhanced migration of macrophages engaged in tissue repair (Takahashi et al. 1986, 1987). SAMe improved cholinergic function and reduced learning deficits in aged rats (Pavia et al. 1997). Rats given 10 mg/kg per day SC SAMe had nearly 50% decreased free radical production, 50% increased glutathione, and nearly 100% increased glutathione peroxidase and transferase in brain tissue (De La Cruz et al. 2000). Forty-one patients enrolled in a DBRPC pilot study received (within 24 hr of ischemia or hemorrhagic stroke) either SAMe 2,400 mg/day IV, SAMe 3,200 mg/day IV, or placebo for 14 days. SAMe improved survival and was well tolerated (Monaco et al. 1996). In a less rigorous single-blind (SB) study, 40 elderly patients with mild to moderate organic brain syndromes treated with SAMe for 2 months showed improvement in 13 out of 19 items on the Sandoz clinical assessment geriatric scale with a 25–45% improvement on scales of energy, drive, confusion, and self-care (Fontanari et al. 1994). In a DBRPC 1-month study of postconcussion syndrome, 30 patients were given either placebo or SAMe 150 mg/day IV. Mean clinical scores of postconcussion symptoms decreased 77% in patients taking SAMe compared to 49% in the placebo group. SAMe also shortened hospital stays (Bacci Ballerini et al. 1983).

Picamilon

Picamilon, a combination of gamma-aminobutyric acid (GABA) and the B-vitamin niacin, decreases cerebral blood vessel tone and increases intracranial circulation rate. A double-blind (DB) controlled study showed that picamilon was more effective than vinpocetine in improving cerebral blood flow (Mirzioan et al. 1989). Picamilon has a mild tranquilizing action and decreases aggression. Paradoxically, it also has mild stimulative properties, improving alertness and cognition. In animal models it counteracts stress and reduces the CNS depressive effect of ethanol. Picamilon rapidly crosses the blood–brain barrier (Dorofeev and Kholodov 1991) and has low toxicity in animal experiments (median lethal oral dose is more than 10 g/kg of body weight). Russian researchers in 16 medical centers conducted large clinical trials using picamilon 20–50 mg, two to three times a day in therapies ranging from 2 weeks to 3 months. Patients with organic brain syndromes due to head trauma, cerebral atherosclerosis, and toxic brain lesions showed the best effects (Kruglikova 1997). Picamilon is useful in patients with cerebral vascular impairment,
particularly with decreased alertness, anxiety, and depression (see Section on ADHD for other uses).

**Cholinergic Enhancing Agents**

The cholinergic hypothesis is based on observations that hippocampal cholinergic dysfunction underlies cognitive impairments in many animal models of TBI (Arciniegas 2001). Cholinergic deficits are also the most consistent pathophysiological findings in AD. The ability of cholinergic agents to improve cognitive function and delay deterioration in AD adds weight to this hypothesis.

**Citicholine**

Citicholine (Cytidinediphosphocholine (CDP-choline), Cch) has been used to treat stroke, dementia, and brain injury in Europe and Japan (Álvarez et al. 1999). After crossing the blood–brain barrier, Cch breaks down into choline (a precursor of Ach) and cytidine (a ribonucleoside). Phospholipid incorporation of the choline restores membrane structural integrity. Cch improves mitochondrial metabolism and synthesis of phospholipids. In animal models, Cch alleviates cerebral hypoxia and protects against ischemia, edema, and neuronal death in the cerebral cortex, forebrain, and hippocampus, in part by decreasing brain glutamate release, boosting ATP levels (Hurtado et al. 2005) and increasing levels of NE, DA, and 5-HT (Petkov et al. 1990). Cch improved memory and cognitive performance in a rat brain injury study (Dixon et al. 1997). In a 6-week study of middle cerebral artery ischemic stroke, 62 patients were given CDP-choline 2,000 mg/day, 41 were given 500 mg/day, and 111 were given placebo. MRIs taken within the first 24 hr and at 12 weeks showed an increase in lesion volume of 1.8% in the 2,000 mg/day group, 34% in the 500 mg/day group, and 84.7% in the placebo group (Mitka 2002). Meta-analysis of controlled trials by the Cochrane Stroke Review Group concluded that patients with acute and subacute stroke benefit substantially from choline precursors such as CDP-choline (Mitka 2002). A more recent review of studies of CDP-choline for stroke was not as enthusiastic. It may be that CDP-choline must be started within 24 hr of stroke onset for benefits (Conant and Schauss 2004). In a study of 30 AD patients randomized to either 1,000 mg/day CDP-choline or placebo for 12 weeks. The patients given CDP-choline showed improved cognitive function without side effects. The effects were more evident in those with early, mild AD (Álvarez et al. 1999). Studies in head-injured patients, including case reports, five open series, three DBRPC, and two comparative studies, indicate that Cch treatment is associated with earlier recovery of consciousness, clinical and EEG improvements, accelerated motor rehabilitation, and shortened hospital stays (Calatayud Maldonado et al. 1991, Levin 1991, Lozano 1991, Spiers and Hochanadel 1999). Cch causes virtually no side effects and toxicity studies confirm its safety. Data suggest that CDP-choline may have a role in age-related memory decline (McDAniel et al. 2003).

**Huperzine-A**

Huperzine-A (*Huperzia serrata*), derived from club moss used in Chinese medicine for inflammation and senility, is a strong acetylcholinesterase blocker with neuroprotective properties. Animal and primate studies show enhancement of learning and memory (Tang 1996, Xu et al. 1996). Three DB trials (more than 450 people) showed significant benefits in AD. Four trials in vascular dementia and AD using Huperzine-A combined with other nicergoline, estrogen compounds, or mental training, showed favorable outcomes. Other trials found benefits in vascular dementia, TBI, age-related memory decline, and schizophrenia (Akhoundzadeh and Abbasi 2006, Wang et al. 2006). RCTs are needed to confirm benefits. In our experience, Huperzine-A is well tolerated with fewer side effects than other cholinergic enhancing agents.

**Herbal Cognitive Enhancers**

**Rhodiola Rosea**

*Rhodiola Rosea* (Golden Root, Arctic Root, or Roseroot) flourishes in the mountains of Eastern Europe, Siberia, and the Far East. It has been used for centuries in Russian and Scandinavian folk medicine. Gerbarg discovered evidence of its use in epic poems dating back to the Greek Bronze Age (Brown and Gerbarg 2004). Since the 1960s, the former Soviet Union conducted extensive animal and human studies of *R. rosea*. The Soviet government seques-tered *R. rosea* research in classified documents because its abilities to enhance physical and mental performance under stress were of strategic interest. It has been used to enhance performance in the military, in cosmonauts, and in Olympic athletes. Declassification of these documents has freed scientists to release their research, but many documents are still difficult to obtain. A comprehensive review, *R. rosea*—“a valuable medicinal plant” (Saratikov and Krasnov 1987c), has been translated by Zakir Ramazanov (2001, personal communication). More accessible reviews are also available (Furmanova et al. 1995, Germano et al. 1999, Kelly 2001, Petkov et al. 1986). Brown et al. (2002) presented a phyto-medical overview in Herbalgram. The Soviets exhaustively analyzed the diets of the people of the Province of Georgia searching for the secret of their longevity. Extensive epide-miologic studies have documented that the high percentage of centenarians and the high percentage of mentally and physically well elderly is based on environmental and dietary (rather than genetic) factors (Agakishiev 1962, Ferrell et al. 1985). *R. rosea* is believed to be an important dietary factor contributing to the longevity of Georgians who live at the highest altitudes. They prepare an extract of *R. rosea* root to make tea. All members of the families, from toddlers to great grandparents, drink *R. rosea* tea regularly.

*R. rosea* extracts contain bioactive alkaloids, polyphenols, and phenylpropanoids including tyrosol and salidroside (found in other plants). High pressure liquid chromatography (HPLC) identified the cinnamyl alcohol betavicianidines, rosavin, rosin, and rosinar as being specific to *R. rosea* (Bikov et al. 1999, Dubichev et al. 1991, Kurkin and Zapesochnaya 1986). The whole root extract has greater physiological activity than individual compounds. *R. rosea* extracts should be standardized to a minimum of 1% salidroside and 3% rosavin and should be free of drying agents such as maltodextrin or other carriers. Soviet scientists identified complex effects of *R. rosea* extracts on brain function: cognitive stimulation with emotional calming; enhanced learning and memory; increased accuracy in mental performance for prolonged periods of time. This powerful plant “adaptogen” protected every organism tested, from snails to humans,
against physical and mental stresses, exercise, toxins, and mental fatigue. Brekhman and Dardymov defined an adapto-gen as a substance that would increase resistance against multiple stressors including biological, chemical, or physical insults; normalize physiology (whether a body parameter was too high or too low, the adaptogen would bring it towards normal); and not perturb normal body functions more than necessary to improve resistance (Brekhman and Dardymov 1969, Panossian and Wagner 2005). R. rosea increases the efficiency of energy metabolism and maintains energy rich compounds in brain (including the brain stem reticular formation and cerebral hemispheres), muscle, liver, and blood (Furmanowa et al. 1998, Kurkin and Zapesochnaya 1986). Mechanisms of action include effects on monoamines in cerebral cortex and brain stem (increasing NE, DA, and 5-HT) and in the hypothalamus (increasing NE and DA) (Petkov et al. 1986, 1990, Stancheva and Mosharrof 1987). R. rosea has “antiarrhythmic” and positive “inotropic” effects on the heart. In the myocardium, it prevents catecholamine release (and cAMP elevation) and stress related depletion of adre-nal catecholamines (Maslova et al. 1994).

DBRPC studies have shown that R. rosea enhanced intellectual work capacity, abstract thinking, and reaction time in healthy subjects while reducing mental and physical fatigue (Saratikov and Krasnov 1987a, Shevstov et al. 2003, Spasov et al. 2000). R. rosea has been beneficial in patients with organic brain syndrome, most dramatically in posttraumatic and vascular brain lesions, especially in early postinjury stages. Piracetam augmented R. rosea’s improvement of cognitive function. Based on findings that R. rosea exacerbated patients described as “volatile or euphoric” (Saratikov and Krasnov 1987b, Ramazanov (2001, personal communication)), there may be some risk of inducing mania in bipolar patients. R. rosea can be even more effective when combined with ginseng or ginkgo. In patients with brain injury, R. rosea has a mild stimulant effect while emotionally calming. It has not shown any drug interactions. In clinical practice, the authors have found R. rosea to be beneficial in a wide range of disorders of memory, cognition, and fatigue. Increased clinical use and research would be highly beneficial.

**Ginkgo biloba**

*Ginkgo biloba* extract has been used to treat AD and cerebral vascular diseases in Europe. An excellent review, including DBRPC studies was done by Wong et al. (1998). Memory improvements with ginkgo are slight at best and are dose related. Side effects are rare and can be minimized by starting at 60 mg/day and increasing gradually to 120 mg b.i.d. in Alzheimer patients. Occasionally nausea, headaches, and skin rashes occur. Although ginkgo somewhat decreases platelet aggregation, it does not appear to affect coagulation or bleeding time (Cott 2002), fibrinogen, prothrombin time or partial thromboplastin time (Kudolo 2000). Nevertheless, caution should be exercised when using ginkgo in patients on anticoagulants, and ginkgo should be discontinued 2 weeks prior to surgery. *G. biloba*’s effects on cognitive performance in healthy adults are slight: long term memory on associational learning improved in a large well-done DBRPC study of 55–57 year olds (Burns et al. 2006). However, similar improvement has not been documented in healthy young adults. *G. biloba* extract has neuroprotective effects and benefits for memory, AAMI, vascular dementia, and AD. In a DBRPC MC 52-week study of 236 patients with AD, *G. biloba* extract (EGb 761) 120 mg/day improved cognitive performance in patients with mild to moderate cognitive impairment and also slowed the deterioration in patients with severe impairment (Le Bars et al. 2002). A DBRPC comparison study of 109 schizophrenic patients found that patients given Haldol plus EGB 360 mg/day had significant reductions in Scales for Assessment of Negative Symptoms (SANS) and of Positive Symptoms (SAPA) compared to patients treated with Haloperidol only. In addition, the EGb-treated group had fewer “extrapyramidal side effects.” These benefits were hypothetically attributed to EGB scavenging of free radicals (Zhang et al. 2001). Ginkgo potentiates CPH and piracetam (Diamond et al. 2000). The author’s clinical experience is that in TBI it is best used as an augmenting agent. Ginkgo is now the subject of the GuidAge 5-year DBRPC study of 2854 elderly subjects with memory complaints enrolled between 3/02 and 9/04 to determine if 450 mg/day ginkgo reduces the conversion to AD (Vellas et al. 2006). In the US, the GEM study has a similar goal and design. Ginkgo may have a stronger role in prevention than treatment of AD. Other sources of polyphenols similar to ginkgo that may help AD prevention include green or black tea, blueberries, resveratrol and cur-cumin (Ramassamy 2006).

**Ginseng**

Ginseng (Panax, Korean) contains compounds with complex effects. It increased production of nitric oxide by endothelial cells (crucial for blood flow and oxygen delivery) in rabbits (Kang et al. 1995). In a DBPC 8-week study of 39 patients with secondary diabetes, ginseng improved psychomotor performance but not memory (Sotaniemi et al. 1995). A DBPC 8-week study of 24 geriatric patients given 80 mg/day of ginseng versus 25 given placebo found no benefits in cognitive performance. This is not surprising because that 80 mg of ginseng is quite a low dose (Thommesen and Laake 1996). Healthy volunteers over 40 years of age were randomized to either ginseng 400 mg/day or placebo for 8 weeks. The ginseng group showed significantly better abstract thinking and reaction time, but no significant differences in memory or concentration (Sorensen and Sonne 1996). One study that merits replication showed cognitive enhancement with a ginkgo/ginseng combination (Wesnes et al. 1997).

**Vinpocetine**

Vinpocetine-periwinkle (*Vinca minor*), a semisynthetic alkaloid derived from periwinkle (*Vinca minor*), has been used in Eastern Europe as a vasodilator for cerebral vascular disorders. Neuroprotective effects include: inhibition of calcium/calmodulin-dependent cyclic GMP-phosphodiesterase 1; increased intracellular cyclic GMP in vascular smooth muscle; reduced resistance of cerebral blood vessels; and increased blood flow. Vinpocetine inhibits the molecular cascade precipitated by increases in intracellular calcium. A review of DBRPC trials in 731 patients with chronic cerebral vascular disease, including PET scan studies of 12 patients with middle cerebral artery infarcts, concluded that vinpocetine improves cerebral glucose kinetics and blood flow in the peristroke area (Bonoczk et al. 2000). The authors find
it helps patients with ischemia secondary to TBI and/or a single photon emission computed tomography (SPECT) scan evidence of blood flow abnormalities.

**Lemon balm (Melissa officinalis), Dalmation Sage (Salvia officinalis), and Spanish Sage (Salvia lavandulaefolia)**

A 4-week DBRPC trial of *M. officinalis* aromatherapy in 71 severely demented patients showed decreased agitation and withdrawal with improvements in activities of daily living. In a DBRPC trial of two different doses of lemon balm in 18 healthy volunteers, the 600 mg/day dose reduced the effects of stress with better ratings of calmness but less alertness, while the 300 mg/day dose improved math processing speed without reducing accuracy (Kennedy et al. 2004). In a DBRPC 4-month trial in patients with mild-to-moderate AD, those given lemon balm showed cognitive benefit and reduced agitation compared to placebo (Akhondzadeh and Abbasi 2006). Another 4-month DBRPC study showed that sage (Salvia officinalis) had similar benefits in AD (Akhondzadeh et al. 2006). In a DBRPC crossover study of *Salvia lavandulaefolia*, 24 healthy undergraduates (ages 18–37) took either placebo or 25 mL or 50 mL. *S. lavandulaefolia*. On Cognitive Drug Research Battery (CDB) and mood ratings at 1, 2, 4, and 6 hr, those given the herb, particularly at higher dose showed significant improvements in Speed of Memory and Secondary Memory factors, alertness, particularly at higher dose showed significant improvements in Speed of Memory and Secondary Memory factors, alertness, calmness, and contentedness compared to placebo. Memory enhancement was attributed to increased efficiency of information retrieval. *S. lavandulaefolia* was chosen rather than *S. officinalis* because it contains the same bioactive compounds as *S. officinalis*, but has a lower concentration of thujone, a terpenoid ketone that can be toxic in high doses (Tildesley et al. 2005).

Two Chinese herbal preparations have shown promise in AD treatment. A 4-week SBRPC study in 52 AD patients given Yi-Gan-San showed cognitive improvement and gentle sedation. Ba Wei Di Huang Wan (BDW), a traditional tonic containing 8 herbs, is known as Rehmannia 8. In a 2-month DBRPC study of 50 AD patients BDW improved cognition and reduced agitation. In addition to cholinergic enhancement, other actions are probable (Dos Santos-Neto et al. 2006).

**Ayurvedic Herbal Preparations**

**Ashwaganda**

Ashwaganda (*Withania somnifera*) has antistress (calming and mildly sedating) effects and may protect against AD (Anonymous 2004). This adaptogen, used in traditional medicines for centuries, has been studied extensively in animals. Data suggest that Ashwagandha is a cholinesterase inhibitor (Hawkins 2000).

Another Ayurvedic preparation occasionally used by the authors, particularly because for those Indian patients who are more receptive to traditional preparations, is Maharishi Ayurveda Student Rasayana (MA-SR). In a 5-month DBRPC study, 34 third-grade students were given either MA-SR or placebo. The MA-SR group showed a 10 point increase in IQ compared to five points in the placebo group with 78% of the MA-SR group showing improvement in IQ compared with 50% of the placebo group (more than would be expected from test–retest practice effects) (Nidich et al. 1993). *In vitro* models show that MA-SR decreases lipid peroxidation and enhances LTP in the hippocampus. Additional clinical studies are needed.

**Nootropics**

**Pyrrolidones**

Pyrrolidones (Racetams) are nootropics; neural metabolic enhancers. Although piracetam has been most frequently studied, aniracetam, oxiracetam, and pramiracetam are more potent. While results in animal studies are intriguing, human studies in mild dementia and AAMI have shown weak support (Itil et al. 1986, Flicker and Grimley 2001). Piracetam increases nerve cell membrane fluidity, activates EEGs, improves red cell deformability, and normalizes hyperactive platelet aggregation. In animal-learning models and aged rodents, effects on memory deficits are potentiated by CDP-choline, idebenone, vinpocetine, and deprenyl (Goulaeva and Senning 1994, Vernon and Sorkin 1991). Human studies combining racetams with CDP-choline and cholinesterase inhibitors would be worthwhile. Although positive studies of piracetam in postconcussion syndrome have had methodological problems (Cicerchia et al. 1985, Russello et al. 1990), in a DBRPC study of 60 patients with postconcussion syndrome of 2–12 months duration, piracetam 4,800 mg/day for 8 weeks reduced the severity of symptoms, especially vertigo and headache (Hakkarainen and Hakamies 1978). In large DBPC studies, piracetam (given within 7 hr of stroke) enhanced language recovery in combination with speech therapy (De Deyn et al. 1997) and improved task-related blood flow in left hemisphere speech areas on PET scan (Kessler et al. 2000). Studies of a combination of piracetam and ginkgo in dyslexia and aphasia showed significant enhancement of cognitive retraining: gingko improved attention and perception while piracetam improved learning (Enderby et al. 1994) (see the Subsection “Dyslexia and Learning Disabilities” further on). The authors (R.B. and P.G.) find in practice that aniracetam 750 mg b.i.d. is effective in improving cognitive function in bipolar patients with anticonvulsant-induced cognitive impairment, in unipolar depressives on antidepressants, for Chronic Fatigue Syndrome (CSF) and in patients with dyslexia.

**L-Deprenyl**

L-Deprenyl is known as a prescription MAOI antidepressant in the US. It is considered to be an alternative agent in this discussion because most physicians are not familiar with its neuroprotective properties in organic brain disorders. Recent data suggest a mechanism of action different from its MAOI effect, when used in very low doses. Animal studies suggest that l-deprenyl protects catecholaminergic and cholinergic neurons by increasing antioxidants (Kitani et al. 2000, Maruyama and Naoi 1999). In a model of rat TBI, l-deprenyl improved cognitive function and neuroplasticity, particularly in the hippocampus (Zhu et al. 2000). Joseph Knoll, the discoverer of l-deprenyl, described a novel mechanism of action at a receptor site for an endogenous enhancer, which selectively improves impulse propagation mediated release of catecholamines and serotonin in the brain. The enhancer effects on catecholamine and serotonin systems are most marked in the hippocampus.
In response to stimulation of this receptor, gial cells and astrocytes secrete significantly higher amounts of numerous nerve growth factors (NGFs). Higher activity levels in enhancer-sensitive neurons appear to delay the age-related degenerative changes in the brain and to significantly increase longevity in animal experiments. In several studies, L-deprenyl slowed the progression of Parkinson’s and ADs (Knoll 2000). Several human studies show slight improvements in cognitive function in early AD (Mangoni et al. 2000). Our clinical experience is that L-deprenyl given in ultra low doses (that do not cause MAO inhibition) giving half of a 5 mg pill 5 days of the week) may help prevent or slow neurodegenerative changes of aging, neurological diseases, and TBI. The authors use it to enhance neuronal repair and response to other treatments. Liquid L-deprenyl citrate may be more effective, convenient, and tolerable but no comparative studies have been done. The neuroprotective potential of L-deprenyl deserves further study.

Phosphatidyl Serine (PS)

Bovine-derived phosphatidyl serine (Ptd Ser or PS) has been studied for AAMI (Caffarra and Santamaria 1987, Cenacchi et al. 1987), AD (Amaducci 1988), and related conditions. DBPC studies have shown modest memory improvement in these conditions (Crook et al. 1991, 1992). Crook found that in AAMI 300 mg/day for 1 month followed by 100 mg/day improved memory. (see for a review: Pepeu et al. 1996). Ptd Ser, a small component of the inner phospholipid layer, may make the nerve cell membrane more fluid (as discussed in the Subsection “SAMe”). Bovine brain-derived Ptd Ser, rich in DHA (22:6n3) increased brain DA, NE, and epinephrine levels in animals (Salem 1989, Salem et al. 1986). In contrast, Ptd Ser from soy, which is low in DHA, did not alter catecholamine levels. The apparent benefits of bovine Ptd Ser may be due to cognitive enhancing effects of omega-3FAs (Hibbeln and Salem 1995). Although no cases of Mad Cow Disease have been reported with bovine Ptd Ser, further research is needed to determine if this is a possibility. Considering the risk of acquiring prions from bovine tissue, at this time we would advise only using products derived from soy beans or from animals kept New Zealand or Australia where the surveillance for prion-related diseases is highly regulated. Although studies of Ptds Ser have used bovine derived products, in clinical practice, the soy-derived compound appears to be effective. Ptd Ser is often combined with other nutrients such as ginkgo despite the fact that the Ptd Ser effect on memory is more robust than that of ginkgo in normal elderly people. Some patients notice improvement in cognition on Ptd Ser, although the research data is limited (McDaniel et al. 2003).

Other Cognitive Enhancing Agents

DHEA

DHEA is produced primarily in the adrenal glands and secondarily in the ovaries and testes. Among its neurochemical effects, DHEA has been reported to improve memory, brain activation on EEG, and mood (Wolkowitz et al. 1999). A 3-month study of normal older men found no change in cognition or well-being with DHEA (van Niekerk et al. 2001). Patients whose DHEA is low for age (e.g., menopausal women who have had ovaries and adrenal glands removed) (Gurnell and Chatterjee 2001, Yen 2001) and debilitated geriatric patients with medical or neurological diseases are more likely to show improved memory and mood when given DHEA. Side effects include insomnia, irritability, slight increases in estrogen or testosterone, and potential interactions with steroids. Effects on prostate can be monitored by serial testing of prostate specific antigen (PSAs). Physicians should only administer pharmaceutical grade DHEA in doses sufficient to restore physiologic levels (25–50 mg/day).

Melatonin

Melatonin has numerous neuroprotective properties. Its secretion is abnormal in AD and Parkinson’s Disease. Melatonin can improve cognitive function to some extent in long-term use (see sections above and for a review: Srinivasan et al. 2006).

ADD

ADD with or without hyperactivity is a constellation of symptoms that appears by age 7 years and often persists into adult life. Symptoms derive from inability to inhibit impulsiveness and/or to focus attention. Although the etiology and pathophysiology are not understood, theories involving DA, NE, and Ach neurotransmitter systems and under-arousal of the brain have heuristic value for research and treatment. It is particularly important to develop more effective treatments for ADHD because of the high incidence in children; frequent comorbidity with learning disabilities, oppositional behavior, depression, anxiety, bipolar, tics, obsessive–compulsive behavior; and high risk of later substance abuse and antisocial behavior. Stimulants such as methylphenidate are the mainstay of conventional ADD treatments. However, many parents would prefer CAM for their children. Their legitimate concerns about potential abuse and long-term side effects are fueled by reports that methylphenidate affects the brain like slow-acting cocaine (Vastag 2001); that stimulants (e.g., amphetamine) deplete the brain of high-energy compounds (Volkow et al. 2001a), SAMe (Cooney et al. 1998), and DA (Volkow et al. 2001b, 2001c); and that liver cancer increases in mice treated with methylphenidate (Dunnick and Hailey 1995, Ernst and Pitterl 2000) (see for a review of CAM for ADHD: Arnold 2001, Kidd 2000 and for a discussion of biofeedback for ADD, Subsection “Neurotherapy” in this chapter). Misuse of prescription stimulants is increasingly prevalent. A survey of middle school and high school students treated with stimulants found that 23.3% reported being approached to sell, give, or trade their medication (McCabe et al. 2004). In a Web survey of more than 9,000 undergraduate college students, 8.1% reported lifetime illicit use of prescription stimulants (Teter et al. 2005).

Dietary Elimination Strategies

Dietary elimination strategies have been supported by acceptable scientific evidence since the 1970s. The typical responder (a sizable minority of ADD children) is a preschooler with...
insomnia, irritability, atopy, physical symptoms, behavioral problems, and sometimes high caffeine levels. Most families have difficulty maintaining the "few foods" diet. Eliminating the more suspicious food items may help in about 50% of children. Methodological problems and investigator bias in sugar elimination studies have left this issue unresolved (Kidd 2000). The role of toxicity from heavy metals (lead, aluminum) and organic chemical pollutants (pesticides, dioxin, polychlorinated biphenols, hydrocarbons, etc.) in the developing brain needs more research.

**Vitamin and Mineral Supplementation**

Vitamin and mineral supplementation (not megavitamins) is promising in studies in normal children, retarded children, and teen delinquents. In a DBRPC 3-month trial \( (n = 245) \), children whose pretesting showed low serum levels of B-vitamins or C-vitamins, those treated with vitamin supplements showed decreased aggression and antisocial behavior as well as improved cognitive performance (IQ increased 2.5 points) in those treated with vitamin supplements. A subset (20% of subjects) showed a mean IQ increase of 16 points (Schoenthaler and Bier 1999). The authors use Bio-Strath, a Swiss tonic of Brewer's yeast grown on antioxidant herbs and high in minerals, vitamins, and nutrients. In a 6-week DBRPC trial of 44 ADHD children, zinc (15 mg elemental) augmented methylphenidate better than placebo (Akhoodzadeh et al. 2004). Zinc was found to be helpful in a 12-week DBRPC study of 328 boys and 72 girls with ADHD. Zinc sulfate 40 mg/day was significantly more effective in reducing symptoms of ADHD than placebo (Bilici et al. 2004). These studies were done in Turkey and Iran where zinc deficiency may be more prevalent. Nevertheless, in a study of middle-class American children low serum zinc levels correlated with inattention but not hyperactivity–impulsivity (Arnold and DiSilvestro 2005). Mineral supplementation for deficiencies of magnesium, iron, and zinc needs further study (Kidd 2000, Arnold 2001).

**Cognitive activators, antioxidants, nutrients, and nootropics**

Cognitive activators, antioxidants, nutrients, and nootropics that have been shown to ameliorate symptoms in patients with TBI, dementia, and learning disorders may also be beneficial in ADD. Conventional and alternative treatments probably improve ADD symptoms by cognitive activation, but CAM treatments may also ameliorate underlying cell membrane dysfunction. Deficiencies of omega-3FAs have been found in a subgroup of ADHD boys (Antalis et al. 2006). Until further study, no treatment recommendations can be offered. Omega-3FAs improved behavior and cognitive function children with Developmental Coordination Disorder (ADHD is often part of this syndrome) (Richardson 2006). Although there have been no studies of Picamilon for adult ADHD, Richard Brown has found it to be extremely beneficial in several adult patients. RCTs in ADD treatment using the these compounds are needed. Acetyl-l-carnitine affects cell membranes, energy reserves, cholinergic function, and EFA utilization (Pettegrew et al. 2000). In a DBRPC study, 20 fragile-X boys with hyperactivity benefited from acetyl-l-carnitine (Torrioli et al. 1999). Dimethylaminophenol (DMAE) is a common component of OTC supplements used in ADHD. Most of the DBPC trials were done so long ago that their methodology is considered inadequate. However, a more recent rigorous trial suggested a modest effect size, though less than methylphenidate (Arnold 2001). The authors prefer meclofenoxate, a combination of DMAE and PCPA, an excellent antioxidant in nerve cell membranes. It is well studied, inexpensive, and low in side effects. It is potentiated by ginkgo and caffeine. The author has found meclofenoxate with pyrrolidones to be particularly effective in a small number of children and adults with ADD and learning disabilities.

**Herbal treatment for ADHD**

Herbal treatment for ADHD may be used for cognitive activation and/or calming. Controlled trials of ginkgo and ginseng are indicated because these herbs improve learning in animals and humans, they affect the appropriate neurotransmitter systems, and they are cognitive activators (Itil 2001, Petkov et al. 1990). An open trial in 36 children with ADHD given American ginseng \( (Panax quinququefolius) 400 \text{ mg/day plus } G. \text{ biloba} 100 \text{ mg/day} \) for 4 weeks found that 74% improved significantly on the Conner's ADHD scale and 44% improved on a social problems measure. Only two children experienced mild side effects (Lyon et al. 2001). \( R. \text{ roseus} \) has a similar profile and may be used in ADHD. However, it can be very stimulating in younger children. Although Passion-flower is a frequent ingredient in OTC preparations for ADD no studies have been done in ADD. Side effects and toxicity have not been investigated. Huperzine (see the Subsection “Cholinergic Enhancing Agents”) is of interest because it has minimal side effects (unlike prescription cholinesterase inhibitors). Pycnogenol\(^\text{®} \) (extract from French maritime pine bark) was superior to placebo in a DBRPC study of 61 children with ADHD. On standardized measures and teacher and parent ratings after one month, students on pycnogenol had significantly greater improvements in hyperactivity, attention, concentration, and visual-motor coordination (Trebatíčka et al. 2006). Larger RCTs are needed to explore these findings. In a DBRPC trial in 36 children with ADHD for 12 weeks followed by 4-week wash-out, those given Bacopa showed better sentence repetition, logical memory, and paired associate learning. These improvements persisted 4 weeks after Bacopa was discontinued (Negi et al. 2000). A study of 40 normal children found that maze learning, perceptual organization and reasoning improved in those given Bacopa compared to controls. However, this was a nonblinded RPC 12-week trial (Sharma et al. 1987).

ADHD children (like adults with AD, TBI and seizure disorders) have excess theta and reduced beta and/or alpha rhythms. Animal data show a reduction of physical activity with appearance of beta frequencies in the sensorimotor areas when an animal is vigilant and still (e.g., a cat waiting to pounce on a mouse). Promising results have been associated with enhancement of alpha and/or beta rhythms, but further controlled studies are needed (Lubar and Lubar 1984, Ramirez et al. 2001, Nash 2000). The authors have found ‘‘disentrainment neurotherapy,’’ a modification of this approach, to be helpful in ADD (Larsen 2006) (see Subsection “Neurotherapy” in this chapter).

**Mind–Body Practices for ADHD**

Meditation, which effects EEG rhythms similarly to theta/beta biofeedback training, improved attention, particularly...
in the classroom, in two controlled studies in ADHD children (Arnold 2001). In a pilot study of 19 boys with ADHD ages 8–13, a program of yoga postures, yoga breathing, and relaxation led to significant improvements on standardized ADHD tests such as the Conners. (Jensen and Kenny 2004). Nineteen children with ADHD were randomized to a yoga program or conventional motor exercises. For all outcome measures, including scores of attention and parent ratings, yoga training was superior with a medium-to-high effect size (0.60–0.97) (Haffner et al. 2006). More studies are warranted. The authors refer children to a program of yogic postures, breathing and meditation combined with games to improve life skills and self-esteem called ART-Excel taught by the Art of Living Foundation (AOLF) that seems to calm the children and improve their attention and behavior.

**Dyslexia and Learning Disabilities**

Early studies of racetams in dyslexic children showed mixed results, probably due to heterogeneity of subjects and inadequate duration. A DBRPC MC study of 225 dyslexic children (ages 7–12 years) using piracetam 3,600 mg/day demonstrated significant improvements in reading and comprehension evident at 12 weeks and sustained for the 36 weeks of the trial (Wilscher et al. 1987). Piracetam was well tolerated with no adverse effects. In dyslexics piracetam preferentially activates the left hemisphere (Ackerman et al. 1991, Tallal et al. 1986, Helfgott et al. 1986). In clinical practice, the authors find aniracetam is somewhat preferable.

**Neurotherapy**

Traditional Neurotherapy (neurofeedback or EEG biofeedback) trains patients to notice and influence their state of alertness based on EEG measures. This form of operant conditioning requires many treatments and patient cooperation. (see for a review of neurotherapy in ADD: Nash 2000, Butnik 2005, Holtmann and Studlar 2006). A modern innovation of neurotherapy uses the International 10–20 system of brain mapping and therapeutic procedures based on changing the frequency or amplitude of “brain waves” at specific sites on that system (Robbins 2000). It requires no effort on the part of the patient. Protocols have been developed for seizures using the sensori–motor rhythm (SMR, 12–15 Hz) (formerly called “lo-Beta”) (Lubar and Bahler 1976, Sterman and Macdonald 1978), ADHD (Lubar and Lubar 1984, Sovik 2000), TBI (Ayers 1987), and PTSD combined with alpha training (alpha–theta protocol) to reduce the risks of re-traumatization during recall (Ochs 1994), and in depressed alcoholics (Peniston and Kulkosky 1989). Quantitative EEGs (QEEGs), measuring frequencies and amplitudes over the entire brain, have improved the quality of diagnosis and treatment protocols. Inhibition of theta and reinforcement of SMR (immobile attention, still, but alert) have been postulated to explain the therapeutic effects of biofeedback. “EEG-driven stimulation” uses the patients brain waves to provide “fed back” to the brain via light emitting diodes (LEDs). Ochs included all brain wave ranges in protocols emphasizing the brain’s flexibility in moving between them. Commercial light and sound machines entrain brain waves to a fixed frequency. Light flashing at exactly the brain’s own frequency can amplify and drive existing instabilities, producing adverse reactions (e.g., seizures) in people with CNS damage. Ochs developed “offsets” to decrease rather than increase amplitudes producing “disentrainment” rather than “entrainment” (Gleck 1988) using radio waves at a level of intensity far below those of cell phone are used. Called the Low Frequency Neurotherapy System (LENS), this method has been beneficial in ADD, PTSD, affective disorders, pain syndromes, chronic fatigue, and fibromyalgia (Larsen 2006). Some of the best responses were in TBI (including patients with seizures). A preliminary, randomized study of 12 mild-to-moderately severe TBI patients with substantial cognitive impairment given 25 LENS (previously called Flexyx) treatments found significant improvements in BDI, mental fatigue, digit span backwards, delayed recall on the auditory verbal learning test (AVLT), ability to function at work and at school, and other measures when compared to a wait-list control group (Schoenberger et al. 2001).

LENS neurotherapy is a promising treatment with few adverse effects when administered by an experienced clinician. Side effects include temporary re-experiencing of symptoms related to trauma. Excess treatment can cause fatigue and restlessness. Biofeedback practitioners use other systems to reduce theta and enhance alpha and/or beta frequencies for ADD/LD children (Fox et al. 2005, Monasta et al. 2002, Becerra et al. 2006, Beauregard and Levesque 2006). Larger RCTs are needed to follow-up on positive clinical experience and preliminary trials.

**Clinical Guidelines in Using Cognitive Enhancing Agents**

The main considerations in choosing alternative treatments are the specific target symptoms, mechanism of action, side effects, cost, and availability. For example, memory deficits respond well to cholinergic agents. Patients who have neural fatigue or problems with drive and energy, in addition to memory and abstract thinking may do best with *R. rosea*, SAMe, idebenone, or dopaminergic agents. Those who need treatment for depression and/or to improve stress resilience may benefit most from *R. rosea*, SAMe, l-deprenyl, and mind–body practices. Impaired alertness and vigilance may be helped by any of the cholinergic agents, *R. rosea*, picamilon, vinpocetine, or SAMe. Patients with a prominent vascular component in their lesion (by history, SPECT scan, or other blood flow studies) may benefit most from picamilon, vinpocetine (with or without) idebenone, or SAMe. Another example of combining agents would be to choose one that works primarily on the cholinergic system and another that works primarily on the catecholamine and/or serotonin system. Patients who, under psychological testing or on EEG, show over-activation of one cerebral hemisphere compared to the other, and who seem to have impaired transfer of information across the corpus callosum (on neurological testing), may do best with one of the racetam agents in combination with a cholinergic agent. The cholinergic compounds for which there is most evidence of efficacy in cognitively impaired populations or in animal models are galantamine, centrophenoxine, acetyl-L-carnitine, and particularly CDP-choline. Centrophenoxine may work best in combination with the racetam agents. Although piracetam has been the most widely used and studied, aniracetam may be more effective.
How to Use CAM Treatments Safely and Effectively

Herb–Drug Interactions

Our discussion of significant interactions between drugs and herbs must be brief and selective. See Tables 108–1–108–3 for a summary of the major side effects and drug interactions. Because alternative compounds tend to have low side effect profiles, few difficulties are encountered combining them with most conventional treatments. However, herbs (such as SJW) that affect the cytochrome P450 (CYP) drug metabolizing enzyme systems or the P-glycoprotein (Pgp) transmembrane pump can reduce serum levels of numerous medications (see Subsection “St. John’s Wort (SJW) (Hypericum perforatum)”) (Cott 2002). John Neeld, Jr., President of the American Society of Anesthesiologists, warned that a number of anesthesiologists have anecdotally reported significant changes in heart rate and blood pressure particularly in patients taking SJW, ginkgo, and ginseng. He recommends that patients be advised to stop herbal medications 2–3 weeks before surgery (Voelker 1999). Herbs which can affect bleeding time (feverfew, garlic, ginkgo, ginger, and ginseng) should not be used with warfarin and should also be stopped prior to surgery. The use of SJW with medications that have significant action on the serotonin system (SSRIs or MAOIs) should be avoided at the current time because of limited testing for safety. Valerian and kava should not be used with other sedating medications, such as benzodiazepines, because of the potential for additive sedative effects. Evening primrose oil and borage oil (a source of omega-3FAs) should not be used with anticonvulsants because they may lower seizure thresholds. Licorice may counteract the pharmacological effects of spironolactone. Chromium picolinate, and gingens may affect blood glucose levels and should be stopped prior to surgery. Herbal laxatives and licorice, by depleting potassium, may affect the therapeutic action of digoxin, beta-blockers, and diuretics (see for more extensive information on interactions between natural products and prescription medications: Miller 1998, Ernst et al. 2001, Scott and Elmer 2002, Fugh-Berman 2000, Hu et al. 2005). When patients taking standard antidepressant medications are giving activating compounds such as R. rosea or SAMe, they may experience over-stimulation and/or induction of hypomania in rare cases. Nevertheless, overall these agents are extremely well tolerated (see for an approach to risk management of herb–drug interactions: De Smet 2006).

The Importance of the Doctor–Patient Relationship

Communication between a patient and his or her physician is the cornerstone of all therapeutic interactions. Thus it comes as no surprise that a patient’s use of CAM becomes part of the therapy. This is particularly important in light of the expanding information regarding interactions between alternative and traditional treatments, which can be both advantageous and adverse. Surveys indicate that only 25–70% of patients inform their physicians about CAM use. Patients often use alternative therapies without consulting a qualified CAM practitioner. Asking a cashier at the health-food store may be the extent of their “consultation.” Obviously, some patients are well informed about CAM from their own research, or from having consulted with an experienced herbalist or other CAM expert. We are practicing in a time of rapidly growing CAM use when few physicians have been trained in CAM therapies. While many physicians are scrambling to meet this challenge, others are ignoring the need to gain competence in this emerging field of medicine. Ignorance and/or insecurity about CAM treatments may contribute to a potential countertransference enactment in which the physician discounts all CAM approaches as unfounded and misinterprets the patient’s interest in CAM as merely a form of resistance (Kenny et al. 2001). This can create a situation in which the patient cannot tell the doctor about their interest and/or use of a CAM. Patients are more likely to share information with a physician who is open-minded and nonjudgmental. We suggest the discussion start with a comment such as, “I am interested in the ways you maintain wellness such as diet, exercise, herbs, and other activities.” This is preferable to, “Do you use any of those things?” Many CAM treatments enhance and maintain well-being, however, an alternative treatment may render a traditional one less effective, creating confusion in the therapy. Open dialogue between patient and physician helps prevent adverse outcomes.

As with all human endeavors, a patient’s desire to pursue a CAM therapy may reflect a spectrum of psychological meanings. No discussion could cover them all, but a few general themes are worth considering. First, to what extent does the desire for CAM indicate a resistance to conventional treatment that should be clarified and interpreted? Could there be negative transference feelings towards the therapist as an inadequate caretaker or as a controlling conservative authoritarian, mistrust or disappointment stemming from unrealistic expectations of cure, or a need to control the therapy by pursuing treatments outside the therapist’s control? Second, to what extent is the patient’s interest in CAM a legitimate expression of dissatisfaction with traditional treatments and a genuine desire to explore other avenues to seek symptom relief? Three additional points should be considered when patients discuss CAM therapies: What is the patient’s knowledge about the particular CAM treatment and with whom has the patient consulted; What is the physician or therapist’s knowledge about the treatment and with whom should she/he consult; How can the therapist support and assist the patient’s pursuit of safe and effective CAM treatments? (see Subsection “Physician Education” below).

Quality of Alternative Compounds

Doctors and consumers are concerned about the quality of alternative products, particularly herbs and nutrients. Advances in biochemistry have enhanced the purity and stability of many compounds (Wagner 1999). Although the publication of specific brands is not the norm in a text of this kind, in the field of alternative medicine it is particularly important to choose products that have proven to be of good quality. To help the clinician find a way through the morass of unreliable, ineffective look-alikes and bargain brands, Table 108–1 lists particular brands that we have investigated. Invariably some products and companies will change over time. Physicians need to stay current using unbiased sources of product information. Independent evaluation of many brands with updates can be found at www.consumerlab.com.
or www.supplementwatch.com Recalls and warnings to stop use of certain brands, which is available at: http://www.fda.gov/medwatch or http://www.cfsan.fda.gov/~dms/supplmnt.html.

**Medical Liability Issues**

Using alternative treatments and compounds from other countries raises the issue of medical liability. The fundamental principles are the same as with mainstream treatments. A good relationship with the patient and family is key. For informed consent, the physician should clearly explain why the alternative treatment is being recommended, what is known about the compound and how it works, the potential risks and benefits, and the risks and benefits of standard treatment options. The entire explanation should be documented in the chart, including the symptoms that have not responded to standard treatment attempts and the particular indications and considerations involved in the decision. This may include the patients’ philosophy, cultural background, or the fact that they have had difficulty tolerating conventional agents. Physicians, wishing to learn more about the background of data supporting the use of CAM treatments, may examine the references cited in this chapter (see for an excellent review of these issues: Cohen and Schou ten 2007).

**Physician Education**

Patients need help to understand how to choose products of quality whose efficacy has adequate clinical and research support. Physicians can educate themselves by starting with a recent review article on the most common herbal remedies used in North American populations (Wong et al. 1998). The Herb Research Foundation, started by Andrew Weil, in coordination with the American Botanical Council, publishes the Herbalgram, a journal that reviews herbs and features abstracts of recent studies in scientific journals. *The ABC Clinical Guide to Herbs* (Blumenthal et al. 2003) contains a collection of monographs, user-friendly descriptions of herbs, lists of research studies, and patient information sheets. The American Botanical Council individual Monographs may be obtained from the Herb Research Foundation for a small fee (Tel: 303-449-2265). When faced with a patient taking an unfamiliar herb or nutrient, a good source of information is the Natural Medicines Comprehensive Database (Tel: 209-472-2244 or www.naturalmedicine.com). However, the clinical recommendations on the Natural Medicines Database website are quite conservative. Detailed information is also available from The Natural Product Research Consultants (Tel: 973-762-0840) or the American Botanical Council (Tel: 512-926-4900). The National Center for CAM (http://nccam.nih.gov) provides information on research trials. *The Desktop Guide to Complementary and Alternative Medicine: An Evidence-Based Approach* (Ernst et al. 2001) is an extremely well-organized and well-documented resource for any clinician. The *Complementary and Alternative Treatments in Mental Health Care* (Lake and Spiegel 2007) offers evidence-based discussions by experts on different aspects of CAM. Another reference is *How to Use Herbs, Nutrients, and Yoga in Mental Health Care* (Brown et al. in press). Drawing upon research and years of clinical supervisory experience, the authors have written this bibilio–supervision to help clinicians understand ways to integrate CAM into standard psychiatric practice. Updated CAM information and resources are available on the Brown and Gerbarg website: www.havehealthymind.com

**Summary**

This review focused on treatments supported by evidence from clinical trials, mechanisms of action, animal models and in vitro studies with relevance to human conditions, and the authors’ experience. All of the substances discussed have relatively low side-effect profiles and high margins of safety. There is reason to believe that alternative agents have neuroprotective effects as well as abilities to help repair the injured nervous system and enhance its plasticity. Although many CAM treatments have not been generally used by physicians in the US, nor approved by the FDA, based on scientific evidence and the above criteria, they can offer significant benefits for many individuals. Clinically, it often requires several attempts to design an effective combination of treatments. A well-informed clinician is best qualified to help patients and their families understand and develop their alternative treatment regimens.

Introduction

Brain stimulation in psychiatry encompasses a growing list of tools for therapeutic neuromodulation (Lisanby 2004a). These tools include electroconvulsive therapy (ECT), transcranial magnetic stimulation (TMS), magnetic seizure therapy (MST), transcranial direct current polarization (tDCS), vagus nerve stimulation (VNS), and deep brain stimulation (DBS) (Figure 109–1 and Table 109–1).

With the introduction of ECT in 1938, brain stimulation has been in continuous use in psychiatry for the past nearly 70 years (Figure 109–2). As with other medical procedures, ECT technique has evolved over this time, becoming progressively safer and better tolerated with innovations in anesthesia and ECT treatment parameters. After the introduction of ECT, there was a 50-year gap before the next brain stimulation intervention appeared in the field of psychiatry. Breaking the five-decade hiatus was the first published use of pulsed magnetic fields to stimulate the brain (a procedure called TMS) in 1985 (Barker et al. 1985). Initially used in neurology for nerve conduction studies, TMS rapidly caught the attention of psychiatrists who were eager to explore whether TMS could represent a less invasive, nonconvulsive alternative to ECT. The therapeutic potential of TMS in the treatment of a number of disorders in psychiatry (including depression, schizophrenia, anxiety disorders) and neurology is under active study with some promising results (Stanford et al. 2007, Lisanby et al. 2002). A parallel line of development has been to use TMS as a more focal means of inducing seizures (a procedure called MST, in an attempt to retain the excellent efficacy of ECT, but with fewer cognitive side effects (Lisanby et al. 2003, Lisanby et al. 2001, Lisanby 2004b, Moscrup et al. 2006).

The next two developments in the field of brain stimulation came just a short decade after the introduction of TMS, and they were the approval of DBS for the tremor of Parkinson’s disease, and the approval of VNS in the treatment of epilepsy in 1997 (Figure 109–2). As was the case for TMS, these new developments originated in the field of neurology. However, psychiatrists rapidly appreciated the therapeutic potential of these novel modalities. VNS subsequently received FDA approval for the treatment of chronic, medication refractory depression in 2005 (Rush et al. 2000). Likewise, DBS is under active study in the treatment of obsessive compulsive disorder and depression (Mayberg et al. 2005, Greenberg et al. 2006). In the past decade, several new technologies have emerged in the field of neurology. These include responsive stimulation paradigms and epidural cortical stimulation. Again, psychiatric interest in these modalities is high, and at a very early stage.

As this timeline suggests, the evolution of brain stimulation techniques in psychiatry appears to be gaining momentum. Often developments in neurology have been co-opted for psychiatric indications. However, it is not clear whether the technologies and dosages that are designed for neurological indications will be ideal for psychiatric indications. Indeed, we are at an early stage of testing the clinical value of recent developments in the brain stimulation armamentarium, and weighing what the new modalities have to offer relative to the original brain stimulation technique in psychiatry—ECT. This chapter reviews the current state of the evidence for each of the brain stimulation modalities.

Brain Stimulation: A Unique Family of Neuromodulation Interventions

Mechanisms of Action

Electrical Stimulation of the Brain

The various brain stimulation modalities share a common characteristic in that they stimulate the brain electrically. This electrical stimulation may be directly applied or indirectly induced via magnetic fields. The direct application of electrical stimulation can be performed transcranially as in the case of ECT, transcranial electrical stimulation (TES) and tDCS. However, electricity can also be applied epidurally (e.g., epidural electrical stimulation), or intracerebrally (as in the case of DBS). The epidural and intracerebral modalities...

are more focal than transcranial application of electricity because they bypass the impedance of the scalp and skull.

The magnetic modalities (TMS and MST) induce electricity in the brain indirectly via the principle of electromagnetic induction. Rapidly alternating magnetic fields will induce an electrical current in a conducting medium, like the brain. The magnetic modalities bypass the impedance of the scalp and skull, but they achieve this enhanced focality non-invasively without needing to implant an electrode within the skull as is required for the direct application of electricity. Therefore, the magnetic modalities offer an unparalleled degree of focality without the need for surgery.

Comparison with Psychopharmacology

Psychopharmacology and brain stimulation differ as therapeutic modalities in several clinically relevant respects (Table 109–2). For example, while psychopharmacology relies on molecular action at presynaptic or postsynaptic receptors or intracellular targets, brain stimulation can induce action potentials via electrical depolarization of axons in a manner that is independent of receptor binding. In this sense, brain stimulation has the potential to work when medications have failed, and also the potential to act synergistically with medications, because their sites of action are distinct. Because stimulation is applied directly to the brain, it avoids the systemic side effects seen with medications that are systemically distributed and may be metabolized to biologically active compounds. Brain stimulation has no metabolites,
does not undergo clearance, is not protein bound, and has no known interactions with the metabolism or clearance of psychopharmacological agents.

While medications continue to be biologically available for hours to weeks, depending upon half-life, brain stimulation is applied in a phasic fashion, and because it is electrical, it is not subject to metabolism or clearance. Brain stimulation modalities that administer alternating currents (AC) (e.g., ECT, DBS, VNS) deliver pulses that typically last a millisecond or less. Direct current stimulation (tDCS) is typically applied for up to 30 min. The phasic nature of brain stimulation provides immediate washout in a manner that is not possible for pharmacological agents that must be metabolized and cleared. However, the transient nature of brain stimulation poses a challenge to the induction of lasting effects that will persist beyond the period of stimulation.

Acute Versus Chronic Effects

The actions of brain stimulation can be separated into acute and chronic effects (Figure 109–3). Single electrical pulses, delivered at sufficient intensity, can induce neuronal depolarization and trigger transynaptic action, resulting in the activation of a function circuit. For example, a single TMS pulse applied to the hand area of the primary motor cortex, can activate the cortical spinal track and induce a visible twitch in the contralateral hand muscle. These acute effects of brain stimulation can induce positive effects, as in the case of a muscle twitch or phosphenes (sensation of seeing light), or the acute effects can be disruptive, as in the case of visual masking.

Repeating pulses at regular intervals can exert even more powerful acute effects on brain function. For example, repetitive TMS (rTMS) to the language dominant hemisphere can induce speech arrest (Epstein et al. 1999). In these studies, speech returns to normal after the stimulation is terminated.

Some brain stimulation modalities, like DBS, deliver repetitive pulses continuously, in which case the therapeutic action may rely on acute effects of the stimulation. However, the less invasive and nonsurgical modalities typically involve intermittent stimulation, which presumably requires the induction of some form of neuroplasticity, or other process yet to be determined, that persists beyond the period of stimulation.

Neuroplasticity

Repeated stimulation of a circuit can induce lasting changes in the subsequent activity of that circuit. Neuroplasticity is

thought to occur through dynamic alterations in synaptic efficacy. For example, repeatedly electrically stimulating the perforant pathway at high frequency induces a lasting increase in the efficacy of that circuit, while low frequencies depress it. These phenomena are termed long-term potentiation (LTP) and long-term depression (LTD), respectively. There is evidence that TMS may act in ways that resemble these aspects of neuroplasticity. Specifically, low frequency rTMS (≤1 Hz) induces a sustained depression in measures of the excitability of the motor cortex, while high frequency rTMS (≥5 Hz) increases motor excitability (Chen et al. 1997, Wang et al. 1996). Recent work coupling TMS with topographical electroencephalogram (EEG) measurements of TMS-evoked potentials provides the first evidence suggesting that these changes in excitability may come about through an enhancement of a brain potential (Esser et al. 2006). While not definitive proof that TMS causes LTP, this in vivo evidence is consistent with that hypothesis.

Impact of Development and Illness on the Brain’s Response to Stimulation
Because brain stimulation acts via neuronal depolarization, and possibly via alterations in synaptic efficacy, it is not surprising that factors that influence neural transmission and plasticity may influence the brain’s response to exogenous stimulation. For example, before the process of myelination is complete, infants and children have higher thresholds for activation of circuits via single pulses of TMS (Mall et al. 2004). Likewise, it has been reported that patients with schizophrenia fail to show inhibitory effects of low frequency rTMS over the motor cortex, which may reflect abnormalities in glutamatergic functioning in that illness (Fitzgerald et al. 2004).

Aging probably also impacts the brain’s response to stimulation. While less relevant for the electrical modalities, cortical atrophy seen with aging or other processes, can reduce the delivered dosage of magnetic stimulation (Kozel et al. 2000). Independent of issues of distance, animal models suggest that aging can also blunt the ability of TMS to induce LTP (Levkovitz and Segal 2001).

Relative Focality and Invasiveness of Brain Stimulation Modalities
The various brain stimulation modalities differ in their relative degrees of focality and invasiveness (Figure 109–4). Noninvasive technologies clearly have the advantage that they may be used with fewer concerns regarding adverse effects, making them more acceptable earlier in the course of illness. Focality is an advantage for brain mapping studies that seek to identify brain regions involved in selected functions. Focality is also a therapeutic advantage if the specific therapeutic target is known, and if stimulation of adjacent regions might be counter-therapeutic. However, if the therapeutic target is broad, or not precisely known, then focality could have drawbacks with respect to efficacy.

DBS is the most focal, since the electrode is implanted directly into the target brain region, but is also the most invasive. On the opposite end of the spectrum, tDCS is the least invasive, but also the least focal modality as it involves the transcranial application of electricity. Also nonfocal is ECT, for the same reasons of scalp and skull impedance faced by tDCS. ECT is more invasive, however, by virtue of

Parallel Approaches: Probing Brain Function in Health and Disease, and Treating Psychiatric Disorders

Brain stimulation modalities have contributed to our field in multiple parallel ways: (1) as tools of discovery to examine normal brain function, (2) as tools to examine the pathophysiology of psychiatric disorders, and (3) as novel therapeutic agents (Figure 109–5).

Unlike neuroimaging that passively acquires information regarding brain function in various conditions, brain stimulation actively changes brain function and induces measurable effects on brain activity. Because neuroimaging is a passive modality, the information yielded in this manner represents correlates of behavior, but cannot test causal relationships. Brain stimulation, on the other hand, is an intervention that can test causal relationships between brain and behavior. As such, brain stimulation can test hypotheses generated via functional neuroimaging. Independent of its ultimate clinical role, noninvasive brain stimulation modalities like TMS have already offered unprecedented means of examining brain-behavior relationships.

Because brain stimulation actively modulates neuronal activity in ways that may be lasting, it additionally carries the potential for therapeutic effects. This potential has been actively explored in a range of psychiatric disorders, as reviewed below.

Integration of Brain Stimulation with Neuroimaging and Neurophysiology

Coupling brain stimulation with functional imaging and/or neurophysiology represents a powerful paradigm for studying neurocircuitry in health and disease, and provides intermediate outcome measures that may be useful in the development of novel treatments. For example, TMS has been successfully combined with positron emission tomography (PET) (Paus et al. 1997), functional magnetic resonance imaging (fMRI) (Bohning et al. 1999), and EEG (Ilmoniemi et al. 1999). A common strategy is to perform the imaging or physiological measures before and after the TMS intervention. However, it is now also possible to perform simultaneous stimulation and imaging.

Simultaneous imaging is useful for examining acute effects of brain stimulation. For example, Strafella and colleagues used dopamine receptor PET to demonstrate that prefrontal TMS releases dopamine in the caudate, providing a functional probe of the activity of frontostriatal dopaminergic regulation (Strafella et al. 2001). On the other hand, the pre/post paradigm may be useful for identifying lasting and chronic effects of stimulation. For example, Speer et al. (2000) found that a course of daily rTMS given to depressed patients induced lasting increases in regional cerebral blood flow in bilateral frontal, limbic, and paralimbic regions implicated in depression. Such results could inform the mechanisms of action of brain stimulation modalities, and could be used to screen for stimulation paradigms predicted to have therapeutic effects based upon their ability to modulate activity in the circuitry implicated in the illness.

Brain Stimulation Tools in Psychiatry

ECT

Definitions

During ECT, an electric current is passed through the brain via electrodes placed against the head to produce a seizure. A series of treatments constitute an acute course of the ECT therapy, which is used to treat several psychiatric conditions when other treatment modalities have either failed, cannot be tolerated, or are not expected to produce satisfactory results quickly enough. The procedure is performed under anesthesia to block the motor convulsion that would otherwise occur in the absence of a muscle relaxant, and to insure adequate oxygenation throughout the procedure. Typically, ECT will relieve the most profound symptoms of depression, the most commonly treated illness, within 2–3 weeks, with treatments usually given 2–3 times per week during the acute course of ECT. Continuation ECT refers to the continued application of ECT in the weeks immediately following the end of the acute course, at a tapered schedule, to stabilize remission. Maintenance ECT refers to the continued use of ECT over the months following a successful ECT course to prevent relapse.

History

Initially, convulsive therapy was performed via chemoconvulsant agents, a procedure introduced by Meduna in 1934 (see for a review of the history of ECT: Dukakis and Tye 2006). The first electroconvulsive treatment was performed on a human patient by the Italian team of Ugo Cerletti and Lucino Bini in 1938. From its inception, the procedure remained almost the exclusive way of treating serious mental illness and steadily gained in popularity until approximately the early 1960s. At that time, it’s popularity started to wane, both as a result of introduction of novel medications and as concerns regarding the side effects of the treatment. In the pre-anesthesia era, besides memory impairment, ECT side effects infrequently included bone fractures secondary to the effects of the motor convulsion. Fractures are now mitigated by the use of a muscle relaxant. The introduction
of the use of anesthesia in combination with a muscle relaxant in the 1970s in many ways revolutionized the safety profile of ECT therapy. Further innovations that progressively improved its risk to benefit ratio in the subsequent decades included the change from sine wave to brief pulse ECT in the 1980s, and the introduction of right unilateral (RUL) ECT (Table 109–3). Today, ECT plays a prominent role in the treatment of medication-resistant disorders. ECT has been in continuous use in psychiatry since its inception due to its unparalleled efficacy in helping with the most treatment-resistant forms of depression, bipolar mania, catatonia or affective episodes in schizophrenia.

Mechanisms of Action
Given the unparalleled efficacy of ECT and its broad spectrum of action, elucidating its mechanisms of action could significantly advance understanding of the pathophysiology of psychiatric disorders and facilitate the development of more targeted and effective treatments. Previous psychological theories based on fear, regression and selective memory loss, have been now discounted in favor of neurobiological theories. Much is known about the neurobiological effects of ECT. For example, ECT exerts a range of neurobiological effects on functional brain activation, neurotransmitter systems, hypothalamic–pituitary–adrenal axis (HPA-axis) (normalizing the dexamethasone suppression test), and neuroplasticity. ECT is also a powerful anticonvulsant. The field presently lacks a single unifying explanation for why ECT should work so well when other modes of treatment have previously failed, and this is the focus of active research.

The ECT procedure involves the administration of anesthesia, the application of electricity, and the induction of a seizure. There is general agreement that it is the seizure itself, rather than the anesthesia or electrical stimulation in the absence of seizure expression, which is responsible for the beneficial clinical effects of ECT. ECT-induced seizures result in a collection of neurochemical, neuroendocrine, and neurophysiological effects (Lisanby and Belmaker 2000). Seizures release neurotransmitters, alter neurotransmitter receptor expression, alter gene expression, exert neurotrophic effects, affect cerebral blood flow and metabolism, and trigger anticonvulsant effects that terminate the seizure. Which constellation of these neurobiological effects is necessary and sufficient for the beneficial effects of ECT, and which contribute to side effects, is a topic under active study.

A clue to the mechanisms of action of ECT comes from the clinical observation that different forms of ECT (e.g., RUL versus bilateral (BL), low dosage versus high dosage relative to seizure threshold) result in differential clinical effects. For example, high dosage RUL provides better antidepressant efficacy than low dosage RUL, but without proportional increases in memory loss (Lisanby et al. 2000). This dissociation demonstrates that efficacy and amnesia can be uncoupled, supporting the view that memory loss is not essential to the mechanisms of action of ECT. Differences in electrode placement and dosage result in seizures that have different patterns of expression. These studies suggest that the efficacy and side effects of ECT are heavily dependent upon the topography of the seizure itself. For example, distinct patterns of effects involving anterior frontal regions have been associated with antidepressant response, while others involving temporal regions have been more strongly linked to the cognitive side effects of ECT (Nobler et al. 1994, Luber et al. 2000). These observations have been used in the development of more focal forms of convulsive therapy that might in future retain the superior efficacy of ECT, but with fewer side effects (Lisanby et al. 2003).

Antidepressants have been reported to increase cell proliferation, neuronal viability, and neurogenesis in rodents and primates. Likewise, ECT exerts neuroplastic effects, increases neurotropic factors, upregulates genes related to neuroplasticity (Erraji-Benchekroun et al. 2007), and increases cell proliferation ( Scalia et al. 2004, Perera et al. 2007) in the hippocampus of rodents and nonhuman primates. Unlike antidepressant medications, ECT induces mossy fiber sprouting. The functional significance of these changes, and their potential relationship to antidepressant response, is a topic under active study.

The anticonvulsant actions of ECT are so powerful that they have been successfully harnessed to treat medication refractory epilepsy and status epilepticus (Lisanby et al. 2001). The massive anticonvulsant action of ECT has been hypothesized to be related to effects on GABA neurotransmission.

Depression is reported to be associated with deficient intracortical inhibition and cortical GABA levels, while ECT increases intracortical inhibition (Bajbouj et al. 2006) and cortical GABA (Sanacora et al. 2003), providing another clue to possible mechanisms of action.

Side Effects
ECT involves a number of risks that need to be evaluated prior to starting the treatment. The risk of death with ECT is relatively low (about 1 per 10,000 patients), comparable to the rate expected from a series of brief anesthetic procedures alone. The most common cause of death with ECT is cardiovascular. Other causes include prolonged apnea, status epilepticus, and cerebral herniation (e.g., in unrecognized cases of brain tumor).

The cognitive side effects of ECT are especially important to consider in the informed consent process and in the selection of ECT treatment parameters. Acutely, ECT causes anterograde amnesia from which patients typically recover soon after stopping ECT. Retrograde amnesia is the most persistent adverse effect of ECT. Shortly after ECT, most patients have gaps in memory for events that occurred close

in time to ECT, but retrograde amnesia may extend back months to years, in some cases. Memory for autobiographical material is relatively less affected by ECT than memory for events of an impersonal nature (Lisanby et al. 2000). While retrograde amnesia often improves during the first few months following ECT, for many patients recovery is incomplete, with persisting amnesia for events that occurred close to the time of treatment (Donahue 2000). Pre-existing cognitive impairment is one of the few predictors of ECT’s adverse effects (Mulsant et al. 1991). Much research has been dedicated to this and it has been shown that the placement of the electrodes (RUL versus BL) as well as technical characteristics of the electrical current applied (pulse shape and width) will affect the degree of risk of memory impairment (Sackeim et al. 2000, Sackeim et al. 1993, Sackeim et al. 1986) with the least risk demonstrated while using unilateral electrode placement in conjunction with ultra-brief pulse delivery. Sine wave ECT is no longer considered standard of care, due to the higher risk of causing long-lasting memory problems. Other side effects of ECT include headache, muscle aches, nausea, and fatigue. ECT produces a transient increase in pulse and blood pressure; occasionally it may affect the cardiac rhythm. Thus, a detailed cardiac history is important to identify individuals at increased risk such as in the immediate post-myocardial infarction setting, unstable angina, or intractable arrhythmias. ECT can be given in conjunction with Obestrics and the use of fetal monitoring. The pre-ECT workup should include complete medical and neurological screening to detect such as history of acute myocardial infarction, space occupying brain lesion or other cause of increased intracranial pressure, unstable aneurysm or vascular malformation, poorly controlled diabetes mellitus, carcinoma, renal failure, or hepatic failure. Although ECT is not contraindicated during pregnancy, careful consideration of risks and benefits is important, as is consultation with Obstetrics and the use of fetal monitoring. ECT has an excellent safety profile, even among the elderly. We recently reported the case of a 92 year old woman who had received 91 ECTs in her lifetime and showed no pathological effects at postmortem examination of her brain when she died of other causes (Scalia et al. 2007). Careful neuropathological examination of nonhuman primates receiving electroconvulsive shock has also failed to reveal evidence of neuropathological lesions (Dwork et al. 2004).

Clinical Studies

There have been numerous studies that describe ECT as a safe and effective treatment for severe or treatment-resistant depression, bipolar disorder (both manic and depressive phases) and schizophrenia. Depression is the most frequently treated diagnosis. The Consortium for Research in ECT (CORE) reported a 75% remission rate among 217 patients who completed an acute course of ECT (Husain et al. 2004). A systematic review conducted by the UK ECT Review Group (2003) found ECT significantly more effective than sham (6 trials, \( n = 256 \) patients, effect size = 0.91) and than pharmacotherapy (18 trials, \( n = 1144 \), effect size = 0.80). Patients with psychotic subtype of depression respond to ECT at higher rates than those without psychosis (Petrides et al. 2001). The efficacy of ECT is quite technique dependent with remission rates ranging from 20% to over 80% depending upon how the treatment is performed. Double-masked, randomized controlled trials demonstrate powerful interactions between electrode placement and dosage relative to seizure threshold in the efficacy and side effects of ECT (Sackeim et al. 2000). The UK ECT Review Group (2003) found BL to be more effectively than RUL ECT (22 trials, \( n = 1408 \), effect size = 0.32) though it should be noted that the efficacy of RUL ECT is dosage sensitive. Several studies have found that high dose RUL ECT is as effective as BL ECT, with the advantages of lower cognitive side effects, especially at long-term follow-up (Sackeim et al. 2000, McCall et al. 2000).

While with optimal technique ECT can be highly effective, success rates in the community hospital setting have been less robust (30–47%, roughly half that seen in clinical trials) (Prudic et al. 2004). Some of these discrepancies may be related to diagnostic comorbidity, but some may also be related to the tendency to halt ECT prior to complete remission (often to mitigate side effects). Only 23.4% of ECT non-remitters immediately following the acute treatment course, were found to have sustained remission at 6 months (Prudic et al. 2004), underscoring the need to “treat to wellness” and not prematurely terminate the acute course of ECT.

Following an effective course of ECT, it is important to initiate maintenance therapy with an antidepressant and mood stabilizer, or in some cases maintenance ECT. Without any form of maintenance treatment, patients relapse at a rate of 54% six months post ECT (Sackeim et al. 2001). Monotherapy with nortriptyline reduced the relapse rate to 60%, but combination therapy with nortriptyline and lithium reduced relapse to 39% (Sackeim et al. 2001).

Current Status in Treatment Algorithms

ECT is usually considered in medication-resistant cases, where several adequate prior drug trials have failed to sufficiently relieve the symptoms. Usually a trial of two or more single action antidepressants (e.g., selective serotonin reuptake inhibitors (SSRIs)) is followed by a dual action antidepressant (serotonin norepinephrine reuptake inhibitors (SNRIs)) trial and possibly a trial of a tricyclic antidepressant (TCA), or monoamine oxidase inhibitor (MAOI) pharmacotherapy, with or without augmentation strategies. However, in cases of severe depression with psychotic features or severe melancholic depression where patient’s safety is a pressing clinical issue, ECT should be considered much earlier.

Most practice guidelines for depression recommend ECT for difficult-to-treat cases, often as a 5th, 6th, or 7th step. In routine clinical practice, however, ECT is often used even later in the course of treatment, due both to its stigma and cognitive side effects. The National Institute for Clinical Evidence (NICE) issued guidance on the use of ECT in the UK which recommended the restriction of ECT to patients with severe depression, catatonia, or prolonged or severe mania, and stated that ECT is not recommended as a maintenance therapy (National Institute for Clinical Evidence 2003). Those guidelines have been critiqued (McDonald 2006, Cole and Tobiansky 2003) for being at odds with the substantial clinical literature on the efficacy of ECT in other conditions (such as schizophrenia) (Tharyan and Adams 2005), and with the clinical utility of maintenance ECT (Kellner et al. 2006). The APA guidelines continue to
support the use of ECT in other conditions and for relapse prevention.

**Patient Selection**

There are several criteria used in selecting ECT as a treatment modality. The first and most obvious one is the diagnostic. ECT has been demonstrated as a very effective treatment for depression, where response rates for depression with psychotic features can approach 90%. It appears the more severe the depression the better the treatment response. For example, Dysthymic Disorder or depressive symptoms in the setting of a personality disorder, have not been particularly responsive to ECT. Persistent catatonia, both phases of Bipolar Disorder, as well as positive and particularly affective symptoms of schizophrenia have all responded well to ECT. A second criterion in selecting ECT is the severity of the symptoms; ECT may and should be considered as an early treatment modality in psychiatric emergencies, particularly where there is little expectation that medications will change the course of the illness. Prior response to treatment is another criterion to be taken into account and may be life saving in cases of recurrent severe depression that has previously responded only to ECT in the past. Another important criterion is the medical safety of the treatment. The risks and benefits need to be carefully weighed for each case, especially if the patient has health conditions that may necessitate modifications to the procedure, such as morbid obesity (with respiratory effects complicating anesthesia and airway protection), central nervous system lesions increasing intracranial pressure, or severe cardiovascular disease.

**Dosing**

ECT dosage planning involves selection of electrode placement, electrical dosage, and methods for individualizing the dosage. Commonly used electrode placements include BL, RUL, and bifrontal (BF). Selection among the electrode placements involves weighing their relative efficacy and risks. For example, RUL or BF may be selected to lower side effect burden, while BL may be selected if RUL or BF are unlikely to be effective (as in the case of a prior failure). Studies suggest that higher relative dosage within the RUL condition enhances its efficacy, while higher dosage within the BL condition enhances its side effects.

Dosage may be individualized by titrating seizure threshold or by using an age-based method. Age is a predictor of seizure threshold, but it only accounts for a small percentage of the variance in seizure threshold, which is highly variable across individuals (Lisanby et al. 1996). An advantage of empirical seizure threshold titration is that it provides a sensitive means of adjusting dosage relative to seizure threshold that has been useful in maximizing the efficacy of RUL electrode placement, which is highly dosage-sensitive in its efficacy.

**Future Directions**

Future directions in the field of ECT include identifying more effective ways of preventing relapse following an effective course of ECT, and reducing the cognitive side effects of the treatment. The CORE group found that only 46% of patients who remit following ECT remain well at 6 months when receiving maintenance treatment with combination pharmacotherapy or with maintenance ECT (the two groups did not differ) (Kellner et al. 2006). In the community setting, the percentage remaining well drops to 36%, perhaps due to less aggressive maintenance treatment or premature termination of the ECT course in the presence of residual symptoms (Prudic et al. 2004). More effective strategies for relapse prevention might involve the combined use of maintenance ECT with combination pharmacotherapy, and a more structured format for adapting the maintenance ECT schedule to fluctuations in patient status.

Regarding the cognitive side effect burden of ECT, beyond electrode placement, shorter pulse width has been reported to reduce amnesia from ECT (Sackeim et al. 2002), but does not possess the speed of action or effect size of ECT. While these novel treatments offer promise for the future, ECT continues to have a unique role in the acute treatment of severe depression.

**TMS**

**Definitions**

TMS refers to the induction of small electrical currents in the superficial layers of the cerebral cortex by applying rapidly alternating magnetic fields to the head. TMS is administered using an electromagnetic coil that is held on the scalp. The coil emits strong, pulsed magnetic fields. Magnetic fields pass through the scalp and skull freely and enter the brain without the impedance encountered by the direct application of electricity. This makes it easier to focus TMS to smaller regions of the brain than is possible with ECT or tDCS. The rapid change in the strength of the magnetic field induces electrical current in the brain through the principles of electromagnetic induction. TMS has been referred to as “electrode-less” electrical stimulation because it uses magnetic fields to indirectly induce electrical pulses. Because magnetic fields are noninvasive, TMS can be given to awake subjects without the need for anesthesia. As such, it represents a noninvasive means of stimulating focal regions of the brain.

“Single pulse TMS” refers to TMS when it is given one pulse at a time, at an irregular rhythm and at low rates (>0.3 Hz). rTMS refers to stimulation that is repeated at regular intervals. The frequency of this repetition generally ranges from 1–25 Hz. “Low frequency rTMS” refers to repetition rates of ≤1 Hz, while “high frequency rTMS” refers to stimulation at higher frequencies (usually 5–20 Hz).

**History**

The first human use of pulsed magnetic fields to stimulate the human brain was reported by Barker, Jalinous, and Freeston from University of Sheffield in 1985 (Barker et al.
The first generation TMS stimulators were capable of low repetition rates (typically < 0.3 Hz). Single TMS pulses proved useful in the study of motor conduction and other basic brain processes. In early work, these very low frequencies of TMS were applied in exploratory studies on the treatment of depression and schizophrenia (Geller et al. 1997, Belmaker and Fleischmann 1995). These early studies typically used large round coils that were nonfocal, but nevertheless, there were early suggestions of benefit that encouraged further work with TMS in psychiatry.

In the mid-1990s, repetitive stimulators capable of higher repetition rates (up to 20 Hz) became available. Higher frequency stimulation was able to influence higher brain functions like language, mood, and memory. Early studies with high frequency rTMS suggested that it might have antidepressant properties when applied to the dorsolateral prefrontal cortex (DLPFC) (Pascual-Leone et al. 1996, George et al. 1995). Subsequently, the potential therapeutic value of focally applied rTMS, targeted to the neural circuitry underlying depression and other disorders, has attained heightened attention.

Mechanisms of Action
Alternating magnetic fields induce electrical currents in the superficial cortex underlying the TMS coil. These electrical currents are called “eddy currents” because they are circular in shape, and are oriented in the plane perpendicular to the plane of the TMS coil. At sufficient intensity, electrical currents will stimulate neuronal depolarization, which can result in an action potential. For example, when the TMS coil is positioned over the hand area of the motor strip, it induces local currents at the site of stimulation that cause the neurons in Primary motor area (M1) to fire. This stimulation activates the polysynaptic corticospinal tract, and results in a twitch in the contralateral hand muscle. Thus, TMS uses magnetic fields to indirectly induce focal electrical currents in the brain, which in turn trigger the firing of functional neuronal circuits and can lead to observable behavioral effects. By moving the TMS coil to the cortical representation of neighboring muscle groups, single TMS pulses can be used to map the homunculus and study the excitability of the corticospinal system.

When moved to other cortical areas, single TMS pulses can exert other effects, such as transient scotoma, or “blind spots” when positioned over the primary visual cortex (V1). This paradigm is called “visual masking” (Luber et al. 2007). Thus, TMS can transiently disrupt functions. This mode of action has been termed the “virtual lesion” technique.

These various actions of single pulse TMS represent the acute effects of the activation of neural circuits triggered by TMS-induced neuronal depolarization (Figure 109–3). Generally speaking, the effects of single TMS pulses are immediate or short-lived. The motor twitch induced by TMS to area M1 is nearly instantaneous, with the hand movement occurring approximately 20 ms after the TMS pulse is applied. Likewise, visual masking operates on a millisecond timescale. However, TMS can exert longer lasting effects when the pulses are repeated at regular intervals (rTMS), or when they are paired with other forms of stimulation (such as in the paired-associative stimulation paradigm (Quartarone et al. 2006) where TMS pulses are paired with electrical stimulation of a peripheral nerve, or when TMS is paired with audiovisual stimuli as in the example of classical conditioning of the brain response to TMS (Luber et al. 2007). The mechanisms underlying these lasting effects of TMS are thought to be related to neuroplasticity and alterations in synaptic efficacy, as reviewed above.

Because rTMS has the ability to induce lasting changes in cortical excitability at the site of stimulation and in connected regions within neural circuits, its application in the treatment of psychiatric disorders has been driven by the attempt to focally alter abnormalities in cortical excitability linked to illness. For example, studies point to reduced activity of the DLPFC (especially on the left), as well as other regions that form a distributed network, during clinical depression. Therefore, studies have applied high frequencies of rTMS, which have been reported to increase excitability, to the left DLPFC in an attempt to normalize activity in this region. Furthermore, some theories implicate abnormal interhemispheric balance in activation between the right and left DLPFC. Building upon these theories, some studies have applied low frequency rTMS, which has been reported to be inhibitory, to the right DLPFC, in an attempt to normalize that interhemispheric balance.

Further supporting the potential therapeutic role of focally modulating cortical excitability, animal studies suggest that rTMS can exert effects on neurotransmitter release, receptor expression, and gene expression that are similar to some of the effects of antidepressant medications and ECT (Lisanby and Belmaker 2000). It should be noted, however, that animal models of the effects of rTMS do not perfectly replicate the effects of rTMS on the human brain, due to size differences and how they impact the strength and distribution of the induced electric fields.

Side Effects
While TMS is clearly less invasive than ECT, it is not entirely without risk. The most serious known risk of TMS is seizure. The relative risk of seizure with TMS depends upon the form of TMS (single pulse versus rTMS), the dosage (intensity, frequency, train duration, inter-train interval), and subject factors that may place the individual at increased risk (such as the presence of a neurological disorder or seizure lowering medications).

Single pulse TMS is generally considered minimal risk when administered to adults lacking risk factors for seizure. rTMS can induce seizures in individuals without predisposing conditions when given at sufficiently high dosages. Safety guidelines (Figure 109–6) were developed to mitigate the risk of seizure (Wassermann 1998). When given within the safety guidelines, rTMS has not induced seizures in appropriately screened individuals. However, since seizure is a possibility, subjects should always be advised of this potential. It is also recommended that rTMS be administered under medical supervision, and that procedures be in place to medically screen and monitor patients for changes in clinical status that could affect seizure risk. The treating clinician should have the proper training and equipment to manage a seizure should one occur (Belmaker et al. 2003).

The most common side effects of TMS are scalp discomfort and headache. These effects are attributable to scalp muscle stimulation, and stimulation of the facial nerve. Earplugs are worn by the patient and administrator to protect hearing. The risks of TMS during pregnancy have not been
Antidepressant medications. Less than that seen with ECT but close to that seen with positive. The average effect size in depression is moderate—given to the DLPFC. However, not all studies have been supported by several meta-analyses (Burt et al. 2002), reveal through randomized controlled trials, (O'Reardon et al. in press) thoroughly studied. Since TMS is experimental, it may carry as yet unknown risks.

Basic Studies
Apart from its clinical potential, TMS has already demonstrated a number of advantages in the study of normal brain function and of the pathophysiology of psychiatric disorders (Luber et al. 2007). Advantages of TMS as a functional probe include the fact that it is noninvasive, has good spatial resolution and excellent temporal resolution, exerts frequency-dependent effects, and can serve as a companion to neuroimaging by testing the functional role of areas of activation seen with PET or fMRI (Figure 109–7). As an example, we used fMRI to identify a network of brain regions implicated in working memory, then used stereotactically applied TMS to test the functional role of those regions. We found that TMS applied to one region, the precuneus, facilitated working memory performance (Luber et al. 2007). This result informs our understanding of the brain networks involved in a normal brain function, and also suggests that future studies might explore clinical applications for TMS-enhancements of cognitive performance.

Clinical Studies
Major Depression is the disorder that has been most thoroughly studied with TMS to date. A growing number of randomized controlled trials, (O’Reardon et al. in press) supported by several meta-analyses (Burt et al. 2002), reveal evidence of significant antidepressant effects of rTMS when given to the DLPFC. However, not all studies have been positive. The average effect size in depression is moderate—less than that seen with ECT but close to that seen with antidepressant medications.

Schizophrenia has also been studied, with some promising results using low frequency rTMS to inhibit temporo-parietal regions of the cortex reported to be hyperactive during hallucinations (Hoffman et al. 2005). Though less studied, TMS has shown some promising early results in anxiety disorders (Mantovani et al. 2006, Mantovani et al. 2007).

Current Status in Treatment Algorithms
At the time of this writing, TMS is not currently FDA approved, and therefore is not included in treatment algorithms. Should it ultimately be found safe and effective for depression, it would likely be most useful positioned between medications and ECT.

Patient Selection
Given the lower effect size of TMS, ECT would remain the primary treatment for the most severely depressed and highly medication resistant cases. TMS might be considered in less severe and less refractory cases after a failed trial of one or more antidepressant medications, or medication intolerance.

Dosing
There are many aspects to TMS dosing (Figure 109–8).

Certain dosage-related factors that have begun to emerge as possibly related to antidepressant response with rTMS include stimulation intensity, frequency, number of pulses administered and duration of the treatment course (Gershon et al. 2003, Padberg et al. 2002, Sachdev et al. 2002). The delivered intensity of rTMS is related to the distance of the coil from the target cortex. Increasing the distance decreases the intensity of the stimulation reaching the brain, which has been found to be negatively correlated with antidepressant response and with the degree of stimulation-induced brain activation as evidenced by functional imaging (Mosimann et al. 2002, Nahas et al. 2001). Other treatment-related factors that have been shown to be related to neurophysiological responses to TMS include variation in coil and stimulator type, waveform shape and polarity, and coil position and orientation relative to target cortex (Thielscher and Kammer 2004, Maccabee et al. 1998, Davey and Epstein 2000, Kammer et al. 2001, Kammer et al. 2001). Even when these factors are held constant, considerable within-subject variability in physiological response to TMS has been reported in the motor system (Wassermann 2002).

Future Directions
Emerging evidence will shed light on the ultimate clinical role of TMS in psychiatric treatment. It will be important to replicate key findings, identify optimal dosing parameters...
to maximize efficacy, examine dose-response relationships, determine patient characteristics that predict response, and explore the impact of concomitant medications on TMS effects. As with ECT, post TMS relapse prevention is an area yet to be definitively addressed. Future work may develop coils optimized for deeper penetration, and pulse shapes that are more physiologically optimized to human neurophysiology. One such example is controllable pulse shape TMS (cTMS) which can induce pulses that are rectangular in shape (like ECT pulses) (Peterchev et al. 2007). Traditional TMS devices induce pulses that are sinusoidal, a waveform that was abandoned with ECT due its inefficiency and excessive side effects.

**MST**

**Definition**

MST is a new convulsive treatment under development that uses alternating magnetic field to cross the scalp and the calvarium and induce a more localized electric current in targeted regions of the cerebral cortex than is possible with ECT. The aim is to produce a seizure whose focus and patterns of spread may be controlled. MST attempts to marry the focality provided by magnetic fields with the powerful antidepressant efficacy of ECT (Lisanby and Peterchev 2006).

Like ECT, MST is performed under general anesthesia. MST is given using a modified TMS device that can administer higher output than conventional TMS devices. The MST procedure is also performed with a muscle relaxant and requires very similar staffing and infrastructure resources to those of ECT. MST is at the stage of clinical trials, and is not presently FDA approved. Current studies concentrate on optimizing the efficacy through discovery and convulsive treatment applied to the putative depressive centers of the brain, while avoiding those brain areas involved in memory formation and consolidation.

**History**

The first MST-induced seizures, induced in rhesus monkeys, were performed in 1998 using a custom modified TMS device (Lisanby et al. 2001). Following safety testing in nonhuman primates (Dwork et al. 2004), the first human case of a 20 year-old inpatient with a medication-resistant major depressive episode treated in Berne, Switzerland, was published in 2001 (Lisanby et al. 2001). The treatments were well tolerated, resulted in a 50% drop in the depression scores and had no effect on Mini Mental State Exam scores, which stayed at 30 throughout the treatment course. The first trial of MST in the US, performed at Columbia University in NY and published in 2003, reported fewer acute cognitive side effects with MST than with ECT in a within-subject cross-over blinded trial (Lisanby et al. 2003). The second center to perform MST in the US was University of Texas Southwestern Medical Center. Now there are also MST centers in Wales (Cardiff University), Scotland (Royal Edinburgh Hospital), and Germany.

**Mechanisms of Action**

Like ECT, MST induces a seizure which is hypothesized to be central to its mechanism of action. As a focal means of seizure induction, MST represents a tool that can be used to study the mechanisms of action of ECT. By inducing seizures from differing regions of the brain, MST could systematically address questions regarding the linkages between seizure topography and outcome.

Seizures induced by MST are distinct from those induced by ECT (Lisanby et al. 2003). MST induced seizures show less impact on parasympathetic outflow, less generalization to hippocampus and deeper brain structures, and result in less serum prolactin surge. Lack of physiological and structural changes in the hippocampus with MST may relate to its differential cognitive profile (Moscrrip et al. 2006).

**Side Effects**

The risks of MST are similar to those of ECT and are largely connected to the risks associated with anesthesia and generalized seizure. In addition, MST coil produces a clicking noise that may potentially affect hearing and to prevent any cumulative damage, earplugs should be worn by both the patient and members of the treating team. With respect to memory, studies suggest MST results in less retrograde amnesia than ECT (Moscrrip et al. 2006, Lisanby et al. 2003), though this result should be replicated in a larger trial. MST seizures are less well generalized and tend to produce less robust motor convulsions. For this reason, it has been noted that the dosage requirement for the muscle paralytic agent (succinylcholine) is lower than with conventional ECT (White et al. 2006). Shortening the period of paralysis could reduce the risks of the procedure by reducing the period of respiratory suppression.

**Clinical Studies**

The first human patient received a course of four MST sessions in Switzerland during 2000, using 40 Hz at 100% intensity of the MST equipment available at that time (Lisanby et al. 2001). The same centre went on to report a second case that received a full course of MST with similar parameters(Kosel et al. 2003) Both patients tolerated the treatments well and their depressions responded. This was followed by a trial on 10 depressed patients who received two MST sessions during a course of ECT, in a blinded, randomized within-subject cross-over trial which found the acute side effects of MST to be superior to ECT (Lisanby et al. 2003). This time a custom-modified Magstim device (Magstim, Whltland, Wales, UK) was used, which consisted of 16 booster modules and was capable of producing 50 Hz stimulation at a peak magnetic field of 1.2 Tesla for 8 s, with a pulse width of 500 μs. Although seizures were induced in all patients, it was noted that in three cases the seizure threshold was at the maximum output of the device, highlighting the need for technological improvements in the equipment. Subsequently, 20 depressed patients were treated with a full course of MST using the same 50 Hz MST device in a 2-center trial conducted at Columbia University and University of Texas Southwestern Medical Center in 2003 (Lisanby et al. 2003). MST improved depression scores and patients demonstrated remarkably rapid reorientation with few side effects (White et al. 2006).

These early trials demonstrated the feasibility of MST in a clinical setting. However, the maximum stimulation of 400 pulses per session was estimated to be on average only 1.3 times the magnetic seizure threshold, perhaps
contributing to the suboptimal antidepressant efficacy since some modes of ECT are known to be highly sensitive to dosage relative to seizure threshold. Subsequently, available MST technology has significantly advanced. A new prototype MST device capable of stimulation at 100 Hz, 100% of stimulator output, for up to 10 s trains became available for animal use in 2004 (Magstim Company Limited). MST at 100 Hz was performed with this device for the first time in 2004 in an ongoing study of rhesus monkeys. Results to date continue to demonstrate a superior safety profile with high dose MST compared to ECT in the nonhuman primate model (Peterchev et al. 2007). Human trials with 100 Hz MST have commenced and demonstrate the feasibility of implementing the new 100 Hz device in the clinical setting, with encouraging early results (Peterchev et al. 2007).

Randomized trials contrasting the efficacy and safety of 100 Hz MST with ECT are underway. In the US, there is currently a two-center (Columbia University Medical Center and University of Texas Southwestern Medical Center) ongoing clinical trial which intends to randomize 75 medication treatment-resistant patients to either ECT or MST. Similar collaborations exist with two UK clinical research centers (Cardiff University in Wales and the Royal Edinburgh Hospital in Scotland) exploring alternate sites of seizure induc- tion, and contrasting MST with gold-standard ECT.

Current Status in Treatment Algorithms
MST is not FDA approved, and as such does not have a defined place in current treatment algorithms. If the hypothesis that MST can approach the efficacy of ECT but with fewer side effects, then it might in future play a role prior to referral to ECT. However, more research will be needed to establish its safety and efficacy before it can be recommended clinically. As general anesthesia is part of the MST procedure, it will still likely be reserved for medication treatment resistant patients after medications have been tried.

Patient Selection
MST is being tested in the population of patients referred for ECT, the primary indication for which is depression.

Future Directions
MST is at the early phases of clinical testing. Unanswered questions about dosimetry, optimal coil placement, patient selection, and mechanisms of action are the topics of future studies.

tDCS

Definition
tDCS uses very weak (1–3 mA) electrical fields applied to the scalp to polarize the brain. The fields are applied using direct current (DC), rather than the AC used in ECT, VNS, and DBS. Since the technique does not actually result in an action potential firing in cortical neurons, the term “tDCS” is favored by some modern investigators, and both terms appear in the literature today. The device is battery operated and easily portable.

History
tDCS is an old technology that has experienced a modern resurgence of interest. Reports from Briain in the 1960s detailing dramatic recovery from even ECT resistant depression from catatonic and manic states and, in one case, of a schizophrenic man with mutism, have not been replicated. However, new controlled work examining the effects of tDCS in cognitive and motor function have been encouraging.

Side Effects
tDCS appears well tolerated with no known serious adverse effects. Common side effects include a slight tingling at the site of stimulation, and some cases of skin irritation.

Mechanisms of Action
Little is known about the mechanisms of action of tDCS. DC polarizes tissue. Polarization can change the firing rate of neurons. tDCS appears to act via an NMDA mediated alteration of neuronal membrane polarization which might lower the threshold for activation, facilitating neurotransmission. Depending on the direction of current flow, this polarization can either inhibit (cathodal) or facilitate (anodal) function.

Clinical Studies
Work with this technology is at the very early stages. Research suggests that tDCS may enhance certain brain functions. Current research is focusing on its potential effectiveness in facilitating recovery from stroke and from certain forms of dementia. A recent double blind, randomized, sham controlled trial of tDCS in depression found significant antidepressant effect after anodal stimulation over the DLPFC given for 20 min a day over five alternate days (Fregni et al. 2005).

A randomized, double-blind clinical trial of 40 patients diagnosed with major depression compared three groups (anodal tDCS of DLPFC, anodal tDCS of the occipital cortex (active control group) with sham tDCS (Boggio et al. 2007). tDCS was applied for 10 sessions during a two week period. In the group receiving anodal tDCS, HDRS reduction of 40.4% was seen compared to occipital (HDRS reduction of 21.2%) and sham tDCS (HDRS reduction of 10.4%). There was a significantly greater number of responders after DLPFC tDCS (8 responders, compared with sham and occipital tDCS (2 and 0 responders, respectively)). There were five remissions in the DLPFC group and no remissions in the other two control groups. Beneficial effects for the active DLPFC group persisted for one month after the end of treatment. This intriguing finding awaits replication.

Current Status in Treatment Algorithms
tDCS is not FDA approved for brain stimulation, and is therefore considered experimental. Much work is needed to demonstrate its efficacy in psychiatry. If ultimately found to be successful, tDCS could represent a safe and cheap alternative that could reach communities with less access to technological advancements. Given its noninvasiveness and lack of known serious side effects, it would be considered prior to the relatively more invasive technologies.

Future Directions
Basic issues of efficacy, indications, patient selection, dose-response relationships, and predictors of response remain to
be worked out. Current tDCS technology uses large, nonfo-
cal electrodes. Future developments might examine opti-
mal electrode configurations and shape to optimize desired
clinical effects.

VNS

Definition
VNS entails the direct, intermittent electrical stimulation of
the left cervical vagus nerve via a pulse generator implanted
in the left chest wall. The electrode is wrapped around the left
vagus nerve in the neck and is connected to the generator sub-
cutaneously. Intermittent left vagal nerve stimulation sends
afferent signals to the nucleus tractus solitarius and con-
ected limbic and cortical areas (George et al. 2000). Implan-
tation surgery involves two incisions—one for the generator
in the chest and another in the neck for the electrode. Surgery
is usually performed under brief general anesthesia, as day
surgery or with an overnight stay. Stimulation parameters are
adjusted with a programming wand that communicates with
the generator. Patients may turn off the stimulation when
needed by holding a magnet over the generator.

History
VNS was originally FDA approved for the treatment of
resistant epilepsy, and in 2005 was approved for the adjunc-
tive treatment of chronic, treatment-resistant depression.

Mechanisms of Action
The left vagus nerve contains 80% afferent fibers, there-
fore stimulating it activates predominantly vagal afferents.
Chronic stimulation of the vagal afferents changes activity
in brainstem nuclei (such as the nucleus of the solitary tract),
and from there, neighboring nuclei (e.g., Raphe) that alter
serotonergic activity in cortical and limbic structures.
Chronic stimulation of the vagal afferents is anticonvul-
sant, and this effect appears to be dependent upon the locus
ceruleus.

Side Effects
VNS is generally well tolerated. Voice alteration, dyspnea,
and neck pain are the most frequently reported adverse
events (George et al. 2005). The surgical implantation
does carry the risks of infection, vocal cord paralysis, and
bradycardia or asystole (all < 0.5% in the US pivotal (D02)
study). In the long-term naturalistic study of VNS for major
depression, only 3 out of 235 patients (1%) terminated VNS
because of adverse events (Rush et al. 2005). VNS does not
cause apparent cognitive side effects (Sackeim et al. 2001).
In fact, neurocognitive performance was significantly improved
with VNS—apparently due to the improvement in depres-
sion (Sackeim et al. 2001). Contraindications to VNS include a history of bilateral
or left cervical vagotomy and use of short-wave diathermy,
microwave diathermy, or therapeutic US diathermy. Patients
with VNS implanted cannot receive routine magnetic
resonance imaging (MRI) scans, but can receive MRI with
a special “send/receive” coil.

Clinical Studies
In the first study of 30 treatment-resistant depressed
patients (Rush et al. 2000), response rates were 40% after
ten weeks of open-label, adjunctive VNS treatment. The
response rate was sustained (46%) and the remission rate
significantly increased from 17–29% after an additional 9
months of VNS, and significant improvements in function
were reported with long-term VNS treatment. In a subse-
quent report of an extended sample (n = 59) (Sackeim et al.
2001), the short (3 months) and longer-term (24 months)
effects of adjunctive VNS treatment (Nahas et al. 2005)
revealed 10-week response rates of 31% (after 3 months),
44% (after 1 year), and 42% (after 2 years). Remission rates
were 15%, 27%, and 22%, respectively, demonstrating con-
tinuous and stable improvement. By 2 years 81% were still
receiving VNS.

However, a 10-week randomized, controlled, and
masked multi-center trial comparing adjunctive VNS with
sham treatment in 235 outpatients with treatment resistant
unipolar or bipolar depression failed to show a significant
difference on the primary outcomes between active and
sham treatment (Rush et al. 2005).

A naturalistic follow-up study of long-term (1 year)
VNS treatment of the same cohort (n = 202) revealed pro-
gressively increasing improvement with a 12-month response
rate of 27.2% and a remission rate of 15.8%. These results,
when compared to a comparably matched but nonrand-
omized control group that received treatment as usual, indi-
cated VNS was associated with greater improvement than
pharmacological treatment alone (27% vs. 13%) (George
et al. 2005). The significant longer-term benefit of adjunc-
tive VNS to active treatment excluding VNS were open
label and treatment was not controlled. On the other hand,
the improvement in VNS patients was not attributable to
medication changes in the VNS patients, nor is a delayed
placebo effect likely in such chronically ill treatment resist-
ant patients.

Current Status in Treatment Algorithms
The FDA label states that VNS is indicated for the adjunc-
tive long-term treatment of chronic or recurrent depression
in patients 18 years or older who are experiencing a major
depressive episode (unipolar or bipolar) and have not had
an adequate response to four or more adequate antidepres-
sant treatments. Consultation with another clinician experi-
enced with treatment resistant depression and VNS is rec-
ommended.

Success rates with VNS are considerably lower than
with ECT and onset of action is comparatively slow (e.g.,
approximately 30% response rate after 1 year). Therefore,
VNS may be worth considering when patients have failed
to respond to less invasive treatments, ECT was ineffective,
or post ECT relapse cannot be prevented with less inva-
sive means. There is hope that VNS might be helpful with
longer-term relapse prevention, but results of controlled tri-
als would be useful to guide practice.

Patient Selection
Steps in the evaluation of a patient for VNS are outlined
in Figure 109–9. VNS is approved as an adjunctive long-
term treatment for chronic or recurrent depressive episodes
in adults with a major depressive episode who have not
had an adequate response to 4 or more adequate antidepres-
sant trials. The efficacy of VNS in other disorders is
unknown.
Determination of what constitutes an “adequate” trial requires careful assessment of whether adequate dosages were prescribed (and taken) for an adequate period of time. Optimally this should be substantiated by careful review of treatment records, pharmacy reports, and blood levels where appropriate. Failed trials should include different medication classes (i.e., not just SSRIs or SNRIs, but also TCAs, MAOIs), or various augmentation strategies with or without ECT. A second opinion from a clinician specializing in treatment resistant depression and knowledgeable regarding VNS is advisable.

Sample clinical scenarios when ECT might be favored over VNS, and vice versa, are outlined in Figure 109–10. For example, VNS does not exert rapid antidepressant action, thus acutely suicidal patients and others in need of rapid response would be more appropriately treated with other strategies. VNS is indicated as a long-term treatment option only for those with chronic or recurrent course of illness.

ECT can be safely used in patients with an implant if the VNS generator is turned off during delivery of ECT, to avoid anticonvulsant effects of VNS. Whether VNS would be useful in relapse prevention post ECT deserves study.

**Dosing**

The optimal dose of VNS is unknown. The published studies were not designed to identify optimal dosing parameters (time on, time off, frequency, current, pulse width). The epilepsy literature suggests that there is a threshold current for efficacy. However, given our current knowledge of VNS dosing, current is typically increased up to >1 mA clinical benefit assessed over several months. The side effects of VNS are known to be dose dependent (e.g., lowering pulse width reduces neck pain, allowing patients to tolerate higher currents).

**Future Directions**

More research is needed to define the dose-response relationships for VNS, investigate optimal medication strategies to augment responses, test the potential role of VNS for long-term relapse prevention, and study its mechanisms of action.

**DBS**

With DBS, intracranial electrodes are implanted and chronically stimulate targeted brain areas. Unlike
lesioning procedures, DBS is believed to be reversible, and the intensity of stimulation can be adjusted according to the acute effect on symptoms.

DBS is FDA-approved for the treatment of Parkinson's disease and is under study for the treatment of severe and treatment-resistant OCD and major depression (Kopell et al. 2004). At this time about 20 patients worldwide have received DBS for depressive disorder, with varying stimulation sites: white matter underlying cingulate area 25 (Mayberg et al. 2005), internal capsule/nucleus accumbens (Bonn/Cologne group), and the inferior thalamic peduncle (Jimenez et al. 2005).

An open label series of six patients with treatment refractory depression treated with DBS and demonstrated very encouraging results (Mayberg et al. 2005). Upon activation of DBS, all six patients spontaneously reported immediate improvement in mood, feeling of calm, increased interests etc. In four out of six patients, antidepressant response was maintained at 6 months, and three of these four subjects achieved full remission. Subsequent controlled studies are needed to establish the safety and efficacy of this most focal, though most invasive, treatment for refractory depression.

**Conclusions and Future Directions**

Brain Stimulation in psychiatry today represents an emerging family of technologies to modulate brain function using electrical and magnetic stimulation. The technologies differ in their evidence basis, focality, mechanisms, and clinical spectrum. Figure 109–11 summarizes the state of the evidence for each. ECT has unmatched efficacy, but the challenges for the future are improving its safety and preventing relapse. TMS is highly safe, and future challenges involve enhancing its efficacy. MST likewise has a good safety profile, and current needs are to optimize and test its efficacy against the gold-standard ECT. VNS is newly approved for chronic illness management, and its role as an adjunctive therapy for treatment resistant depression awaits verification with real-world clinical experience in the post-approval era. DBS offers the promise of placing the electrode precisely in the target circuitry, but this also poses the challenge to the field to identify just what that circuitry is to ensure efficacy.

The potential for brain stimulation in psychiatry has never been more exciting. There are now a collection of technologies that may address different phases of depression (Figure 109–12). Along with this exciting promise, there is also a great need for research in this field to create the science of how intermittent stimulation affects brain function. A better understanding of that science could guide developments in this field. Rather than taking off-the-shelf technology designed for neurological applications, a basic science of brain stimulation optimized for psychiatric disorders offers the promise of creating purpose-built devices tailored to the specific needs of our patients. The stages of drug development (target identification, pharmacokinetics, pharmacodynamics, safety and toxicology) are well known. Less well developed are the device analogues to these stages (Figure 109–13). As we approach rational device development in psychiatry, the device analogues of these stages will need to be addressed through basic and preclinical research.

Chapter 109 • Brain Stimulation in Psychiatry

Introduction

Definition and Staging

Treatment-resistant depression (TRD) is a common and challenging problem facing the practicing psychiatrist. Patients with TRD are at higher risk for suicide, relapse of depressive illness, and increased health-care utilization (Souery et al. 1999). There is no universally accepted operational definition of TRD, which has limited comparisons between studies across the existing literature on the subject (Souery et al. 1999). TRD has been defined as “an inadequate response to an adequate trial of an antidepressant” (Petersen et al. 2005), with response defined as at least a 50% reduction in symptom severity. However, this definition is based on the convention for testing efficacy of a new compound compared to placebo, which shows that a compound is active in depressive illness. In practice, no patient’s goal is to have their depressive symptoms reduced by half, but rather to be restored to their normal, essentially depression-free state. Remission, an essentially complete resolution of depressive symptoms, has increasingly become recognized as the goal of antidepressant treatment both for this reason and because response without remission has been convincingly shown to lead to increased risk of relapse and poorer functional outcomes (Fava 2003).

Lack of response or remission from a single antidepressant trial is so common as to be insufficient to qualify as true treatment-resistance, which is better defined as a minimum of two treatments not fully effective when given at adequate dosage and for sufficient duration (Souery et al. 2006). While some proportion of patients with TRD will actually have an unrecognized bipolar disorder, often Bipolar II Disorder or Bipolar Disorder Not Otherwise Specified (BP-NOS) by DSM-IV-TR criteria, this chapter will focus primarily on unipolar TRD. Also, some patients with ostensibly treatment-resistant depression have actually previously responded to treatment and then have relapsed. While it is not clear how patients who have relapsed are different from those who have not responded, it may be worth making that distinction. Some data suggest that those who have relapsed respond well simply to dosage increase of the agent they had relapsed on, but more study is needed to clarify how best to treat such patients (Fava et al. 2006a, Fava et al. 1994).

One way of quantifying the degree of resistance is to employ a staging system. The two best-known systems are the Thase and Rush 5-stage model and the Massachusetts General Hospital (MGH) staging method (Petersen et al. 2005). In the Thase and Rush method, resistance stage is determined by nonresponse to sequential trials of antidepressant monotherapy with medications with varying mechanisms of action, or with electroconvulsive therapy (ECT). Specifically, Stage I resistance is defined as lack of response to an adequate trial of a first antidepressant medication; Stage II resistance is defined as Stage I plus lack of response to a subsequent trial of an antidepressant with a different mechanism of action, or with electroconvulsive therapy (ECT). Stage III resistance is defined as lack of response to a subsequent trial of an antidepressant with a different mechanism of action; Stage III followed by nonresponse to a tricyclic antidepressant (TCA); Stage IV as Stage III followed by nonresponse to a monoamine oxidase inhibitor (MAOI); and Stage V as Stage IV followed by nonresponse to ECT. Fava (2003) has described some limitations to this method: it assumes a hierarchy of different levels of effectiveness of medications according to mechanism of action; it does not allow for differentiation of medication trials on the basis of dose or duration; and it does not incorporate augmentation and combination treatments.
The MGH Staging method, in contrast, assigns one point per antidepressant monotherapy trial of adequate dose (explicitly defined) of at least 6 weeks duration, and adds 0.5 points for each of the following: optimizing the dose or duration of a medication trial, augmenting, or combining medication trials, with an additional three points added for a trial of ECT (Petersen et al. 2005). One retrospective chart review assessed both staging methods as predictors of remission from the index major depressive episode, and found that the MGH staging score, but not the Thase and Rush staging score, was predictive of remission status in a logistic regression model, although the two staging scores were significantly correlated with one another (Petersen et al. 2005). This study provides some evidence in favor of the MGH staging method, although the Thase and Rush method may be more familiar to practicing clinicians.

The major importance of each of these staging systems is that they emphasize that neither doctor nor patient should be discouraged if a single trial of an antidepressant is ineffective. Good treatment demands persistence on both the doctor’s and patient’s part with trying multiple medications at adequate dosage and over a sufficiently long time to explore the many treatment options now available for TRD, including of course, multiple pharmacologic strategies as well as brain stimulation treatments like ECT. To familiarize oneself with these staging methods, one may wish to read Clinical Vignette 1 and categorize the patient’s stage of resistance according to the two methods.

Prevalence and Predictors

Prevalence

The Sequenced Treatment Alternatives to Relieve Depression (STAR*D) trial, a recent prospective, multi-center, practical clinical trial funded by the National Institutes of Health and not by the pharmaceutical industry, provides some of the best available data on the prevalence and predictors of TRD (Trivedi et al. 2006c). Unlike traditional efficacy trials, STAR*D is highly applicable to real world settings, in that recruitment methods, inclusion and exclusion criteria were designed to obtain a study sample representative of patients seeking treatment for MDD in the community. In the first treatment phase of the study, 2,876 patients in a major depressive episode (MDE) underwent a 12-week trial with open treatment with citalopram titrated to 60 mg daily according to a treatment protocol. The primary outcome measure of the study was remission, an essentially complete resolution of depressive symptoms. Remission rates were 28% using the Hamilton Depression Rating Scale (HAM-D) and 33% using the Quick Inventory of Depressive Symptomatology—Self-Report (QIDS-SR), consistent with previous estimates from efficacy trials. These highly reliable estimates indicate that despite vigorous treatment with a single effective antidepressant, more than half of patients with major depression do not experience significant improvement, and only about one-third attain full remission. Lack of remission to a first antidepressant trial is common rather than exceptional, even with careful and vigorous treatment.

The STAR*D study also provides some of the best available data on remission rates after multiple sequential treatment trials in MDD. Subjects who did not achieve remission following the initial trial of citalopram were eligible to enroll in sequential, open-label, randomized treatment trials that employed varying therapeutic strategies for TRD, including medication switches, medication augmentation, and switch to or augmentation with cognitive behavioral therapy (CBT) (Figure 110–1) (Rush et al. 2006a). The details of these trials are discussed in Sections “Switching Antidepressants,” “Augmentation,” and “Combination Antidepressant Strategies” of this chapter. The cumulative percentage of subjects initially enrolled who actually achieved remission after one treatment trial was 37%; after two sequential treatment trials, cumulative remission increased to 49%; after three trials, it increased only to 50%, and after four treatment trials, only to 51%. Some of these diminishing returns can be accounted for by patient drop-out from the study, and by patients who were satisfied by response without remission, who therefore chose not to advance to the next treatment offered. Nonetheless, the small gains in total remission rates with the third and fourth treatments in STAR*D demonstrate how depressive episodes that are increasingly treatment-resistant become increasingly difficult to treat effectively. For those patients who do ultimately achieve remission with a third or fourth treatment trial, these gains are of course very clinically significant. This finding is consistent with a previous related study, a chart review of naturalistic treatment for depression in two academic centers, where the cumulative remission rate after a mean of 17 months of treatment reached only 50% (Petersen et al. 2005). In a prospective multicenter study of treatment-resistant depression, Dunner et al. (2006) found remission rates of only 3.6% at 12 months and 7.8% at 24 months. However, other data suggest higher remission rates can be achieved in some specialized treatment settings (Quitkin et al. 2005).

Another important consequence of lack of remission is that such patients have a higher rate of relapse, even if they continue the treatment which was associated with remission. In STAR*D, patients who required more treatment steps to achieve remission subsequently relapsed at a much higher rate than those who attained remission with fewer treatments (Rush et al. 2006a). Taken together, these studies clearly indicate that even after multiple treatment trials, only about half of patients with major depression experience remission, the relapse rate is unacceptably high, and there is a great need for more effective antidepressant treatments.

Predictors of TRD

The most commonly identified predictor of nonresponse to antidepressants is chronicity of depression, which clearly lowers response rates. Chronicity of depression is associated with lower response rates not only to active treatments but to placebo as well (Stewart et al. 1989, Stewart et al. 1993). This implies that chronicity of depression may affect response by altering nonspecific factors such as patients’ expectation of response, rather than by altering specific pharmacologic effects per se. In a recent study, chronicity, as measured by the duration of the index episode, was found to predict a decreased rate of remission in the STAR*D Level 1 treatment sample treated with citalopram monotherapy, as it has in many previous studies (Trivedi et al. 2006c).
Other clinical variables have been less consistently associated with nonresponse but several baseline demographic and clinical variables were identified as predictive of nonremission following citalopram treatment in STAR*D. These included male gender (relative risk \[RR\] = 1.22, 95% confidence interval \[CI\] = 1.07–1.39), unemployment (\[RR\] = 1.51, 95% CI = 1.32–1.73), lower income, lower educational status, poorer baseline function and quality of life, and comorbid anxiety disorders (Trivedi et al. 2006c). Other studies have not been able to confirm a differential response by gender (Quitkin et al. 2001), which in any case seems small. This also appears true of the remaining predictors, so that as of this point, treatment response cannot be reliably predicted by any clinical variables except chronicity, which seems invariably to decrease response rates.

**Clinical Vignette 1**

Denise is a 36 year-old divorced woman employed part-time as a customer sales representative. She describes a turbulent and unhappy childhood which she relates to her angry and explosive mother, who is described as often verbally abusive. The patient’s mother appeared to have marked mood-swings by the patient’s description, but never received any psychiatric attention. The patient had many brief periods of depressed mood as a child and adolescent, never clearly meeting criteria for Major Depression until age 16, when she was a junior in high school. At that time, she developed symptoms consistent with a MDE which remained unrecognized and for which she received no treatment.

Over the ensuing years, she has had at least five MDEs, treated with a combination of insight-oriented...
psychiatrist will find it dramatically easier to quickly peruse if at least the medication names and current dosages are noted, as well as side effects, estimated compliance, and therapeutic response. Also to be noted are the approximate dates of start and stop of medication, maximum dosage achieved, duration of the maximum dosage, and the concentration of the highest tolerated dose. With virtually all pharmacy records can be invaluable for the purpose of collection, an adequate clinical record. The patient reports having been treated with fluoxetine very successfully in a previous episode, but she discontinued the medication after about one year due to sexual dysfunction and weight gain, which she attributed to the medication.

In the current episode, which has lasted over two years, she was treated with citalopram for about 5 weeks at a maximum dose of 40 mg with no improvement and was then switched to venlafaxine extended release, which she has taken at a maximum dose of 225 mg for the last eight weeks. She also reports trials of bupropion, escitalopram, and paroxetine with minimal or no improvement. She now reports a slight improvement in her mood, but she is still depressed most of the day every day, is anhedonic, sleeps excessively and has no energy. Since she became unable to work 18 months ago, she has been supported by savings and help from her family. The patient’s family has suggested that she consider ECT but the patient wishes to try further medication trials before considering ECT.

Evaluation of the Patient

Adequacy of Previous Treatment

A critical piece of clinical history to obtain is how vigorous each previous ineffective treatment trial to which the patient has been exposed has been, in terms of both dose and duration. There are few systematic data dealing with what constitutes an adequate dose for second-generation antidepressants, that is, antidepressants other than TCAs and MAOIs. For working purposes, a dose of at least two-thirds the maximum recommended dosage, administered for a total of eight weeks, can be considered an adequate clinical trial. Because notes from previous clinicians are often inadequately detailed, a summary printout of computerized pharmacy records can be invaluable for the purpose of reconstructing the adequacy of previous treatment trials.

While treating a patient, it is essential to their further care to keep a record of approximate start and stop dates, maximum dosage achieved, duration of the maximum dosage, side effects, estimated compliance, and therapeutic response. If at least the medication names and current dosages are consistently written in the margin of each clinical note, the psychiatrist will find it dramatically easier to quickly peruse the chart to look for a particular trial than if all the information is buried in undemarcated text. A simple form such as that reproduced in Table 110–1 can be highly useful when reviewing a patient’s pharmacologic treatment to plan the next step, either by the primary psychiatrist or by a psychopharmacologic consultant. Ideally this information would be collected prospectively, but the table can also be a useful tool to fully summarize a patient’s pharmacologic treatment history for further consideration of options or for use by a consultant.

At least 50% of patients with TRD referred to specialists in several recent studies were found to be on inadequate medication doses, and subsequently responded when doses were raised (Fava et al. 2003b). It is clear for some medications like the TCAs that inadequate dosage is responsible for poor response since response to higher dosages has been shown to be superior to low dosages (Watt et al. 1972). There are essentially no systematic data for second generation antidepressants to support the idea that there is a dose response relationship within usually administered dose ranges. However, it is reasonable to assume that dose response, like most biologic characteristics, has a distribution and that this distribution is such that some patients respond well to very small doses and some require dosages higher than the usual range. This likelihood has been recognized in treatment guidelines which strongly suggest increasing dosage in patients inadequately responsive to treatment with virtually all antidepressant medications, contemplating the possibility that not all response is obtained within the usually administered dosage range (Depression Guidelines Panel 1993, American Psychiatric Association 2000).

Duration of treatment with previous agents is likewise critical. It has become clear that a substantial minority of patients attain their first significant clinical response only late in treatment. For example, in level 1 treatment with citalopram in the STAR*D trial, fully one-third of ultimate responders to treatment were first considered nonresponders after their sixth week of treatment (Trivedi et al. 2006c). While it is beyond the scope of this text to review the evidence for late response, it appears clear that both dosage and duration of exposure to antidepressant treatment are critical variables in gauging adequacy of treatment exposure.

Differential Diagnosis

As in all areas of medicine, differential diagnosis is critical to success in treatment, especially in cases with poor response to initial treatment. Because depression can be associated with non-psychiatric disorders and induced by medication, these must be considered in the evaluation of TRD. A detailed discussion of these issues is presented elsewhere in this book. In this section, we will discuss psychiatric differential diagnosis and the contributions to TRD by psychiatric disorders.

Bipolar Disorder

One source of treatment resistance appears to be the unsuspected presence of bipolar disorder, usually BP II or BP NOS.

Bipolar depression has been shown to be relatively resistant to treatment with usual antidepressants, and the depressed phase of the illness predominates, often with only transient hypomanias, which may not be appreciated by the patient to be pathologic (Angst et al. 2003, Post et al. 2003a). The patient will often experience and describe these as periods of normal mood relieving him from depression. The single most important tool in establishing this diagnosis is gathering information from a reliable collateral informant who has known the patient well over a long period of time (see Clinical Vignette: Follow-Up). Such an informant should be carefully interviewed to determine the occurrence of sudden mood changes, periods of euphoria, irritability, or increased energy and productiveness, associated with the other symptoms of hypomania, including impulsiveness, grandiosity, decreased need for sleep, and increased rate or amount of speech. Epidemiologic data suggest that classically euphoric hypomania accounts for only some hypomanic episodes (Angst et al. 2003), and that it is common for irritability or increased activity rather than euphoria to be the cardinal symptom manifested.

Another useful tool is the use of a bipolar mood chart, enabling the prospective collection of data on mood-swings, mixed states, rapid cycling, sleep length, and the relation of these symptoms to menses and psychological stress. One such chart, publicly available for download at http://www.manicdepressive.org/tools_all.html is reproduced below with an illustrative case of bipolar mood-swings documented (Figure 110-2). Establishing a diagnosis of bipolar disorder is often critical in attaining remission of otherwise intractable depression by the use of mood stabilizing medications, especially lamotrigine and lithium carbonate, which have demonstrable antidepressant actions in bipolar depression and do not precipitate mood cycling, as antidepressants can do (Post et al. 2003b).

### Substance Abuse

It is widely believed that ongoing alcohol or drug abuse may render antidepressant treatment ineffective. Retrospective studies indicate that recovery from depression in patients with comorbid alcohol abuse or dependence is impaired (Mueller et al. 1994). It appears that some alcohol abusing or dependent patients who are depressed are “self-medicating” their depression with alcohol or drugs of abuse, and that antidepressant treatment can be effective for depression in these cases (McGrath et al. 2000a). Some, but not all controlled trials indicate that depression is treatable despite ongoing alcohol abuse or dependence. Recent data is available from a study conducted ancillary to STAR*D which examined the rate of response and remission to an SSRI in a sample of patients prospectively diagnosed with major depression and a concomitant alcohol use disorder (McGrath PJ, unpublished data). In that study, concurrent alcohol abuse or dependence, which did not require inpatient detoxification, did not impair either response or remission, when usual clinical treatment of modest intensity was given to patients treated in either primary or in specialty care settings. It must be noted that the degree of substance dependence in that study was relatively mild and these data are applicable only to patients with similarly mild substance use disorders.

Likewise with drug abuse and dependence, there are studies, albeit fewer, which indicate that depression can be treated in drug abusing or dependent patients. A recent comprehensive review of available literature indicates that there is evidence that antidepressants can be effective in the face of substance abuse and dependence, especially if concurrent treatment for the substance use disorder is provided (Nunes and Levin 2004). The practical clinical conclusion of these data is that evidence of alcohol abuse or dependence should be sought in a patient with TRD and a period of abstinence should be strongly encouraged to help eliminate the possibility that it is a contributory factor to treatment-resistant depression. Nevertheless, treatment of depression can be effective in substance abusers, especially if concomitant treatment of substance abuse is provided.

### Personality disorder

It is very common and tempting to conclude that a patient’s inadequate response to antidepressant treatment is the result of personality disorder, either known or, more often, suspected, based on mood reactivity to environmental or interpersonal stresses, excessive anger, or unstable interpersonal relationships. Most often, it is borderline personality disorder or a mixed personality disorder with borderline features which is thought to limit the effectiveness of antidepressant medication. While the literature reviewing this issue is complex and sometimes contradictory, it appears useful to consider that it is possible for ongoing mood dysregulation to be central to personality disorders such as borderline personality disorder. It might be considered that such dysregulation, which is sometimes incompletely responsive to antidepressant medication, may render depression treatment-resistant. Many clinicians believe that what appears to be personality disorder may be especially likely to be an undiagnosed bipolar mood disorder, with its accompanying irritability, grandiosity, anger, and impulsivity (Katzow et al. 2003). This makes the careful evaluation of patients presenting with treatment-resistant depressive syndromes and concurrent personality disorders, especially DSM-IV-TR cluster B disorders (antisocial, borderline, histrionic, and narcissistic), essential, as bipolar disorders respond to different treatments and can sometimes be worsened by antidepressant pharmacotherapy without accompanying mood stabilization.

Recent reviews of the pharmacotherapy of personality disorder make clear that while most of the evidence is based on case series or open-label clinical trials, there are beginning to be controlled trials to guide this treatment (Raj 2004). These studies provide support for commonly used treatments of low doses of either typical or atypical antipsychotics (Soloff 2000) as well as for MAOIs, SSRIs, and omega-3 fatty acids in the treatment of borderline personality disorder (Raj 2004). Several reviews have emphasized that pharmacotherapy for personality disorder may best be tailored to specific psychopathological states such as impulsive aggression or overwhelming anxiety, with better results than if a treatment is simply selected on the basis of a broadly defined personality category (Gunderson and Phillips 1991, Kapfhammer and Hippius 1998, Soloff 2000).

### Other Psychiatric Comorbid Disorders

Among seriously ill patients, especially those with bipolar disorders or severe personality disorders, the presence of psychosis should be carefully evaluated by both empathic interviewing of the patient and interviewing others who...

know him well. An empathic interview will use open-ended questioning which does not challenge the patient’s view prematurely, to elicit fears about being harmed, delusions of worthlessness or guilt, and delusional beliefs regarding somatic illness. Evidence of guardedness and frank paranoia as well as overvalued ideas and frank delusions should be sought. Delusions of worthlessness and guilt are the most common, although delusions of somatic illness and other delusions also occur. Substantial evidence has shown that such patients benefit more from either an antipsychotic combined with an antidepressant or from ECT rather than from antidepressant monotherapy.

Subtyping of Major Depression
There is some literature suggesting that the subtypes of major depression such as melancholic, atypical, and seasonal may be predictive of outcome with specific treatments. While melancholia does not appear to predict treatment outcome with second generation antidepressants, there are data suggesting that tricyclics may be particularly effective for patients with the melancholic subtype of depression.

For atypical depression, MAOIs have been shown in multiple studies clearly to be more effective than tricyclics. Further, one controlled study has shown that tricyclics and SSRIs are equivalent in atypical depression (McGrath et al. 2000b). Though not definitive, this is presumptive evidence which suggests that MAOIs may be superior to SSRIs for the treatment of atypical depression.

Seasonal depression does not ordinarily present as TRD, but seasonal exacerbation of nonseasonal depression does occur and is responsive to augmentation of the pharmacotherapy with phototherapy, especially if optimized to the sleep phase of the depressed patient (Terman and Terman 2005).

Anxiety disorders are highly comorbid with major depression and some, but not all studies, have shown either delayed response or a poorer rate of response when they are present (Fava et al. 2004). Recent data from the STAR*D study have shown that prospectively identified anxious depression was associated with a significantly poorer response rate to treatment with an SSRI antidepressant (Fava et al. in press). What has not been adequately investigated is whether there are any treatments which are more effective for patients with anxious depression, whether anxious depression forms a subtype based on criteria other than treatment response, and whether concomitant treatment with anxiolytic medication may help achieve remission for these patients.

Medication Management
General Principles
Once the alternative causes of TRD described above have been excluded, there are several important principles in the management of subsequent medication treatment. First, the attitude of the clinician is critical to success. To optimize patient outcomes, the clinician should remain firmly committed to optimizing pharmacotherapy despite the presence of any psychological factors or environmental stressors, which might be thought contributory to the disorder. Given the current state of knowledge of depressive disorders, it is essentially impossible to determine the extent to which antidepressant medication will be effective in any given depression. Therefore, the most rational principle should be to optimize both pharmacotherapy and psychotherapy (we will not discuss optimization of psychotherapy for depression here as it is covered elsewhere in this book). Optimum pharmacotherapy involves characteristics of the clinician which include the ability to tolerate uncertainty regarding the etiology of depression without being paralyzed into inaction, the ability to sustain realistic optimism on both her own part and that of the patient, and a thorough understanding of the medication options available for this condition. For those not specializing in the treatment of depression, this will often require consultation with a specialist, as many of the options, such as the use of MAOIs or the use of brain stimulation techniques such as ECT or vagal nerve stimulation (VNS), require specialized expertise.

Finally, conduct of the treatment must include careful monitoring and documentation of dosage, duration, and result of any medication trial, so that adequate exposure to any treatment can be determined, leaving the result unambiguous. Although rating scales are seldom used outside of research settings, the clinician will often find that these are very helpful in objectifying the judgment of whether and to what degree a treatment is working, and their use should be seriously considered in all such cases. The standard rating scale for depression severity in research settings the Hamilton Rating Scale for Depression (HAM-D), which is available in multiple versions, and rates depressive symptoms reliably. Its advantages include its demonstrated sensitivity to change with treatment and its being a “gold standard” for treatment response in depression research. Its major disadvantage is that it requires clinical time to rate, and the structured inquiry it requires is not comfortable for many clinicians.

Many clinicians will find that a brief self-rated scale is easier to incorporate into their practice. Fortunately, a newly developed rating scale for depression which addresses the difficulties of the HAM-D is publicly available without cost. The QIDS-SR is a 16-item self-rated scale which correlates well with the HAM-D, takes only a few minutes of a patient’s time, and has been shown to be sensitive to change with treatment. It is available for download at the STAR*D website: www.star-d.org. Excellent alternative scales are either the Beck Depression Inventory (BDI) or the revised BDI-II, which has had items substituted to bring it more in line with DSM-IV-TR criteria for Major Depression. These are each 21-item copyrighted self-report scales which are readily available for clinical use at modest cost and have the same advantages as the QIDS-SR over clinician-rated scales.

If a patient with TRD does not improve sufficiently, one possible reason is that an adequate trial was not attained due to intolerable side effect which could not be ameliorated by adjunctive treatment or other strategies. For the reason that it is common for patients with TRD not to have tolerated various medication trials, the option of ultra-slow dose escalation should be familiar to all clinicians. A patient who experiences intolerable activation by an initial dosage of 20 mg daily of fluoxetine, for example, might tolerate 1 mg daily of fluoxetine concentrate more easily and ultimately respond to this treatment if it is increased by only a milligram or two per week. Practical experience shows that patients will develop tolerance to many adverse effects.
of antidepressant medications, especially to activation and gastrointestinal distress, and this procedure will often help a patient seemingly unable to tolerate any medication to have a full therapeutic trial of most agents.

The vigorous treatment of treatable side effects is also helpful in this regard. Hypnotics for insomnia, anxiolytics for anxiety, salt or 9-alpha flurorohydrocortisone supplementation for hypotension, sildenafil for erectile dysfunction, and modafinil augmentation for sedation are examples of adjunctive medications which can be used successfully to enhance tolerability of various agents.

**Dosage and Duration of an Adequate Trial**

The dosage and duration of an adequate trial for most antidepressants have not been fully established, as there are not clear data showing at what point no further benefits are gained. A general principle here is that any treatment which has not produced the desired effect but is not causing significant adverse effects might be effective if the dosage was raised to a higher level. The recommended dosage range in the package insert is determined by many factors which include the manufacturer’s strong motivation to determine a dosage which allows separation from placebo in a pivotal clinical trial for submission to the Food and Drug Administration (FDA) for approval, yet produces the most acceptable side effect profile. This is both understandable and rational in that the lowest effective dosage of any medication should minimize adverse effects, and if it is fully effective, maximize the risk-benefit ratio of the treatment. These dosage ranges, however, do not adequately account for the obvious fact that there will be a distribution of effective dosages for a population of patients, with some patients requiring much higher than usual dosage for maximum or even minimal benefit. Unfortunately, since higher than the recommended dosages have not been tested for safety, raising the dosage beyond the maximum recommended dosage is intimidating for many psychiatrists. Such prescribing, termed “off label,” is sometimes erroneously thought to be prohibited by the FDA. In fact, under federal regulations, any approved medication can be prescribed by a physician for any indication and in any dosage deemed reasonable by prevailing community standards of practice. So in a patient with TRD not responding adequately to a therapeutic trial but experiencing no significant side effects, cautious dosage increase beyond the recommended maximum is a rational and sometimes essential maneuver. Pertinent examples include the recommended maximum dosage of 225 mg daily for extended release venlafaxine, while immediate release venlafaxine has a recommended dosage limit of 375 mg daily. Clearly, a patient experiencing inadequate benefit from 225 mg of extended-release venlafaxine and tolerating it well should be tried on a higher dosage, with appropriate notification to the patient of the rationale for, and potential risks of, “off label” treatment and documentation of this in the medical record. Experienced psychopharmacologists often resort to higher than recommended dosages for patients who are inadequately responsive even in cases where less support for higher dosage levels exists, with careful weighing of the risk-benefit ratio at each decision point and ongoing reaffirmation of informed consent by the patient to this procedure (see Clinical Vignette: Follow-Up). Other examples of frequently-used “off label” prescribing are the use of antidepressant augmentation strategies and combinations of several antidepressants. Some of these augmentation and combination strategies now have efficacy and safety data collected through the conduct of the STAR*D study.

Regarding duration, many efficacy trials of antidepressants have durations of eight or even six weeks. As described previously, there was a high incidence of late response in the STAR*D level 1 study. Late remission rates in that study are perhaps even more striking: approximately one-third of patients who eventually achieved remission with citalopram did so in treatment week 10 or later, sharply underscoring the potential benefit of extending medication trials beyond six or eight weeks in patients who have shown some initial benefit (Trivedi et al. 2006c). An important counterpoint to this finding of late response and remission comes from a recent meta-analysis which found initial improvement from SSRI treatment occurring by the end of the first week of use when compared with placebo (Taylor et al. 2006). Thus, in patients with no evidence of clinical improvement after a six or eight week antidepressant trial of adequate dose, increasing the duration of the trial seems ill-advised for most patients.

**Emergencies**

The major emergencies in treating TRD are the emergence of significant suicidal risk, and the development of psychosis, mania, or a mixed bipolar state where depressive and manic symptoms occur together. As in treating all depressive illness, ongoing assessment of suicidal risk is an essential part of good clinical care. Recent studies suggesting an increased risk of suicidal ideation in both adolescents and adults taking selective serotonin reuptake inhibitors (SSRIs) have resulted in a strong warning by the FDA that treatment with SSRIs could possibly increase suicidal risk. While it is presently highly controversial whether antidepressants do carry some small risk of increasing suicidal thoughts or even behavior, the admonition that depressed patients be monitored for suicidal risk is unexceptionable.

The consistent data showing that untreated anxiety and agitation are associated with an increased risk of suicide should encourage the clinician to address these symptoms early and vigorously with adjunctive medication as a potential preventative technique for the development or worsening of suicidal ideation. Unfortunately, to our knowledge no clinical study has addressed such intervention, probably because of the difficulty of conducting a properly controlled trial in this situation. However, it is reasonable to hypothesize that vigorous treatment of anxiety or agitation with appropriate adjunctive medication may decrease suicidal risk, even among those hospitalized, and should be considered in cases of anxious or agitated patients with significant suicidal impulses. Hospitalization, either voluntary or involuntary, obviously also is an important tool to prevent suicide, although the number of patients who commit suicide while in psychiatric hospitals makes it clear that hospitalization alone is not sufficient.

The development of psychosis or a mixed state should prompt immediate consideration of hospitalization, as both psychotic depression and mixed states have been shown to increase the risk of suicide. A patient’s beginning to...
call repeatedly between sessions in sometimes ill-defined heightened distress would prompt immediate evaluation for the development of psychotic or mixed state symptoms rather than be ascribed simply to personality disorder. In such cases, the relief brought by the early and vigorous use of antipsychotic or anxiolytic medication can potentially be literally life-saving, and should be considered along with the possible need for hospitalization, which is often either unacceptable or not readily available to the patient.

**RCT caveats**
- Designs may be biased or selected to achieve specific aims
- There may be ‘spin’ in reporting results or a bias in publication
- Heterogeneity within groups may be concealed
- There may be a lack of generalisability or clinical practice relevance

Within Class

Clinical wisdom among psychopharmacologists held until recently that if a patient did not achieve remission following a first medication trial, they would be more likely to remit on a subsequent trial with a medication with a different mechanism of action, rather than with a switch to a medication with the same mechanism of action as the first. Indeed, a survey of 423 psychiatrists by Fredman et al. revealed that the most popular treatment choice following an unsuccessful trial of an SSRI was to switch to a non-SSRI antidepressant (44% of respondents), most frequently dual-acting agents or bupropion (Fredman et al. 2000). Data from clinical trials, however, provides some support for switching to a second SSRI following initial unsuccessful SSRI treatment. A recent review described seven open studies of switching to a second SSRI following nonresponse or intolerance to a first (Ruhe et al. 2006). They reported response rates varying from 42–58% in the studies of patients who had not responded to a first SSRI, and response rates from 56–72% in the studies of patients who had not tolerated a first SSRI. They also describe three randomized controlled trials with SSRI arms as a second step of treatment following first SSRI nonresponse (including the STAR*D trial, to be described next), with reported remission rates varying from 17.6–52.1%. It should be noted that the majority of these trials, with a notable exception of the STAR*D study, were industry-sponsored, and as such were subject to potential bias in study design.

STAR*D was the largest study to date to assess prospectively the efficacy of different switching strategies. Seven hundred and twenty-seven patients who did not achieve remission after a 12-week trial of citalopram or who could not tolerate its side effects were randomized into one of the three possible medication switch strategies: switching to a second SSRI, sertraline; to a dual serotonin and norepinephrine reuptake inhibitor, extended-release venlafaxine; or to sustained-release bupropion, whose mechanism of action may involve norepinephrine and dopamine reuptake inhibition (Rush et al. 2006b). Remission rates did not differ significantly among these three groups (sertraline = 17%, extended-release venlafaxine = 26% and sustained-release bupropion = 21%), a finding that was surprising to study investigators. For the reason that there was no placebo control in this study, these remission rates cannot be solely ascribed to the active effects of the antidepressants to which subjects were switched, but may be due to nonspecific effects, including placebo effects and spontaneous remission.

There are several possible mechanistic explanations for the effectiveness of a second SSRI in some patients after nonresponse to a first SSRI. The first SSRI trial may have been too short to yield maximal benefit from this class of medication, and by switching to a second SSRI, the cumulative duration of SSRI treatment is extended, yielding a benefit. An interesting alternative explanation is that remission with a second SSRI may be related to unique pharmacological properties of different SSRIs. For example, paroxetine has been shown to exhibit greater reuptake inhibition for norepinephrine than other SSRIs, and sertraline has been shown to inhibit reuptake of dopamine more than other SSRIs (Nemeroff and Owens 2004). As STAR*D level 2 did not find different remission rates between medications with far more disparate mechanisms of action, this must be considered an exploratory hypothesis at best.

A recent meta-analysis of randomized-controlled trials that compare switching to a second SSRI or to a medication with a different mechanism of action following a first unsuccessful SSRI trial included four double-blind controlled trials including this STAR*D study (Papakostas et al. 2007). They reported 4.5% lower remission rates with a second SSRI compared to a different class of medication, which was statistically significant in the pooled analysis (p = 0.007). They argued that STAR*D was underpowered to detect differences between groups of less than 15% in rates of remission, but that such differences were clinically meaningful.

Between Classes

Dual Mechanism

The recent Ruhe et al. (2006) review of switching strategies included a meta-analysis of the three randomized controlled...
Mirtazapine

Mirtazapine is an antidepressant that acts via central α2 antagonism as well as serotonin 2 and 3 receptor antagonism (Fava et al. 2001). It was previously studied in an open-label trial as a switch option for 103 patients who had not responded to or did not tolerate an adequate SSRI trial (Fava et al. 2001). This study found response rates of 48%, with the most commonly reported side effects being sedation, increased appetite, and weight gain.

Mirtazapine was evaluated in a study with more rigorous methodological design in the STAR*D study, as a third step of medication treatment for patients who did not achieve remission with or could not tolerate two prior medication trials (a trial of citalopram monotherapy followed by either a switch or an augmentation) (Fava et al. 2006b). It was compared to the TCA nortriptyline in a randomized-controlled trial (n = 235), of patients who were, by definition, more treatment-refractory than those in the second step of the STAR*D trial described above. Patients were treated with flexible dosing using a protocol, and received mirtazapine at an initial dose of 15 mg, which could be titrated up to 60mg daily. Nortriptyline was started at 25 mg, and was titrated up to a maximum of 200 mg daily. Remission rates were low for patients treated with either mirtazapine (12.3%) or nortriptyline (19.8%), as were response rates (13.4% vs. 16.5%), and did not differ significantly between the two groups. The authors concluded that antidepressant monotherapy with either of these agents in patients with this degree of treatment-refractoriness is effective for only a minority of patients. Discrepancies between these two studies of mirtazapine may be partially accounted for by the different primary outcomes of response vs. remission, the nonrandomized nature of the first study, and the more treatment-refractory population in this phase of STAR*D. The evidence provides some support for the use of mirtazapine as a switching agent, with a higher expected likelihood of response or remission in less treatment-resistant patients. The side-effect profile of mirtazapine, which includes sedation and weight gain, may make it most appropriate for patients whose depressive symptoms include insomnia and weight loss as some clinicians find tolerance problematic in those without these symptoms.

TCAs

TCAs are used less frequently than SSRIs in current psychiatric practice, due to their side-effect profiles, toxicity in overdose (Nierenberg et al. 2003), and requirements for therapeutic drug level monitoring. Less experience with this class of medication among clinicians likely contributes to lower prescribing rates, as well. While these real disadvantages should not be underestimated, the TCAs remain a useful class of medication for clinicians treating patients with TRD. There is some evidence of benefit of TCAs over SSRIs in melancholic depression (Perry 1996), and TCAs can be obtained at significantly reduced cost compared to antidepressants that are not yet available generically. In addition to the STAR*D study just described, nortriptyline was studied as a treatment for TRD in an open study that enrolled subjects with between one and five prior unsuccessful antidepressant trials in their current MDE (Nierenberg et al. 2003). Patients were treated with nortriptyline at a starting dose of 25mg, which was titrated to a final mean

bupropion

As described above, the STAR*D level 2 trial did not find significant differences in response or remission rates to sustained-release bupropion, extended-release venlafaxine, or sertraline in a large sample of patients who did not remit with or who could not tolerate a first trial of citalopram. In addition to this high-quality randomized controlled trial (RCT), two earlier open studies explored switching to bupropion. Fava et al switched 26 fluoxetine nonresponders to an eight-week trial of sustained-release bupropion, starting at 150 mg with the possibility of dose escalation based on clinical status (Fava et al. 2003a). They noted a remission rate of 23.1% and a response rate of 34.6% using a modified intent-to-treat analysis, which is highly comparable to the findings in STAR*D. Another open study examined 31 patients with MDD who experienced sexual side effects on fluoxetine, switching them to bupropion to determine whether there was an effect on reported sexual side effects (Walker et al. 1993). After a two-week washout followed by eight weeks of treatment with bupropion, 81% of patients described feeling “much” or “very much” more satisfied with their sexual functioning, although some improvement began during the washout, and prior to bupropion treatment. This study did not report response or remission rates during the bupropion trial. Taken together, there is reasonable evidence supporting switching to bupropion following an unsuccessful trial of an SSRI, although no data for its superiority over other switching strategies. Clinicians may consider switching to bupropion in particular for patients who have significant sexual side effects from a trial of an SSRI or dual reuptake inhibitor.

trials that have compared switching to a second SSRI with switching to venlafaxine: the STAR*D trial just described, a trial by Poirier and Boyer (1999), and a trial by Baldomero et al. (2005) (Ruhe et al. 2006). The Poirier (1999) study was a double-blind, randomized controlled trial comparing extended-release venlafaxine to paroxetine in a moderate sized sample (n = 122) of patients with TRD who had previously not responded to at least two prior antidepressant treatments. That individual study found a statistically and clinically significant advantage of venlafaxine over paroxetine, with response rates of 52% vs. 42% (p = 0.044). The Baldomero (2005) study, sponsored by the manufacturer of venlafaxine, was an unblinded randomized trial of venlafaxine extended-release versus “conventional antidepressants” (CAs) following nonresponse or intolerance to a first CA; 92% of CAs were SSRIs. It found 24-week remission rates of 59% in the venlafaxine-treated group vs. 52% in the CA-treated group (p<0.0001). While this represents a small difference clinically, this study achieved a high level of statistical significance due to its large sample size of 3,097 patients. From the meta-analysis of these three studies, Ruhe et al. (2006) reported a number needed to treat (NNT) of 13 for benefit of venlafaxine over SSRI, and concluded that there was “a modest and clinically equivocal benefit” of venlafaxine over a second SSRI following nonremission with either of these agents in patients with treatment-refractory population in this phase of STAR*D. The evidence provides some support for the use of mirtazapine as a switching agent, with a higher expected likelihood of response or remission in less treatment-resistant patients. The side-effect profile of mirtazapine, which includes sedation and weight gain, may make it most appropriate for patients whose depressive symptoms include insomnia and weight loss as some clinicians find tolerance problematic in those without these symptoms.

bupropion

As described above, the STAR*D level 2 trial did not find significant differences in response or remission rates to sustained-release bupropion, extended-release venlafaxine, or sertraline in a large sample of patients who did not remit with or who could not tolerate a first trial of citalopram. achieving a higher maximum dose might be challenging in
the tranylcypromine arm was quite high in the STAR*D study, so

the study due to side effects in the tranylcypromine group

and 13.7% for venlafaxine/mirtazapine, which did not differ
relatively low remission rates of 6.9% for tranylcypromine
titrated to a maximum of 300 mg/45 mg daily. They found
zapine combination was initiated at 75 mg/15 mg daily, and
tranylcypromine was initiated at 10 mg daily and increased weekly
venlafaxine and mirtazapine (McGrath et al. 2006). Tranyl-
cypramine was initiated at 10 mg daily and increased weekly
phrine, and dopamine (Krishnan 1998). MAOIs have been
used since the 1950s as antidepressant medications. Concerns
about the potential for hypertensive crisis that can result following consumption of foods containing tyramine
have limited the use of this class of medication in recent
years, although it remains a highly effective treatment option
for some individuals, which can be prescribed safely with
proper patient education. A relatively conservative MAOI
diet can be found at http://patienteducation.upmc.com/Pdf/
MaoiDiet.pdf although less restrictive diets may be safe and
may contribute to greater adherence (Gardner et al. 1996).
In the STAR*D study, 109 depressed subjects who had
not remitted with or could not tolerate three prior medica-
tion trials were randomized to treatment with the MAOI tra-
nylcypromine or with the combination of extended-release
venlafaxine and mirtazapine (McGrath et al. 2006). Tranyl-
cypramine was initiated at 10 mg daily and increased weekly
to a maximum of 60 mg, the maximum dose according to the
United States FDA guidelines. The venlafaxine/mirtazapine
combination was initiated at 75 mg/15 mg daily, and
titrated to a maximum of 300 mg/45 mg daily. They found
relatively low remission rates of 6.9% for tranylcypromine
and 13.7% for venlafaxine/mirtazapine, which did not differ
significantly from one another. There was higher exit from
the study due to side effects in the tranylcypromine group
(41.4%) than in the venlafaxine/mirtazapine group (21.6%).

There are at least six earlier studies of tranylcypromine
in treatment-resistant depression, four of which were RCTs,
with response rates ranging from 29–75% (McGrath et al.
2006). The two open studies found improved treatment effi-
cacy using high-dose tranylcypromine treatment above the
FDA maximum, using 70–120 mg daily (Amsterdam and
remission rates reported in the STAR*D study include the
relatively treatment-refractory nature of the sample stud-
ed, the short treatment duration achieved, and the lower
target doses of tranylcypromine that were achieved com-
pared with previous studies. That said, dropout in the tran-
ylcypromine arm was quite high in the STAR*D study, so
achieving a higher maximum dose might be challenging in
this population, at least in the hands of physicians not
experienced with using these medications. MAOIs remain an
effective treatment for some patients with TRD, and may be
considered especially in patients whose depression manifests
atypical features, given their demonstrated high efficacy in
this condition (Liebowitz et al. 1988). When switching from
an SSRI to an MAOI, the SSRI should be stopped at least
two weeks prior to initiating MAOI treatment (5 weeks in the
case of fluoxetine) to reduce the likelihood of serotonin
syndrome (Krishnan 1998).

Augmentation

There may be some advantages to treatment approaches
that utilize augmentation, rather than switching, particu-
larly for patients who have derived a partial benefit from the
initial medication trial. There is some evidence of shorter
onset of action with augmentation as opposed to switching,
as it obviates the possible need for a medication washout,
and allows for possible late-effects of the first medication
to occur (Joffe 1997). Some potential disadvantages of aug-
mentation approaches include the greater complexity for
patients of regimens with more than one medication, which
may reduce treatment adherence, as well as the pharma-
dynamic and pharmacokinetic drug-drug interactions that
can accumulate with increasing polypharmacy (Joffe 1997).
Level 2 of STAR*D included both switch and aug-
mentation options; the switch trial was described previously.
Patients were not randomized across all of these options in
equal measure; they were given the choice of whether they
would accept randomization to a switch strategy only, to
an augmentation strategy only, or to either strategy. Sub-
jects who entered the augmentation trial had lower HAM-D
scores at study entry than those who entered the switch trial,
indicating that patients with greater improvement on citalo-
pram were more likely to choose augmentation over switch.
This makes outcome measures between the STAR*D level 2
switch and augmentation studies not directly comparable.

A distinction has been traditionally made in the litera-
ture between augmentation, which involves adding a medi-
cation not traditionally used as an antidepressant to a pre-
viously prescribed antidepressant, and combination, which
involves administering two known antidepressants simul-
taneously. Augmentation strategies, which have a longer-
standing base of evidence, will be discussed first, followed
by combination strategies.

Lithium

Evidence

At least 10 double-blind, placebo-controlled trials of lithium
augmentation in the acute treatment of MDD nonrespon-
sive to antidepressant monotherapy have been conducted.
A meta-analysis of nine of these studies found response
rates of 45% in subjects randomized to lithium (n = 113)
versus 18% in those randomized to placebo (n = 121), yield-
ing a relative benefit of 2.5 compared to placebo (confi dence
interval = 1.6–3.8) (Bauer and Dompnier 1999). While this
benefit of lithium over placebo is both clinically and statisti-
cally significant, most of these studies were of augmentation
of TCAs, and not of SSRIs or other antidepressants used
most commonly today, which limits the conclusions that
can be drawn from them. One of the nine studies found a
Thyroid Hormone

Thyroid hormone has been used in various formulations in the treatment of depressive illness since the 1950s. As with lithium, T3 has been most extensively studied as an augmentation to TCAs, limiting the generalizability of this literature. There are at least four controlled or partially controlled trials of T3 augmenting TCAs, and another eight studies with open-label treatment. A meta-analysis of studies conducted prior to 1996 found a benefit of T3 over placebo when all open studies and RCTs were included, but found no difference when only RCTs were considered (Aronson et al. 1996). The STAR*D data described above are perhaps more applicable to current practice, however, in that T3 was used to augment antidepressants that are more frequently prescribed today. The STAR*D data argue for T3 augmentation of modern antidepressants being at least as effective as lithium augmentation, and better tolerated, providing good evidence supporting its use in TRD.

Buspirone

Buspirone is a partial agonist of the serotonin 1A (5-HT\textsubscript{1A}) receptor, and may act via affecting pre-synaptic autoreceptors on serotonergic neurons. In the STAR*D trial, augmentation of citalopram with buspirone was compared to combination of citalopram with sustained-release bupropion as the second step of pharmacologic treatment following an unsuccessful trial of citalopram in a randomized trial (Trivedi et al. 2006b). While bupropion has been described as a norepinephrine and dopamine reuptake inhibitor, the mechanism that mediates its antidepressant effects remains unclear. In this study, buspirone was started at a dose of 15 mg daily, and increased weekly by 15 mg to a final daily dose of 60 mg, administered in divided doses. Sustained-release bupropion was started at 200 mg daily and increased by 100 mg every two weeks to a final dose of 400 mg daily, also given in divided doses.

This study did not find significant differences in remission rates between the group receiving sustained-release bupropion (29.7%) and the one receiving buspirone (30.1%). However, they did note greater tolerability of bupropion than buspirone. Whether buspirone might be more effective for the subgroup of patients with significant anxiety as part of their depressive syndrome has not yet been addressed by analysis of the STAR*D database.

Pindolol

Pindolol is a beta-blocker that also acts as a 5-HT\textsubscript{1A} receptor antagonist. Inhibition of pre-synaptic 5-HT\textsubscript{1A} receptors on serotonergic neurons has been hypothesized as a possible means of potentiating the effect of SSRIs. While
two placebo-controlled trials from the same research group showed some benefit of augmenting fluoxetine or low-dose trazodone with pindolol, three placebo-controlled trials have failed to show benefit of pindolol over placebo when used for augmentation, including a recent trial of 42 SSRI nonresponders treated with pindolol 2.5 mg three times a day vs. placebo (Perry et al. 2004). Despite lack of clear antidepressant efficacy in that study, pindolol did exhibit active beta-blocking effects at this dose, with reductions in heart rate observed at one week. A positron emission tomography (PET) imaging study found limited occupancy of 5-HT<sub>1A</sub> receptors by pindolol at this dose, indicating that higher doses may be required to achieve physiologic effects on the 5-HT<sub>1A</sub> receptor (Mertinez et al. 2000). The current evidence provides little support for pindolol augmentation in TRD.

**Combination Antidepressant Strategies**

**Citalopram and Bupropion**

Please see Section “Buspirone.”

**Venlafaxine and Mirtazapine**

The combination of venlafaxine and mirtazapine used in the fourth stage of medication treatment in STAR*D was previously described (Section “MAOIs”). The mechanistic rationale for this combination stems from the idea that mirtazapine would reduce inhibition of serotonin and norepinephrine neurons via its presynaptic alpha-2 inhibitory activity while venlafaxine would inhibit reuptake of both of these neurotransmitters, thereby enhancing serotonin and norepinephrine neurotransmission (Stahl 2000).

**Novel Agents**

**Glutamatergic agents**

Because the glutamatergic system is the main inhibitory neurotransmitter system in the brain, agents active in this system have been proposed as augmenting agents for TRD with the rationale that treatment resistance in depressive disorders may arise from excess inhibitory function. Lamotrigine, which inhibits the release of glutamate, did not separate from placebo in a small controlled augmentation trial (Barbosa et al. 2003). An open label trial of riluzole given as monotherapy suggested some efficacy (Sanacora et al. 2007) although there is as yet no controlled clinical trial data to support this interesting finding.

**Atypical Antipsychotics**

Interest in the use of atypical antipsychotics for depression began in 2001 with the first publication of an augmentation study in which 28 patients with major depression unresponsive to fluoxetine monotherapy experienced significantly greater improvement when randomized to receive olanzapine augmentation compared to those continuing fluoxetine monotherapy (Shelton et al. 2001). Two subsequent and larger studies, however, one by the same author, failed to confirm these findings with fluoxetine (Corya et al. 2006, Shelton et al. 2005). Subsequently, seven new double-blind controlled clinical trials have been presented or published since 2006, with five of the seven showing greater efficacy for augmentation with an atypical antipsychotic compared to placebo addition to the antidepressant (Papakostas and Zarate 2007). Because none of the studies tested ziprasidone or quetiapine, there is uncertainty whether the efficacy extends to all of the atypicals or is limited to only some. Nonetheless, this augmentation strategy has become popular with clinicians faced with TRD cases, especially in those where bipolar disorder is known or suspected, since the data for the use of atypical antipsychotics in bipolar disorder is much more robust. The recent approval of quetiapine as monotherapy for the treatment of bipolar depression based on two well controlled clinical trials has reinforced this trend and encouraged the use of atypical antipsychotics in unipolar as well as bipolar depression. The metabolic and neurologic side effects of this class of medication should not be underestimated. They should be discussed clearly with patients prior to initiating treatment, and monitored once treatment has begun.

**Proposed Algorithm for Treatment**

There are no comprehensive treatment algorithms for TRD that incorporate the evidence base accumulated in the STAR*D trial. Prior treatment algorithms must therefore be viewed as models for subsequent algorithm development, and not as definitive tools to guide treatment. With these caveats in mind, the best-known treatment algorithm for major depressive disorder, which notably has an established evidence base, comes from the Texas Medication Algorithm Project (TMAP) (Figure 110–3) (Trivedi et al. 2004). This algorithm was tested prospectively in a nonrandomized design against treatment as usual over a period of 12 months. Symptom reduction was significantly greater in the group receiving algorithm-based treatment. These differences were significant at three months, and persisted through 12-month follow-up. A criticism that has been made of this algorithm is that it relies too heavily on monotherapy trials and does not advocate for augmentation or combination strategies early enough in the decision-tree (Trivedi et al. 2006a). This algorithm is nonetheless a good starting point that in the least includes many of the possible strategies that are available to the clinician confronting a challenging case of TRD.

**General Principles of Management**

It is important to educate patients about several aspects of medication-based treatments for depression. It is not uncommon for patients to believe that antidepressants can be effective even if taken only on days when they feel particularly depressed, and not on days when they are feeling better. Such beliefs and practices will only be elicited if patients are asked about how they are taking their medications, and if this is done in an open, nonjudgmental manner. Educating patients in a straightforward manner about the believed mechanism of antidepressants, and the need for these medications to be taken daily in order to achieve their therapeutic effect, can be helpful in these situations.

It is similarly important to ask detailed questions about patients’ sleep. Irregular sleep patterns, reduced sleep, or disturbed sleep architecture can all have deleterious effects on patients’ moods, and can be addressed both behaviorally and pharmacoologically. Educating patients about basic sleep hygiene can be extremely helpful to patients whose sleep habits are not conducive to good sleep (see Table 110–3).

*Any stage(s) can be skipped depending on the clinical picture.*
Patients’ personality styles can significantly affect their approach to taking medications. Some patients with narcissistic features may wish to have greater control over certain aspects of their treatment, including adjustments in dosing. It is often the case that some degree of flexibility on the part of the clinician, within clinically safe limits, can be very helpful in establishing a therapeutic alliance in such situations. Patients with obsessional or dependent features, in contrast, may go to great lengths to follow psychiatrists’ instructions extremely precisely. Dependent patients, in their eagerness to please their psychiatrist, may minimize side effects or overemphasize benefits from medications, and it is important to find ways of allowing such patients to feel comfortable disclosing their disappointments regarding treatment effectiveness or tolerability. For patients with significant anxiety related to taking medications, it can sometimes be reassuring to start at extremely low doses of medication, and titrate the dose gradually, an approach which also serves to increase tolerability/reduce side effects.

It can be extremely helpful to engage patients’ family members and significant others in treatment planning, which occurs too infrequently in the outpatient setting. Family members can be educated about the natural history of depressive illness, the importance of medication adherence, the triggers that seem to worsen an individual patient’s symptoms, and nonpharmacologic approaches that are being employed as well. In addition, parallel history obtained from family members with a patient’s consent can often elucidate previously unconsidered environmental or biological factors that may be contributing to the refractoriness of a patient’s illness. With the preceding section of this chapter in mind, you may wish to read the Clinical Vignette: Follow-Up for an example of how TRD may be managed in a hypothetical case.

### Indications for Brain Stimulation Treatment

Most patients who initiate a trial of ECT have had at least two prior unsuccessful antidepressant medication trials (Eitan and Lerer 2006). ECT is the sixth step in the Texas treatment algorithm described previously. Factors which may lead to consideration of ECT earlier in the course of treatment of depression include the presence of psychotic features, catatonia, suicidality, and melancholia to the point of food refusal that leads to malnourishment (Eitan and Lerer 2006). The use of ECT and other forms of brain stimulation in the treatment of depression are described in greater detail elsewhere in this book.

### Limitations of Current and Likely Research

There are major obstacles to the development of techniques to increase remission rates in TRD. Despite decades of research, our understanding of the pathophysiology of depression remains rather incomplete. Significant progress in diagnostic techniques, novel medication development, and rational application of the therapeutic armamentarium are unlikely to occur until relevant pathophysiology is further elucidated. New developments in neuroscience will teach us a great deal about how to intervene in TRD. These include functional imaging, the discovery of genes causative of, or predisposing to, depression or related to the likelihood of medication responsivity, the creation of genetic knock-out animal models of relevant neurochemical systems, and the development of neurochemical ligands allowing the probing of the biochemistry of the depressed state.

Of these developments, one likely to find a role in clinical care of TRD is functional brain imaging including positron emission tomography (PET) and functional magnetic resonance imaging (fMRI). A major limitation of this technology will be that imaging is complex, expensive, and sometimes involves radiation exposure. It may play a role in the evaluation and treatment of TRD as more is learned about prediction of treatment response by studying activation of discrete areas of the brain using imaging technology. Already, the confluence of studies suggesting increased activity in the subgenual area of the anterior cingulate cortex (Brodmann’s area 25) has been used to direct the implantation of an electrode for brain stimulation in patients with extremely TRD (Mayberg et al. 2005). Early results with deep brain stimulation targeted to decrease anterior cingulate hyperactivity have been very promising, but not uniformly effective. The fact that some studies have shown decreased rather than increased metabolic activity in this area, while possibly due to differences in imaging techniques between studies, may additionally point to between-patient variability that may be of use in the future to optimize individual treatment outcomes by targeting brain stimulation based on knowledge of an individual’s level of regional activation.

More likely to be widely applicable in the near future is pharmacogenetics, which is molecular genetic profiling to predict drug response. This may be available in only a few years to give a profile from which probability of response to therapeutic agents can be determined and treatment resistance can be categorized by genotype, which will be associated with strategies to relieve it. Even now, some companies are marketing clinical genotyping of polymorphic alleles in the cytochrome system, which are associated with variable expression of drug metabolizing enzymes. The idea behind this is to determine an individual’s genotype to predict whether that individual is a slow, normal- or extensive metabolizer of a particular compound. This would allow selection of an optimal dosage, avoiding the toxicity associated with too high a dose for a slow metabolizer or the lack of efficacy with too low a dose for an extensive metabolizer.
Storytelling is a powerful medium for conveying information. It allows the writer to engage the reader emotionally and intellectually, fostering a deeper understanding of the material being presented. By weaving together facts, figures, and anecdotes, the writer can create a narrative that is both informative and compelling. This approach is particularly effective in fields such as science, medicine, and history, where complex concepts can be difficult to grasp. Through storytelling, the writer can make the material more accessible and relatable, helping the reader to connect with the content on a personal level. In addition to the benefits for the reader, storytelling can also be a powerful tool for the writer. It allows them to express their ideas in a creative and engaging way, and can help to make the writing process more enjoyable and satisfying. Overall, storytelling is a valuable technique that can be used to great effect in a wide range of contexts.

Addiction to legal drugs like alcohol, or to illegal ones like cocaine, is the end result of changes in the brain caused by repeated use of a drug or combination of drugs. The so-called reward system in the brain is especially susceptible to drug use. This phylogenetically ancient system, built around meso-limbic and meso-cortical dopamine fibers, is an essential brain substrate of learning through reinforcement. The system is activated in the presence of normal physical or social reinforcers (food, sex, shelter, company), and this is accompanied by a subjective sense of well-being or pleasure. This orients an organism’s behavior toward procurement of such reinforcers, and thus is essential to survival. What all drugs of abuse, including alcohol, have in common, and what distinguishes them from all other drugs, is their ability to powerfully activate this system, over and beyond usual stimuli like hunger for example. Under the influence of drugs, changes in the activity of the reward system lead to physiological and behavioral manifestations that are the hallmark of addiction, such as craving for more drug, drug-seeking behavior, or withdrawal symptoms in the absence of the drug. The drug becomes an important, if not the most important reinforcer, supplanting other normal healthy reinforcers so much so that an individual’s behavior becomes oriented toward procuring and consuming the drug. As drug abuse becomes more entrenched, drug-induced changes in the brain become more pronounced, as susceptible nerve cells adjust to the frequent presence of a drug in the bloodstream. These changes occur according to patterns predetermined in the genes regulating each nerve cell, and can involve alterations in nerve cell functioning, alterations in neurotransmitter levels and neurotransmitter receptors, changes in morphology, even nerve cell death in some instances.

Clinicians attempting to help individuals struggling with addiction have long sought medications to help them in this task. In 1884, in a pamphlet entitled Über Coca, Freud recommended cocaine for seven conditions, including the treatment of opiate and alcohol dependence, although he later relented on this recommendation. Nonetheless, his search for medications spoke for a whole medical community in need of pharmacological agents to counteract the effect of drug addictions. Cocaine turned out to be every bit as addictive and destructive as alcohol or opioids, although in one sense Freud was anticipating one of the principal mechanisms of medication treatment for addiction, namely substitution with an agonist medication. Fortunately, clinicians now have access to effective medications, especially for alcohol, nicotine, or opiate addiction, while medications for cannabis and for cocaine and other stimulants are under development. This chapter seeks to instruct clinicians on the use of available agents approved by the Food and Drug Administration (FDA) to treat drug dependence. It will also highlight significant findings in medication developments for marijuana and stimulants like cocaine. The next section gives an overview of general pharmacological mechanisms or strategies for treatment of substance use disorders. This is followed by sections detailing medication treatments for each of the major addictive substances, including alcohol, opioids, nicotine, stimulants, and cannabis.
replacement, in which an agonist or analog of the addictive drug is administered in a slowly absorbed and slowly eliminated form. Examples include nicotine patch treatment for nicotine dependence, and methadone or buprenorphine treatment for opioid dependence. Dronabinol (oral THC) is under investigation as a treatment for cannabis dependence. The reinforcing effects of drugs of abuse relate in part to rapid absorption and rapid onset of effect, experienced subjectively as the “rush,” while the ups and downs in blood levels contribute to withdrawal symptoms and drug craving. A slowly absorbed and slowly eliminated agonist replaces the addictive drug, producing little or no euphoria or impairment, while also preventing withdrawal symptoms. This approach seems to be most applicable to drugs of abuse that mimic a neurotransmitter that itself is a direct agonist at a clearly defined receptor (e.g., the nicotinic receptor, and opioid receptors). Addictive drugs, such as alcohol, cocaine, or other stimulants, that may be characterized as indirect-acting agonists, seem to have been less amenable to the agonist replacement approach.

For example, a range of dopamine agonist and stimulant-like medications have been tested for cocaine dependence with some hints of efficacy but no clear signals to date.

**Antagonist Treatment.** Treatment with an antagonist that blocks the pharmacological and reinforcing effects of a drug of abuse is another classic strategy. The prototype here is the opioid receptor antagonist naltrexone, which is a powerful blocker of opioid effects including euphoria and reinforcement, as well as analgesia. This is an efficacious treatment of opioid dependence as long as the patient takes the medication; when a patient on naltrexone tries to use opioids there are no effects, and drug using and drug-seeking behavior tend to cease. However, adherence to naltrexone has typically been poor, as patients tend to stop taking the medication and resume opioids. Adjunctive behavioral therapy and long-acting injectable formulations of naltrexone have shown promise in improving adherence and effectiveness of this approach. Interestingly, naltrexone also displays some indirect antagonism of alcohol effects, and is a modestly effective treatment for alcohol dependence. Blockade of essential neuropharmacological systems in the brain may produce unpleasant effects, and this also seems to have been a limitation of antagonist treatment approaches. Mecamylamine, a nicotinic antagonist, developed originally for treatment of hypertension, has shown some promise in clinical trials as a treatment for nicotine dependence, although it was associated with unpleasant side effects. Neuroleptic medications have been tried as treatments for cocaine dependence based on their blockade of dopamine receptors, but have not been well tolerated, and animal models suggest that, if anything, blockade of dopamine may increase drug-seeking behavior. Disulfiram represents an antagonist strategy of sorts in that it impairs liver metabolism of alcohol, which makes a patient violently ill if alcohol is consumed due to a buildup of acetaldehyde; like naltrexone for opioid dependence, disulfiram is effective for alcohol dependence if the patient remains adherent to the medication, and behavioral strategies have been useful in improving adherence.

**High Affinity Partial Agonists.** The high affinity partial agonist is a relatively new strategy for pharmacotherapy of substance use disorders, with the currently available examples being buprenorphine for opioid dependence and varenicline for nicotine dependence. These agents can be thought of as residing in the middle of a continuum between full agonists and antagonists, binding their respective receptors, but only partially activating them. Thus they suppress withdrawal and replace agonist effects, but in theory have less abuse potential and a better safety profile. Because of high receptor affinity, these agents are not easily pushed off the receptors by other agonists, resulting in blockade of effects of other agonists.

**Indirect Modulatory Strategies.** The neuropharmacological mechanisms of addictive disorders are complex. While it remains clear that meso-limbic and meso-cortical dopamine fibers are essential to the positive reinforcing effects of substances of abuse, animal and human laboratory models have begun to elucidate distinct circuits and neurotransmitter systems underlying withdrawal, cue-induced craving, stress-induced craving, drug-seeking behavior, and relapse after a period of abstinence. GABA (β-aminobutyric acid) and excitatory amino acids (EAA) such as glutamate have been implicated in these phenomena, and a number of medications with effects on these systems have been tried, particularly for alcohol and cocaine dependence where classic agonist and antagonist strategies have not been available. Examples include acamprosate, FDA approved for alcohol dependence and thought to act through EAA mechanisms, and topiramate, an anticonvulsant with GABAergic properties that has shown promise for alcohol dependence in recent clinical trials. The modest effectiveness of naltrexone for alcohol dependence suggests that the opioid system modulates response to alcohol, exerting a relapse preventive effect. Antidepressant medications with a noradrenergic mechanism, including bupropion and nortriptyline, are effective for treatment of nicotine dependence, independent of a history of depressive disorder, perhaps by attenuating dysphoric symptoms that emerge during nicotine withdrawal (Hall et al. 2004). Medications that may dampen the stress response represent another investigative strategy.

**Treatment of Co-Occurring Psychiatric Disorders.** An increased prevalence of other psychiatric disorders among individuals with substance use disorders has been a consistent finding from studies of both clinical samples and community-based surveys of the general population (Hasin et al. 2006). Disorders for which this relationship is best documented, listed in decreasing order of strength of association, include antisocial personality, schizophrenia, bipolar disorder, anxiety disorders, and depressive disorders. There are several possible reasons for such associations, including that substance use may cause psychiatric symptoms, such as mood or anxiety symptoms, as a toxic effect. The possibility that patients may be drawn to substances of abuse as “self-medication” for psychiatric disorders, or that psychiatric disorders may otherwise worsen the prognosis of substance use disorders, has led to the hypothesis that effective treatment of the psychiatric disorder may improve substance use outcome. Depression is the most prevalent disorder observed among substance-dependent patients, and its treatment has received the most study. A series of clinical trials, summarized in two meta-analyses (Nunes and Levin 2004, Torrens et al. 2005), suggest that antidepressant medication is effective in treating depression among alcohol-dependent patients, and that such treatment is associated with improvements in self-reported...
drinking behavior. Similar findings exist in some studies among drug-dependent patients, although the data here are less consistent. Findings were strongest for studies that diagnosed depression during periods of enforced abstinence, or otherwise took pains in the history to distinguish independent depressive disorders from depressive symptoms that are toxic effects of substances. Thus, a good general principle for treatment of substance-dependent patients is to gather a thorough history to determine the presence of other psychiatric disorders, and to determine whether these disorders are being appropriately treated.

**Alcohol**

The presentation of a patient with alcohol-related problems can vary widely, from the visibly intoxicated adolescent who occasionally drinks excessively to the clear-eyed professional who is dependent on a blood alcohol level of 250–300 mg/dL to maintain composure. For this reason, a good set of questions to quickly assess a history of drinking is helpful. A particularly sensitive and specific set of questions is the CAGE questionnaire (Ewing 1984) (Table 111-1):

<table>
<thead>
<tr>
<th>Table 111-1 History of Alcohol Consumption, CAGE Questionnaire</th>
</tr>
</thead>
<tbody>
<tr>
<td>• Have you ever felt you ought to Cut down on your drinking?</td>
</tr>
<tr>
<td>• Have you ever felt Annoyed by criticizing your drinking?</td>
</tr>
<tr>
<td>• Have you ever felt bad or Guilty about your drinking?</td>
</tr>
<tr>
<td>• Have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover (Eye-opener)?</td>
</tr>
<tr>
<td>Other Pertinent Questions:</td>
</tr>
<tr>
<td>• When was your last drink?</td>
</tr>
<tr>
<td>• How much did you drink then?</td>
</tr>
<tr>
<td>• How many days in the past week have you had a drink?</td>
</tr>
<tr>
<td>• How many drinks each day?</td>
</tr>
<tr>
<td>• Do you have any medical illness?</td>
</tr>
</tbody>
</table>

Simply asking about the number of standard drinks consumed per day can also be a useful screen. A standard drink contains roughly an ounce of alcohol, and would include one 12–16 ounce beer, one glass of wine, one mixed drink, or one shot of hard liquor. Evidence suggests that 5 or more standard drinks per day for a man, and 4 or more for a woman, represents heavy or problem drinking and signals the likely presence of DSM-IV-TR alcohol abuse or dependence (Saha et al. 2007, Li et al. 2007, in press).

By knowing the history and current drinking pattern, whether there is medical comorbidity, as well as by observing the patient for agitation, jitteriness, or sweating, the clinician can reasonably determine if the patient is at risk of withdrawal, or worse, of developing delirium tremens (DTs). Insomnia, agitation, tremor, tachycardia may begin within a few hours and last 24–48 hours. If withdrawal is allowed to continue, increasing autonomic instability, disorientation, visual or auditory hallucinations, and seizures can occur after 12–48 hours after drinking ends. DTs, the most severe of alcohol withdrawal states, presents most frequently in the first week after cessation of drinking, and encompasses symptoms of altered consciousness, perceptual disturbances, disorientation, autonomic instability, sweating, and confusion (Pelic and Myrick 2003). It is lethal in approximately 10% of cases (Devenyi and Saunders 1986). For this reason, clinicians have sought to predict who is at highest risk for DTs. A previous history of DTs and tachycardia appear to be sensitive indicators: Lee et al. (2005) found that if neither are present, DTs would occur in 20% of cases; if one indicator was present, DTs occurred in 46% of cases; and if both were present, 100% of cases developed DTs. Other risk factors also reported in the literature include older age, hyponatremia, hypokalemia, blood alcohol > 300 mg/dL on presentation, and abnormal liver enzymes (Wetterling et al. 1994).

**Detoxification**

The goal of detoxification is to safely allow metabolism of serum alcohol while protecting the patient against the consequences of central nervous system (CNS) excitability, now unchecked by the inhibitory effect of alcohol. A second goal is to emphasize that detoxification is only the beginning phase of treatment, and that longer term treatment for alcohol dependence will be necessary (see below).

**Mild Withdrawal Syndrome**

During the detoxification, the presence and severity of withdrawal signs and symptoms need to be assessed. A quantitative and reliable method to do this is with the revised Clinical Institute Assessment for Alcohol (CIWA-Ar). This practical scale evaluates sweating, nausea and vomiting, tremor, agitation, tactile, visual, or auditory disturbances, headache, and orientation, all of which are assessed on a scale of 0–7, except orientation (0–4). This scale has been extensively validated in clinical settings (Sullivan et al. 1989), with a score of 10 being a good cut-off to separate those who will and will not require medications. Hence, patients who score less than 10 and do not have a history of withdrawal seizures or DTs, and do not have medical illnesses, usually can detoxify safely with supportive treatment not necessarily aided by pharmacological intervention (Nuss et al. 2004).

If the patient can stop drinking, then a CIWA-Ar score of less than 10, sufficient psychosocial support (family, friend, housing, adequate nutrition), and daily contact with the patient by a clinician most often indicate that outpatient detoxification can be attempted. In outpatient situations, the clinician may opt to provide the patient with a benzodiazepine at low to moderate dosage to alleviate withdrawal anxiety and insomnia. Benzodiazepines that are slowly absorbed and more slowly eliminated are preferred as they may have less abuse potential (e.g., lorazepam 1 mg three to four times per day; clonazepam, 1 mg three times per day; chlordiazepoxide 25 mg twice per day). If nutrition has been wanting, 100 mg of thiamine (Vit B1) daily will protect the patient from developing Wernicke’s encephalopathy, characterized by the acute onset of ataxia, nystagmus, and ophthalmoplegia, or from developing a sixth cranial nerve palsy. When in doubt, an intramuscular dose of thiamine followed by regularly multivitamins is prudent, given the potentially serious sequelae of Wernicke’s encephalopathy.

When abstinence is not attained, it may be necessary to hospitalize the patient to avoid repeated cycles of drinking and abstinence that may worsen the intensity and dangerousness of alcohol withdrawal reactions (Ballenger and Post 1978).
Moderate to Severe Alcohol Withdrawal Syndrome

When the CIWA-Ar score is above 10 (moderate), or greater than 20 (severe), then medications are required to protect patients from withdrawal symptoms. Blood alcohol levels tend to be elevated in withdrawal-prone patients, although they cannot always be relied upon as a predictor of withdrawal. Benzodiazepines (Ntais et al. 2005), anticonvulsants (Polyarpou et al. 2005), and adrenergic agonists to reduce sympathetic activation (Hawley et al. 1985) form the essential armamentarium available to the clinician.

With the CIWA-Ar, monitoring of vital signs, electrolytes, and nutritional status, the effect of administered medications can be readily assessed. Benzodiazepines remain first-rank medications to treat alcohol withdrawal, since they both effectively treat withdrawal symptoms, and protect against the advent of withdrawal seizures. Several protocols exist; these either involve fixed-dose or symptom-induced dosing (Saitz et al. 1994). The choice of benzodiazepine can be guided by the serum liver enzyme levels (ALT, AST). When normal, diazepam can be used, whereas when liver function tests (LFTs) are elevated, oxazepam or lorazepam are preferred as they are not metabolized by the liver. Table 111–2 illustrates fixed-dose and symptom-induced dosing for at-risk patients (Romach and Sellers 1991, Mayo-Smith 1997, Daeppen et al. 2002).

Two randomized trials comparing symptom-triggered dosing versus fixed dose (Saitz et al. 1994, Daeppen et al. 2002) concluded that administering benzodiazepines when symptomatic shortened the duration of treatment, and decreased the amount of medication used, without compromising on the safety and comfort of patients.

Anticonvulsants and Other Adjunct Medications

Despite ongoing research for better medications to treat alcohol withdrawal, benzodiazepines continue to hold gold-standard status. Nonetheless, among the anticonvulsants, phenytoin, carbamazepine, and those with action on the γ-aminobutyric acid (GABA) system (tiagabine, baclofen, pregabalin), appear beneficial; especially if the patient has a history of withdrawal seizures (Romach and Sellers 1991, Polycarpou et al. 2005, Mariani et al. 2006).

Phenytoin loading has long been used if the patient has a substantial risk of withdrawal seizures because of its ease of administration (iv and po) and tolerability. Practices vary, but a loading dose of 10 mg/kg is generally used, given completely or partially by the intravenous route, followed by 300 mg po every day for 5 days. If no other cause of seizures is found besides alcohol, phenytoin can then be discontinued (Devenyi and Saunders 1986).

Carbamazepine has become increasingly popular, especially for alcohol-dependent patients who have attempted detoxification repeatedly, and have developed neurological and psychiatric morbidity. It is thought that repeated cycles of drinking, withdrawal, and abstinence induce kindling in vulnerable areas of the brain. Kindling refers to a cellular process whereby neurons become sensitized by increasing their response to certain stimuli; leading to epileptogenic activity in instances such as alcohol withdrawal (Ballenger and Post 1978). At an approximate dose of 800 mg a day in divided doses, carbamazepine was found to be equally effective as oxazepam in reducing withdrawal symptoms. Moreover, patients expressed less psychological distress on the SCL-90 when treated with carbamazepine as opposed to patients assigned to oxazepam (Malcolm et al. 1989). Carbamazepine holds therapeutic potential for longer term treatment of alcohol dependence: compared to placebo, patients randomly assigned to carbamazepine drank for fewer days, and drank fewer drinks on the days when they did drink (Mueller et al. 1997).

GABAergic anticonvulsants like baclofen, tiagabine, and pregabalin appear promising for the treatment of alcohol withdrawal. In mice, pregabalin reduced seizure activity caused by abrupt ethanol withdrawal (Becker et al. 2006). In a retrospective chart study, tiagabine is reported to have equal effectiveness against withdrawal symptoms than either lorazepam or oxazepam, and appeared to have a relapse-preventing effect after detoxification (Myrick et al. 2005). Long used as a muscle relaxant, baclofen is reported by an Italian group (Addolorato et al. 2006) to be as effective as diazepam, and recommend that it be considered as a new drug for uncomplicated withdrawal. However, the potential of these medications needs to be further evaluated in larger randomized trials.

Considerable benefit to the patient can be gained by decreasing the sympathetic activation that occurs during withdrawal. By using clonidine, a centrally active α2 receptor agonist, clinicians can reduce heart rate, blood pressure and respiratory rate, as well as the anxiety, restlessness, insomnia and diaphoresis commonly encountered, to the greater comfort of the patient. An analog of clonidine,

lofexidine, with a lesser propensity to cause orthostatic hypotension, has also been used with benefit (Cushman and Sowers 1989). An important caveat is that these medications are probably not effective at preventing withdrawal seizures. Thus, although adrenergic medications are not central to the treatment of alcohol withdrawal, they can add considerable ease for the patient to the experience of detoxification.

Complications such as delirium or hallucinosis can occur during detoxification. DTs is a medication emergency requiring hospitalization and close monitoring of both physiological and mental status. Treatment with a benzodiazepine should be continued, but may not impact the delirium per se. In the absence of medical or psychiatric comorbidity, 0.5–5.0 mg of haloperidol daily, administered po, iv, or im, can be used to control the agitation, disorientation, and perceptual disturbances (Sellers and Kalant 1982). Alcoholic hallucinosis in the presence of an otherwise clear sensorium (auditory hallucinations) can be distinguished from alcohol withdrawal delirium, which involves disorientation and often vivid visual hallucinations. Its treatment implications are less clear, although it is thought to represent chronic toxicity of alcohol to the nervous system, and as such should trigger greater concern and vigilance for emergence of serious withdrawal symptoms.

Benzodiazepine Withdrawal
A mention should be made of benzodiazepine withdrawal, a condition frequently encountered by psychiatrists. While the presentation of benzodiazepine withdrawal may resemble alcohol withdrawal (anxiety, hyperreflexia, insomnia, restlessness, anorexia, emesis, leading to tonic–clonic seizures and life-threatening delirium), there is often more psychomotor and autonomic dysregulation. The onset may occur from 2 to 14 days following discontinuation. For this reason, the duration of treatment should be extended to at least 2 weeks, as manifestations such as delirium can occur into the second or even third week.

Long-acting benzodiazepines such as diazepam or chlordiazepoxide constitute the mainstay of treatment. Diazepam is more lipophilic than chlordiazepoxide and thus has a more rapid onset of action. This is deemed a favorable feature given the serious risks associated with benzodiazepine withdrawal. The clinician can be helped in this task by familiarity with a given benzodiazepine equivalent potency compared to lorazepam (Devenyi and Saunders 1986) (see Table 111–3).

A common practice is to convert the estimated daily dose of benzodiazepine into diazepam equivalents and reduce the dose by approximately 10 mg every 2–3 days, or as the patient tolerates. As the dose reaches approximately 20 mg of diazepam, the dose should be tapered by 5 mg every few days. Carbamazepine has also been shown to be effective in benzodiazepine withdrawal (Reis et al. 1989, Schweizer et al. 1991), and there is some evidence from animal studies that levetiracetam may be particularly well suited to treat benzodiazepine withdrawal (Lamberty et al. 2002).

Withdrawal from benzodiazepines or other sedative hypnotics can also, like alcohol withdrawal, develop into delirium in its most severe forms. Again, this is a medical emergency indicating hospitalization for close physiological and mental status monitoring.

Treating Alcohol Dependence
While some individuals remit from alcohol dependence without specific treatment and do not relapse, alcohol dependence is often a chronic-relapsing illness, calling for long-term treatment. Part of the difficulty in treating individuals struggling with alcoholism is that the diagnosis of alcohol dependence paints with same color individuals who are in fact very different types of “alcoholics.” Age alone, for example, is a significant discriminator. Alcoholics who started to drink before age 20 have more severe alcohol-related problems, have a family history of alcoholism, more cravings, more overt aggression and a poorer social functioning than those whose drinking started after age 20 (Johnson et al. 2000a). The importance of this distinction between early onset and late onset alcohol dependence extends also to treatment response, as alcoholics with onset before age 20 had worse drinking outcomes when treated with fluoxetine (then evaluated as a treatment for alcohol dependence) than later onset alcoholics (Kranzler et al. 1996, Pettinati et al. 2000). Nonetheless, medications can assist patients seeking treatment for excessive drinking. More specifically, available medications target drinking by different mechanisms, allowing the clinician to match treatment and patient. For example, disulfiram creates a sense of psychological threat that deters from active drinking, acamprosate appears to maintain established abstinence by reducing cravings to drink, and naltrexone reduces the reinforcing effect of alcohol. Hence, clinicians can reasonably make a best-fit recommendation for treatment.

Disulfiram
Disulfiram blocks the enzyme acetaldehyde dehydrogenase, a key enzyme that transforms acetaldehyde derived from alcohol into acetate. When alcohol is consumed—even in small quantity—the inhibition of the enzyme causes the accumulation of acetaldehyde, which leads to an increasingly unpleasant sensation as the blood concentration of acetaldehyde increases. This reaction, known as the disulfiram–alcohol reaction, involves a general sensation of malaise, nausea, perhaps vomiting, restlessness, tachycardia, hypotension, sweating, and dyspnea. In severe reactions there may be respiratory depression, cardiovascular collapse, arrhythmias, myocardial infarction, acute congestive heart failure, unconsciousness, convulsions, and death. It usually begins 20–30 minutes after drinking, and will continue as long as alcohol is being metabolized. The strength of the reaction...
vares according to the amount of alcohol ingested. Severe reactions are generally restricted to patients with underlying medical vulnerabilities, and thus patients with cardiovascular or renal or other serious systemic illnesses should not be treated with disulfiram in most cases. Detailed informed consent regarding the risks of disulfiram is important at the outset of treatment. In the case of a severe disulfiram reaction, supportive measures to restore blood pressure and treat shock should be instituted in hospital. Medical management of severe reactions involves oxygen, carbogen (95% oxygen and 5% carbon dioxide), vitamin C intravenously in massive doses (1 g) and ephedrine sulfate. Antihistamines have also been used intravenously. Potassium levels should be monitored, particularly in patients on digitalis, since hypokalemia has been reported.

Disulfiram renders the enzyme inactive within 12 hours of ingestion by irreversibly binding to it. In clinical terms, no tolerance to disulfiram develops with ongoing use: the longer a patient takes disulfiram, the greater the proportion of enzymes blocked, and the more sensitive to alcohol the patient becomes. Hence, even discontinuing disulfiram for 1–2 days will not change the strength of the reaction; normal alcohol metabolism returns approximately 2 weeks after stopping disulfiram (Devenyi and Saunders 1986), although this may vary. Similarly, there are some patients who appear less sensitive to the disulfiram reaction; this may simply represent poor medication adherence, although higher disulfiram doses may be required for some patients.

Patient selection and the environment in which the medication is given are most important. Patients with a strong motivation to stop drinking, who feel they lack the self-determination to carry it through can benefit the most from disulfiram, especially if it can be given in a supervised setting (Serény et al. 1986). Supervised daily intake can be made an integral part of a network therapy as it testifies concretely to motivation to be in treatment (Galanter 1993, Jung and Namkoong 2006). It is especially important for a successful outcome to involve a significant other in monitoring daily intake of disulfiram. This can be a family member, close friend, or it could be a clinician or clinic where the patient attends regularly. Disulfiram is a powerful treatment if the patient takes the medication. Conversely, the most common reason for treatment failure is nonadherence. Patient, physician, and the designated medication monitor need to agree to a plan. The designated monitor should witness and confirm that the patient has taken the medication each day, verbally reinforce and encourage adherence, and report to the treating clinician if the medication is not taken. Nonadherence should trigger a clinic or office visit to review the plan and seek to bolster the patient’s motivation.

Disulfiram, at a dose of 250–500 mg per day, should be administered at bedtime. While disulfiram is usually well tolerated, one must monitor liver enzymes as cases of hepatotoxicity have been reported (Berlin 1989). Contraindications to its use include digitalis intake for heart disease, liver disease, neuropathy, and chronic hypotension. Patients can be given a card provided by the manufacturer to alert emergency personnel of its use. This card also carries a description of the reaction in case they are called during its occurrence (Available from Odyssey Pharmaceuticals upon request).

In randomized trials (Fuller and Willford 1980, Gerrein et al. 1973, Serény et al. 1986) disulfiram was effective in producing more abstinent days for periods of up to a year. It is a medication that can also be integrated into various psychosocial treatments with ease, especially with the designation of a medication monitor as noted above (Gallant 1991). Disulfiram may be especially useful for the patient with alcohol abuse in combination with cocaine or other drug dependence, a frequent occurrence. To the extent that alcohol functions as a disinhibitor, or as a conditioned cue triggering other drug use, elimination of alcohol from the picture with disulfiram may improve other drug problems as well. Interestingly, Carroll et al. (2004) have reported that disulfiram is effective for treatment of cocaine dependence, independent of whether the patient is drinking alcohol. The authors hypothesize that disulfiram may produce this effect through its inhibition of the enzyme dopamine-β-hydroxylase, the first enzyme in the biosynthetic chain of dopamine, for which cocaine is a blocker of the synthetic reuptake system.

Naltrexone

When alcohol is ingested, the rewarding, calming, and euphoric effect that is experienced in some individuals appears linked to the activation of the opiate system. This is supported by reports that alcohol increases plasma levels of β-endorphins, especially in individuals with a strong family history of alcoholism (Gianoulakis et al. 1996). Congruent with this observation, naltrexone, an opiate receptor blocker, has been shown to decrease drinking (Volpicelli et al. 1994, Stromberg et al. 2001, Gonzales and Weiss 1998, O’Malley et al. 1992) and the number of relapses during a course of treatment (Garbutt et al. 1999). Three meta-analyses have corroborated the efficacy of naltrexone to treat alcohol dependence (Kranzer and Van Kirk 2001, Streten and Whelan 2001, Srisurapanont and Jarurusaisin 2002).

Naltrexone also appears to reduce cravings for alcohol (Williams 2005), and its abstinence-promoting effect has been positively correlated to the degree of craving, as assessed with the Obsessive Compulsive Drinking Scale (Anton et al. 1995). Whether severity of craving identifies a trait that segregates among alcoholics is a tantalizing prospect, on which genotyping studies may bring further clarity. An increased risk of alcohol dependence has been associated with a variant of the μ-opiate receptor named A118G (Bart et al. 2005). The presence of this variant in individuals has been correlated with greater stimulation from alcohol in laboratory investigations of nonalcohol-dependent volunteers (Ray and Hutchison 2004). Moreover, patients with this variant displayed a better treatment response to naltrexone than those without this variant (Osln et al. 2006). If replicated, this could be a useful clinical marker to assist clinicians in selecting treatment. This also points to the future promise of pharmacogenetics to better match patients with pharmacological treatments from which they are most likely to benefit.

The usual dose of oral naltrexone is 50 mg per day. Doses as high as 150 mg per day may be indicated, although higher doses have been associated with reversible liver toxicity. Prior to administration, liver enzyme status should be verified with a blood test, and patients should be informed to watch for signs of possible liver toxicity (Physician’s Desk Reference 2006). In addition, clinicians should ascertain that the patient is not using opiate medications or drugs, as administration of naltrexone would precipitate withdrawal. Common side effects encountered with naltrexone
include nausea, gastric upset, and diarrhea. As with any oral medication, compliance is key to successful treatment, and it is worth inquiring candidly from patients concerning their routine about medication intake. Lack of a specified routine likely points to irregular medication intake (Orwig et al. 2006; Rosen et al. 2007). As with disulfiram, involvement of a significant other to monitor medication adherence can be useful. Naltrexone can also be dosed on a three times per week schedule (e.g., 100 mg on Monday, 100 mg on Wednesday, 150 mg on Friday), which may make monitoring more convenient, for example in conjunction with three times per week clinic attendance. Shortcomings with oral naltrexone adherence have stimulated interest in long-acting formulations, one of which has just become available.

Long-acting naltrexone (380 mg per injection unit) is a microsphere formulation for intramuscular gluteal injection that can be administered monthly by a health care professional, as part of a comprehensive care program involving regular contact with a clinician (Vivitrol 2007). In addition to the safeguards mentioned for oral naltrexone, one must also monitor injection site, as local reactions such as hyperemia and induration can occur, especially if the medication is injected repeatedly at the same site. Clinical trials have shown it to be well tolerated and effective at reducing drinking days, extending time to a first drinking day, and better abstinence rate (Dunbar et al. 2006; Garbutt et al. 2005; Kranzler et al. 2004). In the pivotal clinical trial (Dunbar et al. 2006) naltrexone was most effective in patients who had achieved at least brief abstinence prior to beginning medication. This could indicate that the medication is most useful in the more highly motivated patients, or it could indicate that the mechanism of action depends in some physiological sense on a period of abstinence. Injectable naltrexone should be particularly considered for patients with a history of relapse, or with uneven adherence to prior treatments, and could for example be administered to patients immediately after completion of a detoxification (inpatient or outpatient) in an effort to reduce relapse in the postdetoxification period.

Two clinical notes of interest concerning naltrexone. A report by Hernandez-Avila et al. (2006) looked at the effectiveness of targeted naltrexone use versus daily use. During counseling, high-risk situations were identified, and the patients were then instructed to take naltrexone prior to these high-risk situations. This approach produced a greater reduction in daily drinking than did daily naltrexone or targeted placebo use. These results suggest that clinicians can discuss with patients ways to take oral naltrexone that may be most suited for their drinking pattern. Another report by Pettinati et al. (2006) reviewed 29 published trials of opioid antagonists, most with naltrexone, and found that it may have greater effectiveness in reducing heavy or excessive drinking, as opposed to inducing complete abstinence. This concurs nicely with the observation that naltrexone may be of most benefit for those who derived a greater sense of reward from drinking alcohol excessively.

Acamprosate

Acamprosate is an analog of the amino acid taurine, and was approved for the treatment of alcohol dependence in December 2004 (Boothby and Doering 2005). With chronic or excessive alcohol consumption, the brain glutamatergic system becomes sensitized and disinhibited; once a patient is abstinent from alcohol, an hyperactive glutamatergic system may elicit agitation, cravings for alcohol (abstinence craving) that may lead to relapse (Mariani and Levin 2004). Acamprosate appears to confer a relapse prevention effect by antagonizing the glutamate system, which in turn is thought to reduce cravings to drink (Jung and Namkoong 2006). Worldwide clinical experience with acamprosate is considerable, with over 1.5 million alcohol-dependent patients treated, at the time of approval in the United States (Berglund et al. 2003; Mason 2003; Mann et al. 2004).

Two meta-analyses have found that acamprosate improved drinking outcome, with a relatively small effect size overall, and both concurred that the strongest effect was on prolonging abstinence (Kranzler and Van Kirk 2001; Mann et al. 2004). It does not seem to be as effective if patients are actively drinking at the time of treatment. This is reminiscent of findings from naltrexone trials, where there is some evidence that the medication effect is larger for patients who achieve abstinence prior to beginning medication.

Acamprosate is well tolerated, and can be started at the treatment dose of 660 mg three times a day, although doses up to approximately 3 g per day have been used (Anton et al. 2006), preferably once the patient has undergone detoxification and has stopped drinking. Diarrhea, headache, and abdominal pain are the most frequently experienced side effects.

Because of their different mode of action, and different impact on drinking behavior, treatment combining naltrexone and acamprosate has had conceptual appeal. In one randomized, double-blind, placebo-controlled trial including 160 patients, naltrexone outperformed acamprosate in terms of abstinence maintenance. When combined, the medications were better than placebo or acamprosate monotherapy, but not naltrexone monotherapy (Kiefer et al. 2003). In a recent published trial, naltrexone also was found superior to acamprosate in terms of abstinence maintenance (Morley et al. 2006). Although acamprosate has not fared well in these trials compared to naltrexone, these results should be interpreted with caution because of the great differences encountered among alcohol-dependent individuals seeking treatment. However, the COMBINE study, described in more detail below, found no evidence for an added benefit of combining acamprosate with naltrexone. COMBINE also found no evidence for benefit of acamprosate alone.

Combined Pharmacotherapies and Behavioral Intervention for Alcohol Dependence: The COMBINE Study

Given the public health importance of treating alcohol dependence, there is great interest in making treatment accessible to as many individuals with alcohol dependence as possible. One concern about the institutions where treatments for alcohol dependence were first developed and tested is that these tended to be tertiary care, specialty settings. There, specially trained clinicians administered the treatments being evaluated, raising the question of whether this extensive training of the clinicians was a pivotal factor for treatment effectiveness. The COMBINE study was devised to test whether these treatments can be effectively delivered using models adaptable to primary care, nonspecialty settings (Anton et al. 2006).
The COMBINE study examined the treatment effects and interactions of naltrexone (oral), acamprosate, and two behavioral interventions: medical management (aimed at reproducing primary care settings) and combined behavioral therapy (a more intensive individual therapy designed specifically for alcohol dependence). Each behavioral therapy was matched to four possible medication therapies: placebo, acamprosate, naltrexone, or naltrexone–acamprosate combination. In addition, a no-pill option was paired with the combined behavioral therapy, for a total of nine possible medication–behavioral therapy combinations. Carried out at 11 academic centers in the United States between 2001 and 2004, the COMBINE study examined the effect of these therapies on 1,383 recently abstinent alcohol-dependent patients. All treatment groups improved substantially after treatment entry, suggesting a large favorable effect attributable to entering treatment itself, be it motivation, or nonspecific therapeutic effects of the clinic milieu. Beyond this large early nonspecific benefit, a small further advantage was found for naltrexone, compared to placebo. There was no evidence of efficacy for acamprosate. The results of this study demonstrate the feasibility of treatment for alcohol dependence with medications in conditions approximating primary care settings, and a modest effect of naltrexone. More work is clearly needed to understand clinical predictors of benefit from naltrexone or acamprosate, in terms of patient characteristics or the accompanying treatment conditions.

An interesting aspect of the COMBINE study highlighted the impact that an intervention by a trusted clinician can have. Administration of a placebo pill with medical management led to better outcomes than the more intensive combined behavioral therapy intervention. Clinical attention to the problem of alcoholism can have a significant impact. It also speaks of the power of the placebo effect, which should always be considered by physicians prescribing medications for psychiatric disorders. Overall, naltrexone as well as acamprosate and disulfiram are effective tools that can bring treatment of alcohol dependence in the mainstream of primary care medicine.

Treatment of Co-Occurring Psychiatric Disorders and Alcohol Dependence

Major depression is common among alcohol-dependent patients and is associated with worse clinical outcome (Nunes and Raby 2005). Although there have also been negative studies, two meta-analyses (Nunes and Levin 2004, Torrens et al. 2005) support the conclusion that treatment of major depression in alcohol-dependent patients is an effective strategy associated with improvement in depression and modest improvement in self-reported drinking. A favorable medication effect was more likely in studies that required patients to be abstinent before depression was diagnosed and treatment initiated. This suggests that a careful history is needed to separate independent mood disorders from transient depressive symptoms that may result from chronic alcohol use, and that ideally the diagnosis should be made during at least a brief period of abstinence to minimize confusion of alcohol effects with independent depression. Behavioral therapy may be effective for treatment of depression for some alcohol-dependent patients who show interest in therapy.

In terms of choice of antidepressant medication for an alcohol-dependent patient, the findings are complex. Serotonin reuptake inhibitors (SRIs) probably have a greater margin of safety among alcoholics because they are less sedating and arguably less prone to adverse interactions with alcohol. However, most of the positive evidence for efficacy comes from trials of tricyclic antidepressants. Most of the trials of SRIs were negative, although two such trials that diagnosed depression while patients were abstinent on an inpatient unit were positive (Nunes and Levin 2004). Furthermore, several trials of SRIs in alcohol-dependent patients not selected for depression have now shown that SRIs may actually worsen drinking outcome for drinkers with early age of onset, many of whom have depressive symptoms (Kranzler et al. 1996, Pettinati et al. 2000). A prudent approach would be to begin with an SRI, exercising particular caution in early onset alcoholics, and if the response is not adequate to switch to an antidepressant with a noradrenergic mechanism.

Anxiety and anxiety disorders are also common among alcohol-dependent patients. One clinical trial supports the efficacy of buspirone for alcoholics with elevated scores on a scale of general anxiety after completion of detoxification (Kranzler et al. 1994). Buspirone is a well-tolerated, non-sedating medication and should be considered among alcohol-dependent patients whose anxiety can be shown to persist in abstinence. The SRI antidepressant sertraline has been studied among alcohol-dependent patients with posttraumatic stress disorder (PTSD). In a finding reminiscent of the SRI trials with early versus late onset alcoholics, sertraline was found to be more effective than placebo in reducing drinking among patients with early onset PTSD and mild alcohol dependence, but less effective than placebo for the patients with early onset alcohol dependence and late onset PTSD, (Brady et al. 2005).

Future Research

Other promising developments include a report on topiramate, an anticonvulsant with a broad spectrum of action, including effects on GABAergic and glutamatergic systems. With medical management, topiramate reduced self-reported drinking, and cravings for alcohol in a double-blind, randomized, placebo-controlled clinical trial (Johnson et al. 2003). A large-scale clinical trial seeking to replicate this effect is now completed and under analysis.

The advent of a long-acting injectable naltrexone also promises to extend abstinence from alcohol, especially when compliance with taking oral naltrexone daily is a major difficulty. Coupled to the enhanced response to naltrexone that appears associated with the A118G allele of the μ-opiate receptor gene, it may become possible to identify those individuals most likely to benefit from this form of treatment and reduce the burden of alcoholism.

Opiates

“Opiate addiction is a curse wrapped-up in a gift.” This statement from a patient accurately describes how opiates can ensnare people into a painful state of physical and psychological dependency. As clinicians well know, the benefit of effective pain control can become dulled by the development of tolerance unless opiates are carefully used. Even then, patients who have used opiates for pain control can
develop such a state of physical dependence that withdrawal symptoms ensue if opiate intake is not continued. Hence, for addicted as well as tolerant patients, the problem posed by opiates is often how to overcome withdrawal. Fortunately, even though opiate withdrawal can be painful and stormy, it is not life threatening as alcohol or sedative withdrawal can be. Opioid withdrawal may begin anywhere from 4 to 24 hours after the last dose of opiate drug or medication, depending on the half-life. Typically, it will begin with yawning, rhinorhea, tearing, tachycardia, back and limb pain, abdominal cramps, leading to restlessness, irritability, muscle cramps, and shaking chills. As withdrawal appears to closely follow the clearance rate of opiates from receptors, first symptoms emerge sooner with a short-acting opiate like heroin, and later with methadone. In any case, treatment must begin with detoxification to ease the transition to a nondependent state, followed by ongoing maintenance treatment.

**Detoxification**

Detoxification is only the beginning of treatment for opioid-dependent patients, as the need or desire for opiates can persist long after the detoxification is complete. It follows that long-term treatment is usually necessary to assist with abstinence from illegally procured opiates, and to develop alternate coping strategies to deal with the individual daily enticements (persons, places, and things) associated with opioid use that can lead to relapse.

Patients with opiate dependence can present with a variety of medical conditions that relate to the drug using lifestyle, and that may require intervention. Daily intravenous injections can produce local and disseminated infections such as phlebitis, cellulitis, endocarditis, cardiac valvular disease, and pulmonitis. Rates of hepatitis C have sky-rocketed in the last decade and warrant performing a hepatitis screen on admission if LFTs are abnormal (Liao et al. 2006). Hepatitis B can also transmitted by unclean needle use, although its impact may have been somewhat reduced by widespread availability of the Hepatitis B vaccine in recent years. Certainly, any drug-dependent patient not already vaccinated or carrying Hepatitis B antibodies should be encouraged to undergo Hepatitis B vaccination. Intravenous drug use is also a major mode of transmission of HIV. The more widespread availability of needle exchange programs and other modes of access to clean needles (e.g., pharmacies) have had a beneficial public health effect in reducing blood-borne disease transmission among drug-dependent patients. There is also evidence that chronic heroin use affects physiological mechanisms of aging, accelerating the process of premature aging (Missippien and Reese 2006). These and other medical concerns make heroin and drug use in general a major public health problem.

Detoxification methods are usually based on the premise that an intense short-lived withdrawal (measured in terms of days) precedes a milder but more protracted one (lasting weeks to months). Most methods aim at aiding patients withstand the rigors of the initial phase. This is achieved by using the medication on which the patient is dependent (detoxification of low potency opiate like propoxyphene), by using medications that exert a cross-tolerance effect (methadone substitution in heroin dependence), by using medications that provide relief of withdrawal symptoms (benzodiazepines for restlessness and insomnia), or finally, by using medications that target withdrawal-induced sympathetic activity (alpha-2 adrenergic agonists) (Kleber 1981).

The methods currently in use include the following:

1. alpha-2 adrenergic agonists clonidine and lofexidine;
2. long-acting mu-receptor agonist methadone;
3. mu-receptor partial agonist buprenorphine;
4. rapid detoxification with general anesthesia. Methadone and buprenorphine are also used following detoxification for opioid agonist maintenance treatment.

**Alpha-2 Adrenergic Agonist Based Treatment**

The use of this class of medication is predicated on its inhibition or reduction of the opiate withdrawal symptoms caused by sympathetic nervous system hyperactivity (insomnia, tachycardia, sweating, nausea, malaise). Other symptoms such as craving for opiates, muscle aches, and pain are not significantly suppressed however (Jasinsky et al. 1985). Thus, clonidine is not usually used by itself but is rather often combined with a benzodiazepine (for anxiety), NSAID (for muscle pains), and medications for GI distress. In general, clonidine-based detoxification is not as effective as detoxification methods based on agonists (methadone or buprenorphine), but it remains a useful component of the armamentarium.

Clonidine and lofexidine belong to this class of medications, and although not FDA approved for this purpose, clonidine is well known in the medical community as a useful medication to treat opiate withdrawal symptoms and to attempt detoxification with. Lofexidine could not obtain FDA approval as an antihypertensive medication in the 1980s, rendering it unavailable for use as medication to treat opiate withdrawal. However, its lack of hypotensive effect gives it an advantage over clonidine, in that sufficient dosages can be given to bar withdrawal symptoms with less concern of producing iatrogenic hypotension. This appears to be due to the high affinity of lofexidine to only one of the three subtypes of alpha-2 adrenergic receptors, as opposed to the high affinity of clonidine to all receptor subtypes (Herman and O’Brien 1997). Since opioid withdrawal may involve nausea, vomiting and diarrhea, and consequent volume depletion, attention to hydration (oral or parenteral if necessary) is always important during opioid withdrawal. Lofexidine has been used in Europe for opiate withdrawal treatment, where it has proved to be as effective as clonidine with less hypotension and sedation when used at doses up to 2 mg/day (Bearn et al. 1996). Lofexidine is currently being reevaluated as a medication for opiate withdrawal in the USA.

Most detoxification methods using clonidine involve an abrupt cessation of opiate intake, with a transfer onto clonidine that same day, preferably performed as an inpatient. Typical methods for short and long-acting opioids are outlined in Table 111–4.

Symptoms of withdrawal begin to diminish usually within 30 minutes, with a peak effect reached after 2–3 hours. The blood pressure should be checked before each dose, and when lower than approximately 85/55 mm Hg the dose should be held, and the patient encouraged to remain supine and to drink a lot of fluids. Clonidine detoxification should not be attempted in pregnant patients, or patients with cardiac disease, or in patients who have been on antidepressants, as these tend to produce desensitization of alpha-2 adrenergic receptors.
Clinicians have attempted to address two shortcomings of this method by devising ways to shorten the duration of the detoxification, and by attempting to expand the effect of clonidine to more fully cover all the symptoms of opiate withdrawal.

Vining et al. (1988) described a method of “ultra rapid detoxification” in which the opiate antagonist naltrexone is used to precipitate withdrawal, and clonidine preceding and following naltrexone is used to treat the withdrawal symptoms. For those symptoms not responsive to clonidine, adjuvant medications such as oxazepam for muscle cramps and insomnia or antiemetics are used. Table 111–5 illustrates the typical inpatient (or outpatient) course of treatment with this method.

This method requires trained and experienced medical personnel to assess vital signs and the severity of withdrawal symptoms to adjust medications, including monitoring for hypovolemia and intervening as needed, as well as the appropriate medical setting. There is some evidence that this method shortens the time required for detoxification. However, it does not appear to result in longer periods of abstinence (O’Connor and Kosten 1998).

Some clinicians have combined clonidine with buprenorphine, a partial μ-receptor agonist to offer a more complete control of withdrawal symptoms and offer a more comfortable detoxification.

The usual methods involve a 3-day detoxification procedure, or a longer procedure up to 14 days, either method involving clonidine administration (0.1–0.4 mg po q 4–6 hours prn, not exceeding 1.2 mg per day) with buprenorphine induction and detoxification (see below) (O’Connor et al. 1997).

While a good adjunct medication to support opiate detoxification using other agents, clonidine-assisted detoxification itself is not popular among dependent individuals. A recent comparison of detoxification methods revealed that clonidine-assisted methods produced the lowest retention in opiate dependence treatment (Collins et al. 2005)

Methadone for Detoxification

Most hospital-based opiate detoxification programs use methadone, a long-acting μ-receptor agonist. Its half-life is approximately 72 hours, it can be taken orally, and it reduces or eliminates all the components of the withdrawal syndromes. The extensive experience acquired in the medical community with its use has also rendered it quite safe.

The first hurdle for the clinician is to determine the initial dose. When dealing with someone who is tolerant to medically prescribed opiate, the initial dose can be arrived by the use of an analgesic potency conversion table (see Table 111–6), once the daily dosage of the prescribed opiate is known.

These figures are approximate as they are based on dosages that provide nearly equivalent analgesic effect

\* Recommended dose is 0.1–0.2 mg po, but may be increased as required.

Once the initial dosage of methadone is set, based on the absence of withdrawal and on vital signs, it should be continued at least for another day. The dosage can then be decreased over a period of 5–10 days. Two practices are most commonly used for this: the dose is either decreased by a fixed amount, either 10% or 5 mg every day or two until zero dosage is reached (linear withdrawal method), or it can be decreased by 10 mg/day until a dose of 10 mg is reached. Following this, it is decreased at a slower rate of 2 mg/day by the inverse exponential withdrawal method (Strang and Gossop 1990).

Even though the acute withdrawal can be managed by these methods, the clinician must be aware that fatigue, insomnia, irritability, and anxiety may persist for several weeks to even months. These must be addressed even though there may no longer be any signs of acute withdrawal. This subacute withdrawal syndrome may respond nicely to low dose clonidine (0.1–0.2 mg, three to four times per day). Insomnia can be treated with medications like zaleplon or trazodone, as improved sleep tends to reduce anxiety and irritability (Sullivan et al. 2006). Benzodiazepines are very useful during acute withdrawal, but are best avoided or else used with particular caution because opioid-dependent patients are at increased risk to develop benzodiazepine dependence. If used, recommendations such as a low dose of a long-acting benzodiazepine, a taper schedule, and close monitoring for signs of abuse of the benzodiazepine should be implemented. Nonsteroidal anti-inflammatory medications like ibuprofen, ketorolac, or tramadol can be used for pain if present. Sufficient fluid intake and proper nutrition, with vitamin supplementation if necessary, should also be encouraged.

Buprenorphine for Detoxification
Methadone is a safe, well-known treatment to help with opiate withdrawal, and it has the virtue of being inexpensive. However, methadone also has drawbacks for detoxification. Withdrawal symptoms often emerge after a taper is completed, increasing risk of relapse; it has a certain stigma attached to it because of diversion and misuse; and it can only be administered for treatment of opioid dependence either on an inpatient unit or in specially licensed clinics. The high affinity partial agonist buprenorphine is an alternative, which is a superior agent for detoxification in most respects, and can be prescribed by any physician who has taken a brief certification course. As a partial agonist, buprenorphine relieves withdrawal symptoms, while having a ceiling on its agonist effects, resulting in greater safety (low risk of overdose) and low abuse potential, and the starting dose for buprenorphine is less dependent on the amount of opioids the patient has been taking. Because it has very high affinity for opioid receptors, it dissociates from the receptors very slowly, thus having an inherent self-tapering effect. Several multisite clinical trials in community-based treatment settings have demonstrated its effectiveness and high acceptability for opioid detoxification (Amass et al. 2004, Ling et al. 2005). One drawback is its expense (it is substantially more expensive than methadone). Another drawback is that if buprenorphine is given too close in time to the last doses of other opioids, particularly with slowly eliminated agents such as methadone, withdrawal can be precipitated because a partial agonist is displacing full agonists from receptors. For this reason, when initiating buprenorphine,
it is important to wait until a patient is clearly developing withdrawal symptoms before starting buprenorphine, and greater delay is prudent when the patient has been taking a long-acting opioid such as methadone. After withdrawal signs and symptoms begin to emerge a test dose of 2 mg sublingual can be administered. If withdrawal symptoms should begin to improve, or at least do not worsen, then another 2 mg can be given 1 hour later, followed by 4 mg, for a total of 8 mg to 16 SL on the first day. The most accepted method involves a 3-day protocol, which provides good control of withdrawal symptoms with few side effects. After initiation of buprenorphine, the first day dose is repeated on the second day, and decreased to 4–8 mg on the third day. Abrupt withdrawal of buprenorphine leads to a comparatively mild withdrawal syndrome (Cheskin et al. 1994). Early reports on this form of detoxification suggest that it may lead to better retention in longer term treatment (Renzelli and Capretto 2006). Longer detoxification protocols also exist; involving a more gradual 10–14 day taper schedule was also shown to be effective in several multisite clinical trials (Amass et al. 2004, Ling et al. 2005).

It is important to bear in mind that withdrawal precipitated by buprenorphine can be atypical in its presentation, with impaired sensorium, and less of the typical symptoms of autonomic overdrive. Precipitated withdrawal can be treated with waiting and adjunctive medications (e.g., clonidine).

Summary of Opioid Detoxification Techniques

As outlined above, clinicians and patients have several effective pharmacological treatment regimens to choose from for treatment of opioid withdrawal. The most serious drawback with detoxification is that the risk of relapse to opioid dependence after completion of detoxification is very high. Thus, it is important to have a strong aftercare plan in place, consisting of either residential treatment, a solid outpatient program, or pharmacological treatment with either agonist maintenance (methadone or buprenorphine) or antagonist treatment with naltrexone. For patients with a history of relapses, long-term pharmacological treatment is indicated in most cases. The following sections describe maintenance treatment with methadone, buprenorphine, and naltrexone.

Maintenance Treatments

Methadone

Methadone maintenance was introduced over 30 years ago by Dole and Nyswander (1965) and represented a major advance in the treatment of opioid dependence. It allowed many chronic opioid-dependent patients who had previously been refractory to psychosocial treatments to become abstinent and lead productive lives. Methadone maintenance treatment is tightly regulated by Federal regulations, and can only be administered at specially licensed clinics, according to criteria summarized below. In principle, methadone maintenance is indicated for any patient who has failed to maintain abstinence and relapsed after one or more attempts at “drug-free” psychosocial treatment. According to the regulations, to be eligible for methadone maintenance, an individual must show evidence of at least 1 year of physiological dependence, demonstrated by at least a positive urine toxicology, and signs and symptoms of opiate withdrawal. Having met this criteria, the following individuals can be eligible:

- Individuals from penal institutions who met the criteria prior to incarceration (risk of relapse is high in such individuals despite the fact that they may have been abstinent for some time in prison).
- Pregnant women (methadone maintenance is the treatment of choice in pregnant opioid-dependent patients; since it is most likely to eliminate or minimize drug use, it appears to be relatively safe in pregnancy, and it prevents withdrawal symptoms, which can be harmful to the fetus).
- Patients previously on methadone maintenance for up to 2 years after treatment is terminated.
- An individual younger than 18, after two documented attempts at opiate detoxification or drug-free treatment at least 1 week apart. A parent or legal guardian must sign Form FDA-325 Consent to Methadone Maintenance.

Individual states are permitted to make these criteria more stringent, but not less so. Federal regulation prohibits daily doses greater than 120 mg without first obtaining permission from state authorities. Some patients, particularly those who are rapid metabolizers of methadone, may require higher doses; for patients who continue to use opioids despite methadone doses in the 100–120 mg range, drawing of peak and trough methadone blood levels should be considered to assess rate of metabolism, and permission sought to attempt higher doses if appropriate.

The reason for methadone’s effectiveness in maintenance treatment lies is its pharmacokinetics and in the phenomenon of tolerance blockade. Methadone displays the prototypical pharmacokinetic profile of an effective agonist substitution agent, with relatively slow absorption, and long half-life. It is absorbed from the stomach and reaches peak plasma levels in about 4 hours, which contrasts with the rapid spikes in blood level associated with injection, inhalation, or insufflation of heroin. It becomes tightly bound to proteins in all tissues, including the brain. After 3–4 weeks of daily intake, methadone concentration reaches a steady state level. Further, with chronic administration at adequate doses (in the 60–100 mg per day range) methadone induces marked tolerance in the brain opioid system, such that other agonists are effectively blocked. Thus, after 1–2 weeks on methadone, as the dose is titrated upward, patients will begin to report that they no longer get high when they take heroin, and heroin use often ceases completely at that point. Because of tolerance, intoxication or sedation are also avoided, so that methadone maintenance should not impair functioning, allowing patients to work and otherwise function normally in society. If sedation persists as a side effect, this suggests that the dose is too high, or that the patient does not tolerate methadone well. Estimating the initial dose for maintenance is similar to that for withdrawal (see above), and the practice of observing the patient for 1–2 hours is worth repeating here. The maintenance dose should aim at eliminating any sign of withdrawal, not produce any euphoria or sedation, and prevent the use of any illegal opiates (as evidenced by urine toxicology and report from the patient). What this dose will be varies considerably from patient to patient, but a national survey reported that better retention was obtained with doses in excess of...
60 mg per day (Hargreaves 1983), and that the target dose range is usually 60–100 mg. Generally the dose is started lower, at 20–30 mg per day, for safety reasons, and gradually increased over 1–2 weeks into the target range. The concern here is that since methadone is a full agonist, and a patient’s level of tolerance may vary, too high an initial dose of methadone could lead to overdose, particularly if the patient continues to use illicit opioids on top of the methadone at the outset. However, it cannot be stressed enough that, as in many other instances in psychopharmacology, the most common reason for treatment failure with methadone maintenance is inadequate dosage, and every effort should be made to advance the dose to the target range, or beyond as tolerated, until abstinence is achieved.

The public health benefits of methadone maintenance have been documented thoroughly: to name three, methadone has reduced the spread of HIV among intravenous users of heroin (Barthwell et al. 1989, Novick et al. 1990), and methadone use has decreased needle sharing with all the health ramifications that ensue from it (Ball et al. 1988), and methadone reduces the risk of opioid overdose, an otherwise common cause of death among opioid abusers. Also, there are the considerable benefits of the reduction in personal suffering from achievement of abstinence and the social benefits of getting patients back to normal social functioning.

Special Management Issues During Methadone Maintenance

Three situations that may be encountered while on methadone maintenance warrant special mention: (a) the patient who continues to use drugs despite apparently adequate methadone doses; (b) the patient who needs surgery; and (c) the pregnant patient.

Continued Drug Use During Methadone Maintenance. The optimal response to methadone maintenance is full remission of opioid dependence (i.e., abstinence confirmed by regular urine toxicologies) and of any other substance use problems. Anything short of that should warrant clinical attention and ongoing efforts to achieve full remission. Full coverage of this topic is beyond the scope of this overview chapter, but several main points should be highlighted. Firstly, methadone maintenance treatment almost always reduces the quantity of illicit opioids used, usually substantially, even if complete abstinence is not achieved. Although this does not represent remission, it is often a clinically significant improvement, suggesting that methadone treatment should be continued and augmented, and not abandoned. Secondly, ongoing opioid use should prompt efforts at increased counseling and behavioral treatment, increased methadone dosage, and/or blood level studies to determine if the patient is a rapid metabolizer. The effectiveness of methadone maintenance has been shown to depend upon concurrent counseling (McLellan et al. 1993). Specific behavioral methods, such as voucher incentives, exchangeable for goods and services, contingent on drug-free urines, have been shown to increase abstinence among methadone maintained patients (Pierce et al. 2006). Nonopioid substance use is also common since methadone does not have a specific pharmacologic effect on nonopioid drug use. Alcohol, cannabis, cocaine, and benzodiazepines is frequently seen. Again, the presence of these other substance problems should not prompt discontinuation of a methadone treatment that is otherwise succeeding in reducing opioid use. Instead, specific treatment efforts for each of these substances should be mounted, including both counseling and behavioral therapies, as well as the pharmacologic approaches described elsewhere in this chapter.

Surgery or Pain Control During Methadone Maintenance. In the case of surgery requiring general anesthesia, the opiate-dependent patient may require larger than expected doses of anesthetic because of preexisting tolerance. Tolerance also means that methadone is not an effective analgesic in patients maintained on methadone (Kreek 1979). If the patient requires analgesia, the maintenance dose of methadone does not contribute analgesia. Efforts should be made to control such pain with nonopioid medications or nerve blocks. Additional opioids can be carefully added to control pain, but need to be administered at the usual frequency and dosages, at least initially, to avoid an overdose. The patient on methadone maintenance therapy should not receive any partial agonist medications like buprenorphine, or full antagonists, like naltrexone that would induce a sudden withdrawal. For the whole perioperative period, the patient should receive his/her usual methadone opiate dose.

Pregnancy and Methadone Maintenance. The pregnant patient with opiate dependence presents with special challenges. Opioid withdrawal, which is unpleasant but benign for an adult, can cause seizures, organ damage, premature labor, and even death to a fetus (Fisher et al. 2006). Thus, opioid withdrawal is to be avoided during pregnancy. Methadone maintenance is currently the treatment of choice since it will prevent withdrawal, reduce or eliminate illicit opioid use, and has a good safety record in pregnancy. The clinician should seek the lowest dose that will keep the patient comfortable, as this reduces the risk of withdrawal for the fetus or neonate. As the pregnancy advances, this dose may need to be adjusted because of the increased fluid volume and metabolic rate (Finnegan and Kaltenbach 1992). The safety of buprenorphine in pregnancy is not yet fully established, although a large multisite trial is currently underway.

At birth, the newborn will be physiologically dependent on opioids and will require close monitoring in a neonatal intensive care unit preferably. The neonate, contrary to the mother, lacks a fully functional enzyme system to metabolize opiates, delaying thus the onset of withdrawal, and often attenuating its severity. With methadone, 45–68% of neonates need treatment for neonatal abstinence syndrome, the presentation of which ranges from failure to thrive to hyperreflexia, tremor, diarrhea, and dehydration (Senay 1999). Treatment with oral phenobarbital or morphine is usually effective (Ebner et al. 2007). If it is medically necessary to withdraw a mother from methadone because of the emergence of a severe comorbid medical condition (such as cardiovascular or pulmonary illness), withdrawal should be performed gradually to avoid worsening of the physiological stress due to the illness. Preferably, withdrawal should occur during the second trimester. During the first trimester, fetal organ development may be affected, while the risk of premature labor and other adverse fetal outcomes is excessive during the third trimester (Kleber 1999).

Methadone is an effective treatment, especially for the patient using illegal opiates like heroin with a strong psychological dependence, a situation where the cross tolerance...
with heroin provides a stabilizing effect. In the era of HIV, the public health benefits are undeniable. Given this impact, methadone will continue to remain in the armamentarium available to the clinician for the foreseeable future.

**Buprenorphine**

A major advance in the treatment of opiate dependence was the 2002 approval by the FDA of buprenorphine for office-based treatment of illegal and medical opiate dependence. From a doctor who is qualified to prescribe buprenorphine, patients can receive treatment in total confidentiality in a range of clinic or office-based settings. The need is large: according to latest estimates, there are between 810,000 to 1 million chronic users of heroin, and only 200,000 patients receiving methadone maintenance treatment (McCance-Katz 2004). With buprenorphine, the goal is to expand the availability of opiate dependence treatment to primary care settings, beyond the capability of the methadone clinic system. There, one hopes, the clear benefits rendered by methadone programs can be expanded, while the strong stigmatization larded onto opiate-dependent patients can be avoided.

To dispense buprenorphine for treatment of opiate dependence, physicians who already hold a DEA license to prescribe controlled substances must meet certain requirements as specified in the Drug Abuse Treatment Act of 2000 (see Table 111–7), mainly completion of a brief training course. Courses are offered online or by seminars sponsored by professional organizations such as American Academy of Addiction Psychiatry (AAAP) and American Society of Addiction Medicine (ASAM). Physicians who are Board Certified in Addiction Psychiatry or have passed the ASAM certifying examination automatically qualify. Afterward, the physician submits a notification request to the Center for Substance Abuse Treatment of the Substance Abuse and Mental Health Services Administration (CSAT/SAMHSA). After verification with the DEA for an established number, a unique DEA number solely for the purpose of prescribing buprenorphine will be assigned. The physician may opt to be listed on a physician locator on the Substance Abuse and Mental Health Administration SAMHSA’s Web site as a provider of buprenorphine treatment.

As previously described in the section on detoxification above, Buprenorphine is a high affinity partial agonist at the μ-opiate receptor, binding the receptor but only partially activating it, while blocking access to the receptor by other opioids. Advantages include greater safety, including, importantly, low risk of respiratory depression, and lower abuse liability due to the ceiling on agonist effects, and muted withdrawal effects due to slow dissociation from the receptor. When compared to ascending oral doses of methadone, SL buprenorphine displayed a ceiling—that is, did not produce any further effect beyond a certain dose— for inducing respiratory depression (Walsh et al. 1994). Buprenorphine is available as 2 mg and 8 mg tablets for sublingual administration, as either buprenorphine alone or buprenorphine–naloxone combinations. Buprenorphine has been available for a number of years by injection for analgesic purposes, but this parenteral formulation has been diverted and abused (Auriacombe et al. 2004). To counteract any potential for parenteral abuse, a 4:1 combination of buprenorphine–naloxone (2/0.5 and 8/2.0 mg tablets) for sublingual administration has also been produced. As naloxone is a poorly absorbed SL, when buprenorphine–naloxone is placed under the tongue, the predominant effect emanates from buprenorphine, an effect that can last as long as 96 hours (Walsh et al. 1994); if an opioid-dependent individual attempts to dissolve the buprenorphine–naloxone combination for illicit injection purposes, naloxone will cause precipitated withdrawal, which is a strong deterrent, as well as blocking most of the effect of buprenorphine, thus diminishing its reinforcing effect (Stoller et al. 2001, Comer and Collins 2002).

The previous section on buprenorphine for detoxification, provides a brief overview of methods for inducting patients onto buprenorphine, and a more detailed coverage is provided below. Readers may wish to read recent reviews on establishing a buprenorphine practice where many details beyond the scope of this chapter can be gleaned (McCance-Katz 2004, Boothby and Doering 2007).

**Induction Procedure for Buprenorphine**

The goal of induction is to establish the dose of buprenorphine that will eliminate all withdrawal symptoms, decrease or abolish the use of other opiates, minimize cravings, with few side effects. Buprenorphine can be used for opiate dependence due to prescription as well as from illicit opiates. Dependence on prescription opiates like Oxycodone is growing problem in the United States, especially among recreational and street drug users (Cicero et al. 2005).

Like all of medicine, selecting the patients most suited for this treatment is key. The Center for Substance Abuse Treatment (2004) has published guidelines to help clinicians in this regard (see Table 111–8).

Induction onto buprenorphine first requires a medical and psychiatric evaluation. Many psychiatrists will want to establish a relationship with a medical clinic to obtain a report from a recent medical examination that includes blood chemistry with LFTs and hematology results. A room dedicated to induction, with vital sign monitoring equipment and comfortable chairs, is also useful. Buprenorphine has been known to increase LFTs, especially in individuals

Previously infected with the hepatitis virus (Petrey et al. 2000), although short of sensitivity to buprenorphine itself, there are no absolute medical contraindications to buprenorphine treatment. However, the individual seeking treatment must meet criteria for opioid dependence, as evidence by the history of increasing use, tachyphylaxis requiring ever increasing dosages, and evidence of withdrawal, or of intravenous injections such as drug marks, or else, evidence of past opioid dependence in the face of imminent risk of relapse. Documentation and evaluation of withdrawal is paramount for verifying dependence, as well as for proper induction.

Prior to receiving the first sublingual dose of either buprenorphine or buprenorphine/naloxone, individual seeking treatment must display signs of mild to moderate withdrawal. This is important because in the absence of withdrawal signs, the partial agonist action of buprenorphine will precipitate withdrawal, causing profound discomfort to the patient. An objective scale like the Objective Opioid Withdrawal Scale (OOWS) can assist the physician in estimating the extent of withdrawal (Handlesman et al. 1987), or the Clinical Opiate Withdrawal Scale (Wesson and Ling 2003). Using these scales, a minimal score of 3 on the OOWS, or 13 on the COWS is required to proceed with the induction. This can be usually achieved by instructing the patient to abstain from all opioids from around 9 pm on the evening prior to the induction until the scheduled time to present at the office, optimally in the morning, best if not on a Friday. If at the scheduled time, the minimal withdrawal scores are not obtained, the patient should wait or return home until the next day, with the admonition to avoid taking any opioids, which would only delay the induction further.

Day 1 of Buprenorphine Induction

Either buprenorphine alone or the combination of buprenorphine/naloxone can be used for short-acting opioids. A first dose of 20/0.5 mg or 4/1 mg of buprenorphine/naloxone can be used. It is important to tell the patient to keep the tablet under the tongue until the tablet is completely dissolved, and only then swallow. The patient should then be monitored for the next 2 hours, during which some relief from withdrawal is experienced, usually within 30–45 minutes. If so, another dose similar to the first dose can be given, up to 8 mg for the first day, although clinicians can prescribe up to 16 mg if clinically indicated. If, however, the patient reports worsening of withdrawal symptoms shortly after receiving buprenorphine, this suggests a precipitated withdrawal. In this case, the clinician may consider giving another dose of buprenorphine to favor the agonist effect and relieve withdrawal, or else may opt to delay continuing the induction until the next day, or treat specific withdrawal symptoms, as outlined in Table 111–9.

This eventuality can be avoided by ensuring that objective withdrawal signs and symptoms are documented prior to induction. For patients dependent on long-acting opiates like methadone, the induction process may be more arduous. According to the Clinical Guidelines for the Use of Buprenorphine in the Treatment of Opioids Dependence, patients on methadone should decrease their dosage to 30 mg a day or less a week before buprenorphine induction is scheduled (McNicholas 2004). At least 24 hours should precede the beginning of the induction process, allowing for withdrawal signs and symptoms to emerge and be tabulated with the OOWS or the COWS. In this instance, buprenorphine alone is preferred, starting at 2 mg, adding 2 mg every 1–2 hours, usually not exceeding 8–16 mg in the first day.

For patients with past history of opiate dependence who are now abstinent but seeking relapse-prevention treatment, withdrawal symptoms are usually not present. They should be given 20/0.5 mg dose, with a very gradual, slower rate of dosage increase aimed at decreasing cravings and psychological dependence.

Before departing at the end of the first day, patients should be advised that they may experience some withdrawal, for which some of the medications mentioned above may be used.

Day 2 of Buprenorphine Induction

When patients return, clinicians should inquire about withdrawal problems since leaving the office, and about any use of opiates, preferably verified by urine toxicology. If withdrawal signs are noted, the buprenorphine dose should be increased to reach 12–16 mg per day, in 2–4 mg increments. Sedation would suggest excessive dosing, for which the dose should be lowered. Should the patient continue to present with withdrawal symptoms or cravings, the dose may be increased further on a third day of induction. The maximal approved daily dose is 32 mg, in divided doses.

Once the patient has reached a stable and optimal dose, it may be continued as a daily dose, or taken only twice or

thrice weekly. Evaluation of different dosing frequencies did not reveal differences in treatment retention, opiate abstinence, or reduction in HIV risk between these dosing frequencies. The dose is thus adjusted to reflect the number of days when buprenorphine is not taken. For example, if taken three times a week, the dosage on Monday would be double the daily dose to account for Tuesday, similarly on Wednesday, and on Friday, the dose is tripled to account for Friday, Saturday, and Sunday (Marsch et al. 2005).

**Buprenorphine Maintenance**

Buprenorphine treatment is currently best conceived as a maintenance treatment. Several reports from clinical trials have confirmed the efficacy of buprenorphine for the treatment of opiate dependence (Strain et al. 1996, Johnson et al. 2000b, Fudala et al. 2003). Johnson and colleagues compared high methadone (60–100 mg) and low methadone (20 mg) doses to 8 mg of buprenorphine as maintenance treatment. After 18 weeks, treatment retention for patients on low methadone and buprenorphine was similar, and only bested by high methadone treatment, suggesting that for some patients with severe opiate dependence, high dose methadone treatment may prove more effective (Johnson et al. 2000b).

Given the unique pharmacological properties of buprenorphine could its use alter the chronicity of opiate dependence, and serve as a transition to abstinence? A study by Kakko et al. (2003) looked at the 1-year treatment retention and abstinence between two groups: one maintained on 16 mg of SL buprenorphine and another who underwent a 6-day detoxification with buprenorphine, followed by placebo capsules. The results differed dramatically between the groups: at the end of 1 year, no one from the detoxification group remained in treatment, and all had left treatment after a return to opiate use. Seventy-five percent of patient in buprenorphine maintenance remained at 1 year, and 75% of all urine samples were negative for any drug. Even though both arms of the trial were provided with an intense psychosocial treatment, the dismal outcome of those receiving placebo highlights the persistent and grave nature of opiate dependence. Moreover, there was a 20% mortality rate in the detox/placebo group as opposed to 0% in the buprenorphine group. Published mortality rate during methadone or buprenorphine treatment is about 1% (Soyka et al. 2006). Hence, it appears that maintenance treatment with buprenorphine leads to better outcomes. If abstinence can be achieved, it seems that it should occur after a longer period of time on maintenance treatment, long enough to shore up psychosocial skills damaged by drug use. How this transition should be made with buprenorphine remains to be fully worked out presently.

Buprenorphine is also having a social impact; by bringing the treatment of opiate dependence into ordinary medical practice, it reduces and shields the patient from the stigmatization that methadone treatment centers often draw. Its dual indication for analgesia as well as for opiate dependence makes buprenorphine an attractive choice for those with a chronic pain syndrome who are seeking an agent with a favorable side effect profile.

**Anesthesia-Assisted Heroin Detoxification**

This highly publicized method of detoxification promises a fast and painless way to withdraw from opiates. In light of the high cost of these procedures (up to $15,000) and the lack of insurance coverage, it was important to investigate whether this procedure offered a distinct advantage over more traditional methods. Only recently has the practice of anesthesia-assisted opiate detoxification been systematically evaluated. Collins et al. (2005) compared anesthesia-assisted opioid detoxification to buprenorphine-assisted and clonidine-assisted opioid detoxification, each followed by transition to naltrexone antagonist treatment lasting 12 weeks (see below). Thirty-five patients were assigned to receive anesthesia, 37 to receive buprenorphine, and 34 to receive clonidine. All patients met criteria for opiate dependence for at least 6 months and were seeking treatment. Treatment outcomes were opioid withdrawal scores (measured by the Subjective and Objective Opiate Withdrawal Scales; Handleman et al. 1987), induction onto naltrexone treatment, and treatment retention. For those assigned to anesthesia-induced detoxification, withdrawal scores peaked before detoxification; after the procedure, withdrawal scores did not differ significantly from the other two detoxification methods. Ninety-four percent of those receiving anesthesia and 97% with buprenorphine received at least one 50 mg dose of naltrexone, in contrast to 21% with clonidine detoxification. Beginning naltrexone treatment lowered the risk of dropping out during the outpatient treatment phase. Overall, retention in treatment during the outpatient phase was similar for all treatments, nonetheless, 20% of anesthesia and 24% of buprenorphine assigned patients completed all 12 weeks of outpatient treatment, compared with 9% in the clonidine group. No group differences were found in urine toxicology for opiates or any drug. Another study by Favrat et al. (2006) compared clonidine- to anesthesia-assisted detoxification. Better opiate abstinence rates at 3 months were seen with anesthesia, but that difference disappeared at 6 months.

As previously mentioned, withdrawal from opiates can be painful and protracted, but rarely dangerous. This fact makes the report of two severe adverse events for the anesthesia group in the study by Collins et al. (2005) especially noteworthy. One patient developed pulmonary edema and aspiration pneumonia 14 hours after extubation, necessitating intensive care unit monitoring and treatment. With reevaluation of the medical history, prior episodes of complicated pneumonias were found. Another patient with diabetes mellitus and a prior episode of diabetic ketoacidosis developed ketoacidosis within 48 hours of anesthesia detoxification. The possibility of detoxication without pain has made anesthesia-assisted detoxication alluring to patients. However, the findings of Collins and colleagues suggest that anesthesia provides no added benefit over cheaper, safer buprenorphine-assisted detoxication as a bridge to naltrexone treatment. Unless the clinician faces exceptional circumstances, this appealing form of treatment cannot be recommended.

**Opiate Antagonist Treatment: Naltrexone**

Naltrexone is an antagonist at the μ-opioid receptor, and blocks the action of endogenous and exogenous opiates at this receptor. This effect on endogenous opiates is thought to account for naltrexone’s effect to reduce drinking (see section on alcohol dependence). In the context of opiate dependence, its action on exogenous opiates prevents...
readdiction to opiates, and allows patients to continue treat-
ment despite lapses or relapses without having to undergo
repeated detoxification. While on naltrexone, all objective
and subjective effects are blocked, rendering heroin no longer
rewarding. In this context, at least when studied in a human
laboratory, heroin-addicted individuals taking naltrexone
gradually diminish and stop their use of heroin (Mello et
al. 1981). When ingestled by someone without opiate depen-
dence, naltrexone produces few or no side effects. In recently
detoxified individuals, complaints of worsening abdominal
pain, nausea, diarrhea are frequent as withdrawal symp-
toms are worsened by the introduction of naltrexone. Aside
from instances in which patients already have elevated liver
enzymes or liver failure and who should not receive naltrex-
one, a review of several studies has failed to demonstrate
that naltrexone causes elevation of liver enzymes (O’Brien
and Cornish 1999).

Contrary to methadone or buprenorphine, no depend-
ence develops with naltrexone: it provides no reward, and
does not cause withdrawal. To not feel any effect may be a
disadvantage to someone who is used to feeling some drug
effect. Overconfidence in having overcome one’s depend-
ence is one pitfall that hurls many individuals with opiate
addiction and leads to relapse.

For those who must approach the treatment of opi-
ate dependence without resorting to some form of substi-
tute opiate (like methadone or buprenorphine), naltrexone
represents a very good option. Physicians, other health care
professionals, individuals in critical administrative, techni-
cal, and social occupations would be particularly well served
by this treatment approach. Judiciously, O’Brien and Corn-
ish (1999) wrote: “For someone recovering from addiction
who works in a field such as nursing, pharmacy or medi-
cine, there is an added benefit to naltrexone maintenance:
it reduces the concern about relapse felt by colleagues who
are aware of the person’s history.” In this way, professionals
in health services and other fields can find solace against the
stigmatization that comes with addiction; especially if there
is a policy of witnessed naltrexone intake.

For those addicted to heroin, the results of naltrexone
treatment are mixed. In most trials, the drop out rates are
high, as high as 70%, with a further surge associated with
methadone use and a high number of heroin bags per day
used (Tucker et al. 2004, Sullivan et al. 2006). Other con-
cerns also arise. One is related to whether naltrexone might
lead to greater incidence of depression in opiate dependent,
although rates of depression are high among heroin users.

Research to date does not support a link between naltrexone
and accrued depression (Ritter 2002). Another is a higher
rate of overdose during naltrexone treatment due to reduced
tolerance. Existing data suggest that the mortality rate during
methadone use and a high number of heroin bags per day
used (Tucker et al. 2004, Sullivan et al. 2006). Other con-
cerns also arise. One is related to whether naltrexone might

ent, although rates of depression are high among heroin users.

methadone or buprenorphine treatment (Ritter 2002). Time
in treatment is the most important factor leading to naltrex-
one’s effectiveness, as with time in abstinence, patients feel
gradually more secure against their impulse to seek heroin to
overcome physical and psychological adversity (Johansson et
al. 2006). For all these reasons, naltrexone is only effective if
integrated in a structured rehabilitation program.

Naltrexone treatment begins with detoxification as out-
lined above. There are no preferred methods beyond what
is dictated by the opiate being abused, and time available.
However, buprenorphine has been reported to be a useful
bridge between an agonist like heroin and an antagonist like
naltrexone (Collins et al. 2005, Nunes et al. 2006). Ideally,
one should allow as much time as possible between the end
of the detoxification and starting naltrexone to avoid pre-
cipitating withdrawal. Medications like clonidine can ease
residual withdrawal symptoms and remove a strong incen-
tive to resume heroin use. When to begin naltrexone after
detoxification is a question of clinical judgment, as the cli-

As already mentioned, the psychotherapeutic struc-
ture surrounding naltrexone treatment is of paramount
importance, and there have been efforts to define which
type of intervention work is the best. Two strategies have
yielded encouraging results: contingency management and

rate was far below the 50% rate usually seen in methadone or buprenorphine treatment (Johnson et al. 2000b, Mattick et al. 2004), without the added risk of lethality due to decreased opiate tolerance (Ritter 2002).

Although in theory, naltrexone, like buprenorphine, could be dispensed in primary care settings, in practice, naltrexone therapy for opiate dependence requires a level of ancillary care that would necessitate specialty level training in most instances. Another difficulty arises from noncompliance with naltrexone, in that if the patient relapses while not taking naltrexone, dependence rapidly returns, and resumption of naltrexone intake can be complicated. This may be addressed by long-acting naltrexone (see in alcohol dependence section) or by naltrexone implants that would allow for constant medication levels with less of an emphasis on compliance. This new approach notwithstanding, for the moment, treating opiate dependence with naltrexone will likely be carried out in specialty settings for selected patients.

**Treatment of Co-Occurring Depression and Opioid Dependence**

Major depression is common among opioid dependence and has been associated with poor outcome. Several studies suggest that tricyclic antidepressants are effective for treatment of depression in opioid-dependent patients who are on methadone maintenance, and that such treatment is associated with improvement in drug use (Woody et al. 1975, Nunes et al. 1998). However, other trials, particularly trials of serotonin reuptake inhibitors, have been negative (for a review, see Nunes and Levin 2004). A reasonable recommendation would be that major depression should be identified and treated among opioid-dependent patients, once the opioid dependence has been stabilized with methadone, buprenorphine, or naltrexone. It is important to take a careful history in an effort to identify a clear-cut major depressive syndrome, as opposed to depressive symptoms that may reflect toxic effects of drugs.

**Summary**

The recent approval of buprenorphine for the treatment of opiate dependence has brought forth an excellent medication that can be used in a primary care setting. It can be used for detoxification, to help transition to naltrexone treatment, or can be used as a maintenance tool if abstinence-based treatment is not successful. Clonidine or Lofexidine are good ancillary medications to help control withdrawal symptoms, although their popularity as tools for detoxification is waning. Methadone continues to be a well-used medication for both detoxification and maintenance treatment, although the regulations surrounding its use do not make it amenable to primary care. Anesthesia-based detoxification does not appear to provide any added benefit when compared to detoxification with buprenorphine, and involves a significant risk of medical complications and adverse events.

Naltrexone remains an excellent option for those patients who must receive an abstinence-based treatment.

**Nicotine Dependence**

Ever since European colonizers discovered tobacco in the new world, written reports have crossed the centuries to attest to its addictive properties. Bishop Barthalamus de las Casas wrote in his memoirs dated from 1532, at the inception of tobacco cultivation in Hispanola (now the Dominican Republic) by Spanish colonists: “The fashion of smoking is widespread among colonists and when they are asked why they do it, their only answer is they cannot do without it anymore” (Brongers 1964). But it is only recently that tobacco has been linked to life-threatening disease; in the USA, approximately 430,000 die each year of illnesses related to tobacco smoking (Giovino 2002). For both primary care and addiction medicine objective, helping patients quit smoking deserves the most dogged persistence from clinicians, something Mark Twain knew very well: “To quit smoking is one of the easiest things in the world, I must have done it over a dozen times.” While many individuals succeed in quitting on their own, others find it a most difficult and vexing task, and may turn to clinicians for guidance and assistance. This section will discuss briefly nicotine’s effects in the brain, and will describe FDA-approved medications to treat nicotine dependence.

**Features of Nicotine Dependence**

Nicotine can induce all the features of a psychoactive substance, in that it induces repeated use (usually daily smoking of cigarettes for 98% of smokers), tachyphylaxis of effects causing to smoke more and more often, tolerance to the aversive effects of nicotine such as nausea, and clear symptoms of withdrawal upon cessation of smoking (dysphoria, anxiety, irritability, and cravings for tobacco). Smoking is the preferred method of consuming tobacco, likely because inhaled nicotine reaches the brain within 15 seconds, and because it allows the smoker to exactly titrate the nicotine dose to achieve the desired effect (Malaiyandi et al. 2005). Rapidly repeated inhalations tend to deliver a stimulating effect, while slower inhalation favors a calming, soothing effect. Although nicotine is emphasized as the main psychoactive substance in tobacco, there are over 4,000 substances in unadulterated tobacco (George and O’Malley 2004). Some are known to inhibit brain monoamine oxidases and perhaps add to the reinforcing properties of tobacco (Fowler et al. 2003). Most of the approved treatments for nicotine dependence resort to nicotine replacement therapy as the main pharmacological intervention. Bupropion and varenicline therapy for nicotine dependence will be discussed separately.

**Nicotine Replacement Therapy**

All forms of nicotine replacement therapy (NRT) have demonstrated good efficacy in clinical trials of smokers seeking to quit smoked tobacco over placebo. These are summarized in Table 111–10 (George and O’Malley 2004, Silagy et al. 2004).

All forms of NRT deliver good efficacy to support efforts at quitting smoking. Approximately 2 weeks after starting NRT, the patient should be encouraged to set a quit date. In preparation for this date, patients are instructed to rid themselves and their home and office of all cigarettes and smoking paraphernalia. Quit date notwithstanding, all patients should be instructed to reduce their smoking when starting NRT. Heavy smokers tend to prefer a high NRT beginning dose. From there, patients are encouraged to gradually decrease their NRT dose over a period of weeks to months. Side effects are usually few, but common ones include nausea (especially if smoking is continued while on
NRT) and gastric irritation from increased stomach acidity. Caution is warranted in patients with histories of gastric or duodenal ulcers, gastritis or reflux; as well as patients with cardiovascular disease.

The NRTs that deliver constant nicotine like the patch provide a more uniform effect most suited to those who experience predominantly nicotine withdrawal symptoms (agitation, nervousness, restlessness, insomnia). On the other hand, rapidly acting NRTs provide a comprehensive contextual (reproducing the ritual of smoking with the inhaler for example) and physiological relief of craving for nicotine. This is in part related to the fast rate of desensitization of nicotinic receptors after exposure to nicotine, and rapid resensitization after nicotine is catabolized. An overnight resensitization after exposure to nicotine, and rapid resensitization after nicotine is catabolized. An overnight observation that the first cigarette of the day is the most satisfying. The issue of contextual use is fertile ground for supportive therapy aimed at preventing continued smoking in tobacco-prone circumstances and settings.

On the issue of supportive therapy, a meta-analysis looking at the effectiveness of NRT (Silagy et al. 2004) found that it was beneficial in facilitating the likelihood of quitting, but that it was not essential to the success or NRT. This makes NRT a particularly useful method to help patients quit smoking in primary care settings.

Antidepressant Medications: Nortriptyline and Sustained Release Bupropion

Two antidepressant medications have demonstrated effects on smoking independent of their effects on depression: nortriptyline and sustained release bupropion. To date, six clinical trials (see Hughes et al. [2005] for review) have shown that doses of 75–100 mg of nortriptyline doubled the quit rate (OR = 2.1), but that between 4 and 12% of participants interrupted treatment because of side effects such as dry mouth and constipation. This high rate of side effects occurrence has placed nortriptyline on a second-tier level compared to sustained release bupropion or NRT.

In 1997, the FDA approved sustained release bupropion for nicotine dependence. This derived from a serendipitous observation that there was an antismoking effect among US veterans receiving bupropion to treat depression, regardless of an antidepressant response. Its efficacy in inhibiting smoking was demonstrated in a pivotal clinical trial against placebo, during which the 150 and 300 mg doses demonstrated better efficacy than placebo, with better smoking cessation rates achieved with the highest dose (44.2% for 300 mg; 38.6% for 150 mg; 19.9% for placebo) (Hurt et al. 1997). The mechanism by which it exerts this effect is linked to its blockade of dopamine and norepinephrine reuptake, and to some antagonism of nicotinic acetylcholine receptor (Ascher et al. 1995, Slemmer et al. 2000). The simplicity of its use and the good tolerability have made bupropion a first line agent against nicotine dependence.

Treatment with bupropion does not require that patients quit smoking at the inception of treatment. Rather, clinicians are advised to set a quit date approximately 1 week after bupropion is begun, although many smokers prefer to gradually reduce their smoking as their cravings decrease. While there continues to be a contraindication to the use of bupropion patients have a preexisting history of seizures, the rate of new onset seizures with bupropion is about 0.3%, and is mostly associated with the use of the immediate release formulation at a dose exceeding 450 mg. The most common side effects reported are headaches, agitation, and insomnia. An emerging consensus supports the use of bupropion for at least 6 months after smoking cessation (Steinberg et al. 2006), and success at 6 months appears related to increased age, continued use of medication, longer time to the first morning cigarette. Certain variants of the catechol-o-methyltransferase gene (COMT) may also predict a positive smoking cessation outcome with bupropion (Berrettini et al. 2007). However, as the results of the double-blind trial suggest (Hurt et al. 1997), a good number of smokers do not quite smoking with bupropion. As in treatment of other forms of addiction, failure of an initial quit attempt should prompt adjustment of the treatment regimen followed by renewed quit attempts. The more quit attempts a patient makes, the more likely he/she is to ultimately succeed in achieving sustained abstinence from nicotine. Nonetheless, results with bupropion prompted the investigation of combined medications, either combined NRTs or NRT with bupropion.

Combined Treatments for Smoking Cessation

On the assumption that combining slow- and fast-acting NRTs might provide more comprehensive effects in inducing smoking cessation, Bohadana et al. (2000) found combined transdermal nicotine with a nicotine inhaler superior to transdermal nicotine with a placebo inhaler. Sustained release bupropion combined with transdermal nicotine had a better effect than placebo with transdermal nicotine (Jorenby et al. 1999). A similar effect was also demonstrated with the nicotine inhaler and bupropion (Croghan et al. 2007). It appears that combining medications with different mechanisms of action is a worthwhile strategy should the single agent alone not deliver the expected results.
Varenicline

The newest FDA-approved medication for nicotine dependence is the nicotine receptor antagonist varenicline. Nicotine receptors come in complex pentameric arrangements of alpha (2–10) and beta (2–4) subunits with extensive brain distribution, and the one targeted by varenicline is the alpha-4/beta-2 subtype. Animal studies indicate that beta-2 receptor subtypes are involved in nicotine reinforcement, but not in withdrawal (Bessen et al. 2006). A major reason why varenicline can deliver a therapeutic effect is due to the fact that it is a partial agonist. This means that while varenicline binds potently to the alpha-4/beta-2 nicotinic receptor, it stimulates less receptor-mediated activity than nicotine itself. This is important because of the rapid desensitization characteristic of nicotinic cholinergic receptors. It also binds the receptor with greater affinity than nicotine, so that it blocks the effects of nicotine, if, for example, a patient smokes while on the medication. The end result of these pharmacological properties is the blockage of nicotine-induced dopamine release in the meso-limbic system, where neuronal systems related to reinforcement are located. This blockade is the proposed mechanism for the effect of varenicline in tobacco smokers.

In industry-sponsored trials, abstinence from tobacco is evaluated by measuring carbon monoxide in the exhaled breath of participants. High CO reflects recent tobacco use. During the clinical trials reviewed by the FDA, continuous abstinence rates were greater with varenicline than with placebo, and comparatively better than abstinence rates with bupropion in the last 3 weeks of 12-week trials (Gonzales et al. 2006, Jorenby et al. 2006, Tonstad et al. 2006). The differences in abstinence rates were all statistically significant. Of particular clinical interest were the poststudy evaluations of abstinence rates, up to 40 weeks after conclusion of the acute phase. In these instances varenicline was better than placebo, but not statistically superior to bupropion. Nonetheless, varenicline represents a significant advance in the treatment of nicotine dependence.

When starting varenicline treatment, the manufacturer recommends that a quit date be set, and to begin varenicline a week before the set date. It is recommended to take varenicline with food to reduce the incidence of nausea, the most common side effect. The recommended titration is 0.5 mg per day with food for the first 3 days, then 0.5 mg twice a day for the next 4 days, followed by 1 mg twice a day. The treatment is then continued for a first period of 12 weeks. If the patient achieves abstinence, clinicians may consider continuing treatment for an additional 12 weeks to encourage long-term abstinence.

Besides nausea, insomnia, headaches, and gastric disturbances are the other commonly encountered side effects. Although the necessity of supportive therapy during varenicline treatment is not as of yet fully ascertained, good clinical care would suggest that its provision would favor a positive outcome.

Co-Occurring Psychiatric Disorders and Nicotine Dependence

Major depression is common among cigarette smokers and predicts failure to successfully quit. Furthermore, smoking cessation has been associated with worsening of depression (Covey et al. 1997), suggesting that nicotine might actually exert antidepressant effects for some patients. As noted above, noradrenergic antidepressants, including bupropion and nortriptyline, are effective for treatment of smoking cessation, regardless of whether the patients suffer from major depression at the time of treatment. Some evidence suggests that nortriptyline works by reducing dysphoria that follows a quit attempt. One limitation of this literature is that smokers with current major depression have generally been excluded from medication trials. Clinical experience would suggest that smokers who are being treated with medication for major depression can be encouraged to quit smoking and will sometimes succeed.

The majority of patients with schizophrenia smoke cigarettes and are nicotine dependent. Here nicotine, which can enhance cognitive performance, may function to self-medicate of cognitive deficits that are part of the schizophrenia syndrome, or it may relieve side effects of neuroleptics. Recent evidence suggests that an allele of the nicotine receptor may be associated with schizophrenia (Olincy et al. 2006) In any case, smoking is responsible for substantial health problems among schizophrenic patients. More research is needed on the treatment of smoking in schizophrenia, but a reasonable clinical recommendation would be to attempt to treat smoking in schizophrenia, while carefully monitoring the effects of abstinence from nicotine on mental status.

Future Directions

Tobacco dependence continues to be the object of intensive research efforts. Several lines of investigations deserve to be brought to the attention of the clinician: (1) the potential impact of manipulating the hepatic cytochrome system as a therapeutic tool; (2) research into treating the use of smokeless, oral tobacco.

Cytochrome CYP2A6 is the main enzyme that catalyzes nicotine into cotinine. There are 26 documented variants of the gene for CYP2A6, leading to some CYP2A6 allele combination that results in a greater or lower turnover rate of nicotine. A slow nicotine metabolizer may be more prone to experience the aversive effects of nicotine, such as nausea, dizziness, and malaise; as a result, inheriting such an allelic pair of genes may confer some protection against nicotine dependence. Messina et al. (1997) were the first to hypothesize that the metabolic rate set by the allelic pair of CYP2A6 gene variant might increase or decrease the risk of nicotine dependence. This has been substantiated in multiple cohorts of patients of different ethnicities, with the Japanese population displaying the highest frequency of low activity alleles (Malayandi et al. 2005). In Japanese cohorts, individuals possessing high activity CYP2A6 alleles smoked their first cigarette of the day earlier after awakening than individuals with low activity alleles. Moreover, nicotine withdrawal symptoms were more prominent in high activity CYP2A6 group (Kubota et al. 2006).

Based on these population genetic studies, the thought occurred that mimicking gene defects by pharmacological blockade of CYP2A6 could provide a treatment for nicotine dependence. Familiar to psychiatrists, the antidepressant tranylcypromine offers such an intriguing possibility, and some evidence exists to support this use (Sellers and Tyndale 2000). Other similar agents are in development.
Oral Smokeless Tobacco

Although great attention is focused on tobacco smoking, oral smokeless tobacco use is quite widespread, and is increasing in the USA especially among young male adults (NIH Consensus Statement 2006). There is some evidence that NRT may be effective for this type of tobacco use (Ebbert et al. 2007), although a recent trial with sustained release bupropion did not induce significant abstinence rates in smokeless tobacco users (Dale et al. 2007). More research attention needs to be directed at this important public health issue.

Stimulants: Cocaine and Amphetamines

With this section on stimulants, we will begin to discuss addiction disorders for which no FDA-approved treatment exists. The devastation brought upon by the crack epidemic of the 1980s gave great impetus to develop effective treatments for stimulant addiction. Unfortunately, despite many studies on many different compounds, pharmacological agents of sufficient effectiveness to warrant FDA approval for the treatment of cocaine dependence have not emerged. At the same time, behavioral therapies, including cognitive–behavioral relapse prevention and voucher incentives made contingent on abstinence, have been shown to be effective for treatment of cocaine dependence. Thus counseling and behavioral treatment should be considered the treatment of choice for cocaine dependence at this point.

We now briefly review medications that have shown some promise in clinical trials. These medications may be considered if counseling and behavioral treatments have failed. An overall pattern in the field of cocaine medication development is that after small, single site open or placebo-controlled trials look promising, large placebo-controlled trials fail to replicate the positive effects. This may represent placebo effects that bias the initial tests of new agents, or effect sizes that are quite small. The effect size may simply be small across the board, or a favorable effect could reside in a subgroup. Another formulation is that a given medication might impact only one phase of the recovery process, for example abstinence induction versus relapse prevention (Bisaga et al. 2006), suggesting that combinations of medications might be needed.

Antidepressant Medications

The tricyclic antidepressant desipramine was the first medication to show promise for treatment of cocaine dependence. An initial placebo-controlled trial showed that desipramine increased the likelihood that patients would initiate at least 3 consecutive weeks of abstinence, confirmed by a negative urine toxicology (Gawin et al. 1989). Two subsequent studies showed similar trends for desipramine (Weddington et al. 1991) and the related tricyclic antidepressant imipramine (Nunes et al. 1995). However, a number of other trials of desipramine failed to replicate any beneficial effects. One possible explanation is that desipramine may have been effective in more mildly ill, or more motivated patients who presented to treatment early in the cocaine epidemic; a conclusion supported by a subsequent clinical trial in which desipramine showed no advantage over placebo overall in terms of cocaine use outcome, but was superior among patients with less severe cocaine dependence at treatment entry (Carroll et al. 1994). Another trial showed some promise for desipramine among cocaine-dependent patients with major depression, although the findings were not definitive (McDowell et al. 2005). Other recent trials suggest that desipramine was ineffective for opioid-dependent cocaine users with a history of depression (Kosten et al. 2004), and that the behavioral treatment regimen of voucher incentives contingent on abstinence may be effective among cocaine abusing opioid addicts with a history of depression (Gonzalez et al. 2003). Interestingly, a recent trial has shown that another noradrenergic antidepressant, bupropion, may be effective for cocaine dependence when combined with a behavioral regimen of voucher incentives contingent on abstinence (Poling et al. 2006). Studies of SRI antidepressants for cocaine dependence have been negative (Schmitz et al. 2001). At the least, the findings suggest that independent major depression should be identified and treated among cocaine-dependent patients with either medication or behavioral therapy, and that more research is needed to pursue a potential synergy between antidepressant medications such as bupropion and behavioral treatment with voucher incentives.

Disulfiram

As alcohol and cocaine are frequently abused simultaneously, clinical trials with disulfiram (see section on alcohol dependence) were conducted with cocaine and alcohol-dependent patients (Carroll et al. 1993, McCance-Katz et al. 1993). Patients on disulfiram displayed better cocaine and alcohol outcomes, but it was not clear whether the effect on cocaine depended on a reduction in alcohol use. Another trial was conducted in strictly cocaine-dependent patients (Carroll et al. 2004), which showed that patients on disulfiram significantly reduced their use and displayed greater abstinence than those receiving placebo. The authors noted that greater benefits were accrued to patients on disulfiram who were not alcohol dependent when they began treatment, or abstained from drinking during the study, implying a direct effect of disulfiram on cocaine use. Disulfiram is an inhibitor of dopamine-β-hydroxylase, which catalyzes the conversion of dopamine into norepinephrine; inhibition of the enzyme leads to an increase in brain dopamine levels, which could counteract depletion of dopamine resulting from chronic cocaine use. It has also been hypothesized that disulfiram treatment may make cocaine use less pleasurable and more aversive. In summary, disulfiram may be considered for treatment of cocaine-dependent patients, with or without concurrent alcohol use. Guidelines for treatment of alcohol-dependent patients with disulfiram (see above section on alcohol dependence) should be consulted. Patients should be warned to remain abstinent from alcohol, because any alcohol intake will trigger an unpleasant disulfiram reaction.

Baclofen, Topiramate, and Other GABA Active Medications

In recent years, the GABA system has received increasing attention as a potential target for pharmacotherapy of cocaine dependence, especially since it has been observed that potentiating GABA neurotransmission decreases cocaine self-administration. For example, baclofen, a GABA-B receptor agonist (frequently used as a muscle relaxant) decreased cocaine seeking in baboons (Weerts et al. 2007), cocaine self-administration in humans (Haney et al. 2006), and cocaine use in a randomized, placebo-controlled trial (Shoptaw...
et al. 2003). Other GABA-B receptor modulators are also being investigated (Weerts et al. 2007, Lhuillier et al. 2007). Topiramate (Kampman et al. 2004) and tiagabine (Gonzalez et al. 2002) have shown some promise in small clinical trials. Gabapentin showed a nonsignificant trend toward prevention of relapse among patients who were abstinent from cocaine at the outset of the trial (Bisaga et al. 2006).

**Stimulant-Like Medications**

There has been considerable interest in the idea of treating cocaine dependence with other stimulant-like medications in what amounts to an agonist replacement approach. Medications that have shown some promise include d-amphetamine (Grabowski et al. 2004), bupropion (Poling et al. 2006), and modafinil (Dackis et al. 2005). Findings have been mixed and more research would be needed before these can be recommended as routine treatments. However, for patients who have been refractory to other forms of treatment and present with persistent cocaine abuse, medications in this class may be worth considering. With amphetamine, the risk of the abuse liability of the medication needs to be considered, and long-acting formulations should be considered. The effect of bupropion seems to depend upon combining it with behavioral therapy, specifically contingency management. With any of these medications, stimulant-like side effects of cocaine or abused stimulants and the medications may be additive and should be monitored.

**Treating Co-Occurring Psychiatric Disorders and Cocaine Dependence**

Depression is a common complaint seen in patients with cocaine dependence. Depression and cocaine dependence display similar neurochemical features in terms of monoamine and other transmitter systems (see Markou et al. [1998] for review). The difficulty for clinicians is to ascertain whether a patient presents with a depressed state arising from cocaine withdrawal or intoxication, or whether there is a preexisting or independent depressive disorder. Clinicians can inquire about previous periods of abstinence lasting at least 2–3 months. The persistence of depression during an extended period of abstinence, or prior to the onset of drug or alcohol problems, is more likely to represent an independent depressive disorder.

Treatment for depression in cocaine-dependent individuals can be approached as outlined in the previous section on antidepressant medications.

Attention deficit hyperactivity disorder (ADHD) is an increasingly recognized psychiatric disorder conveying an increased risk of substance use, especially stimulants. The link between ADHD and stimulants could represent an attempt to self-medicate ADHD symptoms, or could reflect impulsive behavior (Wilens et al. 1995). In either case, it is plausible to hypothesize that treatment of ADHD symptoms could lead to improvement in substance use. A recently published double-blind trial of sustained release methylphenidate (up to 60 mg/day) for cocaine-dependent individuals with ADHD revealed a small favorable effect of the medication on one of the several cocaine use outcome measures (Levin et al. 2007). Both these trials found sustained release methylphenidate relatively safe with little abuse potential. As with depression, symptoms of ADHD may be difficult to distinguish from toxic effects of chronic cocaine use. It seems fair to conclude that cocaine-dependent patients with clear-cut childhood onset ADHD should have their ADHD treated, although again the equivocal findings of the clinical trials suggest caution in terms of how much improvement in cocaine use symptoms may be expected.

**Methamphetamines and Other Stimulants**

Presently, as the use of methamphetamine is expanding across the USA, there are no known effective pharmacological methods to treat methamphetamine addiction. Animal studies are investigating specific antagonists to methamphetamines (Ginawi et al. 2005), manipulating the endocannabinoid system to prevent relapse to methamphetamines (Anggadiredja et al. 2004), or GABA(B) agonists like baclofen to decrease self-administration (Ranaldi and Poeggels 2002). Research in this area continues to be a high priority (Voci et al. 2005).

**Marijuana and Cannabinoids**

Like cocaine, cannabis found in the marijuana plant is mentioned in historical texts going back 6,000 years, although many of these records revolve around the cultivation of hemp for textile production. Smoking, eating of marijuana leaves, and use of hashish make cannabis the most widely used illegal drug worldwide, with nearly 150 million people using cannabis annually (UNODCCP 2002). However, the number of individuals seeking treatment for cannabis dependence has been low, although increasing in the past few years (SAMHSA 2003). This trend seems to be driven by several factors. (1) Marijuana is perceived as an innocuous drug in many circles, but with the increasing potency of the available cannabis, regular daily users may experience an abstinence syndrome if they decrease or stop smoking. This abstinence syndrome, which was only clearly identified in the past decade, is characterized by irritability, restlessness, insomnia, anorexia, even aggressive behavior, lasting up to several weeks after stopping cannabis, and of sufficient severity to force a return to daily smoking (Budney et al. 2003). The realization of an inability to control the use of cannabis often brings people to treatment. (2) Unlike heroin, alcohol, or cocaine, cannabis rarely brings individuals to the edge of destitution. However, some individuals realize that regular cannabis use dulls their attention and concentration, renders them inattentive to details, decreases their motivation, thus diminishing their professional acumen, or bothers their significant others. Events like being passed over for a promotion, increasingly negative performance evaluation, or repeated firings may drive home the deleterious effects of regular cannabis use. Some patients have referred to this as “their life reaching a plateau and going no further.” (3) Cannabis smoking, like tobacco smoking, can lead to pulmonary disease (Joy et al. 1999), and can precipitate psychosis in individuals with increased risk of psychosis by virtue of a family history of mental illness, or smoking cannabis before the age of 15 (Arnseneault et al. 2004). Hence there is an increasingly pressing need for effective treatment modalities for cannabis dependence.

Presently, there are no FDA-approved medications to treat cannabis dependence, although three leads appear promising.

Some addiction medicine physicians have been using synthetic Δ⁹ tetrahydrocannabinol (THC) found in the
medication dronabinol, currently approved and marketed for treatment of HIV-related wasting and chemotherapy-induced nausea, to help patients overcome the cannabis abstinence syndrome and dependence. This represents an agonist substitution strategy, similar to nicotine replacement products such as nicotine patch for cigarette smoking. Haney et al. (2004) have found that at a dose of 50 mg (10 mg, 5×/day) dronabinol reduced cannabis withdrawal symptoms, and restored psychomotor performance impaired by withdrawal. Clinical experience suggests that a model can be followed that is similar to that for nicotine replacement. Namely, the patient sets a quit date and uses dronabinol as a pharmacologically equivalent, but longer acting oral Δ^9 THC substitute to stabilize and minimize withdrawal symptoms, and to abolish any urge to use cannabis. Once this is achieved, dronabinol is gradually reduced and discontinued. With this procedure in mind, clinicians report using from 20 to 80 mg/day of dronabinol to stabilize patients, with a gradual decline in the daily dosage over a period of 8–12 weeks. In the hands of one of the authors (WNR), this approach has provided satisfactory results for both the physician and the patient. A formal clinical trial of this approach using up to 40 mg/day of dronabinol is being conducted by one of the authors (FRL).

Alpha-2 receptor agonists such as clonidine or lofexidine may be helpful to treat the cannabis abstinence syndrome. Cone et al. (1988) have shown that pretreatment with clonidine reduces the increase in heart rate caused by acute cannabis use. Conversely, abstinence syndromes, be they from alcohol, opiates, or cannabinoids all involve some degree of sympathetic activation (Sell et al. 2005). Clonidine or lofexidine could be useful medications to help patients traverse the cannabis abstinence syndrome phase if it proves problematic for them.

Lastly, the FDA is currently investigating the cannabinoid antagonist rimonabant as a possible antidiabetes medication. An indication for the treatment of cannabis dependence is not being sought presently. However, some human clinical investigations indicate that pretreatment with rimonabant attenuated the increased heart rate and the intoxicating effect of smoked marijuana (Huestis et al. 2007). More independent investigations are being conducted to further evaluate rimonabant as a potential therapeutic tool for cannabis dependence.

Summary
Like the pharmacology of psychiatric disorders in general, the pharmacological treatment of substance abuse disorders is rapidly advancing, driven by active research. A number of FDA-approved medications for addictive disorders are available, including methadone, buprenorphine, and naltrexone for opioid dependence, disulfiram, naltrexone and acamprosate for alcohol dependence, nicotine replacement (patch, gum, etc.), bupropion, and varenicline for smoking cessation. Other potentially promising medications are emerging, including disulfiram and baclofen for alcohol and cocaine dependence, tiagabine for cocaine dependence, topiramate for alcohol and cocaine dependence; for which of these, data are accumulating to support their use in addiction disorders. Clinicians can expect that in the coming years, more medications will be at their disposal to assist patients in overcoming addictions to legal and illegal drugs.

Introduction
Mood disorders including major depressive disorder (MDD), minor depressive disorder, dysthymic disorder, and seasonal affective disorder are common conditions in women. A number of studies find that women are twice as likely as men to develop these illnesses (Hasin et al. 2005, Kessler et al. 1997), with the highest risk occurring during their childbearing years (Kessler et al. 1993, Kessler 2003). Given these statistics, it is not surprising that many women who are pregnant will develop a depressive disorder. It is estimated that between 14% and 23% of pregnant women will suffer from significant depressive symptoms or a depressive disorder while pregnant (Bennett et al. 2004, Gaynes et al. 2005). Although some reports find that the highest absolute risk of depression is during the third trimester (Evans et al. 2001, Hobfoll et al. 1995) recent meta-analyses do not show differences in the relative risk according to stage of pregnancy. (Bennett et al. 2004, Gaynes et al. 2005).

Some suggest that the regular prenatal care received by most pregnant women affords an opportunity to screen and treat those who are depressed. Advantages are that for some women, the only time that they will have health insurance is when they are pregnant or immediately postpartum; for other women pregnancy may be the time a young women is most likely to see a medical provider. Since depression can occur anytime in pregnancy, the relatively frequent visits to an obstetrical provider constitute multiple opportunities to screen for depressive symptoms or follow the severity of the condition. Finally, women who are pregnant are more likely to adopt positive health habits, and they may consider treatments that decrease stress and promote mental health.

On the other hand, primary-care physicians and obstetrical providers may be reluctant to identify a unipolar mood disorder during pregnancy because they may have difficulty linking the patient with mental health service and may not be comfortable treating MDD on their own. If an obstetrical provider does wish to initiate treatment, antidepressant medication is easiest to administrate in an obstetrical setting, but such treatment necessitates exposing the fetus to medication. In such instances consultation and collaboration with psychiatric providers is optimal, since together they can offer patients a treatment plan and information about the relative risks of various treatments as well as the lack of treatment. In this chapter, we review information on the risks to a fetus that is exposed to maternal depression and we provide an overview on the risks and benefits of treating depression during pregnancy, which may be helpful to providers with pregnant patients.

Some maintain that the safest strategy to protect a fetus is for the depressed mother to avoid medication. However, depression can be a devastating illness, and for some women, it is not possible to stay healthy while medication free. Moreover, there may be risks to the fetus associated with the underlying illness or associated behaviors. As an example, compared to pregnant patients who are not depressed, those with a mood disorder are more likely to smoke, use hazardous substances (alcohol or illicit drugs), have concurrent general medical and other psychiatric conditions, and are less likely to have adequate prenatal care (Kitamura et al. 1993, Misra et al. 2001, Pritchard 1994). The underlying biology of the depressive illness may also contribute to perinatal risk. Stress has been associated with adverse birth outcomes including low birth weight (LBW) and preterm deliveries (Hobel et al. 1998), and depression is a stressful illness. There is also information suggesting associations between depression and specific perinatal events including miscarriage, delivering early, delivering an LBW infant, structural anomalies, and perinatal adaptation. These topics are reviewed below.

Stress, Mood, and Adverse Birth Outcomes
Spontaneous Abortion
Preclinical data suggest that high levels of stress may lead to spontaneous abortion (Nepomnaschy et al. 2006). Establishing an association between stress and miscarriage in
humans has been more difficult possibly because the majority of miscarriages occur prior to the fifth week after the last menstrual period, but studies have focused on miscarriage after 6 weeks of pregnancy. Some studies support the animal literature and suggest, specifically, that psychological stress contributes to rates of early pregnancy loss that are not attributable to malformations (Schenker et al. 1997, Neugebauer et al. 1996), but not all studies agree (Klebanoff et al. 1990). Interestingly, one study found that urinary cortisol levels were elevated in women who went on to miscarry, compared to women who did not experience early miscarriage (Nepomnaschy et al. 2006).

There have been fewer investigations into a possible association between a depressive disorder and miscarriage. Among women with recurrent spontaneous abortion, depressive symptoms conferred a higher risk of subsequent miscarriage, although the group of women who conceived \( (n = 41) \) was small. A cohort study \( (n = 972) \) of women identified as pregnant in an emergency room setting did not find differences in risk of spontaneous abortion according to level of depressive symptoms (Nelson et al. 2003).

### Preterm Delivery and LBW

Using the Beck Depression Inventory (BDI) \( (\text{range} 0–63) \) administered at 28 gestational weeks to determine depressive symptoms, researchers found that scores of \( \geq 21 \) significantly predicted an increase in PTD and LBW in the offspring of adult women, but not adolescents (Steer and Scholl 1992). Negative findings in adolescents may be due to the fact that the BDI detects adjustment problems rather than depression in this age group (Steer and Scholl 1992), or it may be a result of the small cohort size and limited power to detect differences in birth weight or length of gestation in a group already at high risk of these outcomes. Nonetheless, the adjusted odds ratio for PTD among adult women was 3.4 \( (95\% \text{ CI} 3.3–3.6) \), whereas the odds ratio for LBW delivery was 3.9 \( (95\% \text{ CI} 3.8–4.2) \). There was an increment in the risk of lighter birth weight or shorter gestation: a one point increase on the BDI elevated the risk of PTD by 7\% and LBW baby by 6\%.

Investigators in a pregnancy study that used the Center for Epidemiological Studies Scale for Depression (CES-D) \( (\text{range} 0–60) \) found that women in the most symptomatic group were at high risk of PTD (Orr et al. 2002). The median CES-D score among the 1399 pregnant African-American women was 16, a threshold used to identify individuals at high risk of depression (Radloff 1977). Researchers compared the top decile of symptomatic women to the remaining group of gravidas. Women in the top decile had scores ranging from 33 through 57. Spontaneous PTD occurred in 12.7\% of this symptomatic group but only in 8.0\% in the remaining cohort. After adjusting for drug use, low prepregnancy weight, smoking, and previous poor perinatal outcome, the risk of PTD among high CES-D scorers was 1.96 \( (95\% \text{ CI} = 1.04–3.7) \).

In an investigation (Andersson et al. 2004) that assessed perinatal risk for women who had a depressive disorder diagnosis generated by administration of the Patient Health Questionnaire (PHQ) (Spitzer et al. 2000), investigators did not find an association between diagnosis of a mood or anxiety disorder and deliveries that were preterm, LBW, or SGA. However, the number of women with these illnesses was small, hence limiting power.

Among all of these studies is the profound problem of adequately controlling for negative health habits that are not equally distributed among depressed and nondepressed pregnant women. One investigation attempted to account for possible confounding factors through the use of propensity scores and found that the risk of LBW delivery was still higher among women suffering from a depressive illness (Oberlander et al. 2006).

### Congenital Anomalies

Some of the most problematic adverse perinatal outcomes are development of congenital malformations. We are unaware of studies that controlled for medication use and specifically investigated whether there is an association between depression during pregnancy and the development of congenital malformations in the child. On the other hand, there is a single study that assessed associations between severe life stress during the first trimester of pregnancy, such as having a spouse or a child develop and/or succumb to a life-threatening illness, and risk of neural-crest defects (Hansen et al. 2000). The type of anomalies that were investigated in this national linkage study included craniofacial and conotruncal heart defects (e.g., double-outlet ventricle, tetralogy of Fallot, and ventricular septal defects). To the extent possible in a linkage study, investigators controlled for medical conditions and health habits that could have confounded an association including seizure disorders, diabetes, alcohol abuse, and smoking, although residual confounding from these or other poor health behaviors may be responsible for the presumed association.

In summary, the literature does not support an association between depression and subsequent miscarriage. High levels of stress may increase the risk of early miscarriage, although more work is needed to definitely establish this association. Similarly, stress has been associated with PTD, early delivery, and congenital malformations. Depression may also be associated with PTD or delivery of an LBW baby, although definitive studies are needed.

### In Utero Exposure to Antidepressants and Birth Outcomes

Over 80\% of women will take a medication at some point in their pregnancy (Headley et al. 2004). The rate of antidepressant use during pregnancy is about 13\% (Cooper et al. 2007) and tends to be higher during the early first trimester, before women confirm a pregnancy (Yonkers, unpublished data). Thus, many fetuses are exposed to antidepressants in utero, but given the likelihood that a woman may also take other medication, the possible effects of antidepressants need to be differentiated from those of other compounds.
While many antidepressants agents are currently available, in current practice the selective serotonin reuptake inhibitors (SSRIs) are most commonly used. Pregnant women are also more likely to be undergoing treatment with SSRIs than with other antidepressants (Cooper et al. 2007).

**Spontaneous Abortion**

Several investigations have found that women taking antidepressants are at higher risk of spontaneous abortion (Chambers et al. 1996, Chun-Fai-Chan et al. 2005, Einarson et al. 2001, Einarson et al. 2003, Kulin et al. 1998, Pastuszak et al. 1993, McElhatton et al. 1996). A meta-analysis of studies completed prior to 2005 \( (n = 3567) \) showed that 8.7% of controls and 12.4% of pregnant women exposed to antidepressants had a spontaneous abortion (\( RR = 1.45; 95\% CI = 1.19–1.77 \)) (Hemels et al. 2005). While risk was significantly higher in women who were taking SSRIs compared to controls (12.4% vs. 8.4%; \( RR = 1.52\% \); 95% CI = 1.17–1.98), differences were not significant between the various classes of antidepressant agents. The possible effects of an underlying illness and confounding health habits were variably controlled among the studies included in this meta-analysis.

**Preterm Delivery**

PTD has been associated with tricyclic and SSRI use (Chambers et al. 1996, Costei et al. 2002, Djulus et al. 2006, Ericson et al. 1999, Kallen 2004b, Simon et al. 2002) and may be greatest for exposures occurring during the third trimester (Chambers et al. 1996, Costei et al. 2002, Kallen 2004b). Fortunately, these deliveries tend to be shortened by 1 week or less in those exposed compared to those not exposed (Simon et al. 2002, Sivojelezova et al. 2005, Einarson et al. 2003), although very premature deliveries are far less common and may not be detected unless sample sizes are large. While this literature shows differences in outcomes for women who took antidepressants compared to those who did not take antidepressants, there are little differences between classes of antidepressant medication associated with these outcomes (Djulus et al. 2006, Sivojelezova et al. 2005). Thus, it remains possible that this effect is the result of some unmeasured factor not related to the specific drug, including the underlying illness, health habits, or other characteristics of the exposed cohort. In the few studies that have attempted to analytically control for the underlying illness, one found that SSRIs no longer increased risk of PTD (Oberlander et al. 2006), while the other showed continued risk of PTD among SSRI users (Simon et al. 2002).

**Low Birth Weight**

Reductions in overall birth weight, or an increased likelihood of either delivering an LBW or an SGA infant, have been found after in utero exposure to SSRIs (Kallen 2004a, Oberlander et al. 2006, Simon et al. 2002) and TCAs (Kallen 2004a). However, large linkage studies have been required to show these events since the increase in risk was typically small. In one study, the risk of SGA went from 7.4% among those exposed to an SSRI to 8.5% among controls (Oberlander et al. 2006). Attempts to control for maternal depressive illness do not appear to remove the risk of delivering smaller babies (Simon et al. 2002, Oberlander et al. 2006). In the later report, the difference in risk of delivering an SGA infant for mothers who had a history of depression and took SSRIs compared to moms with a similar history and personal characteristics but no antidepressant exposure was 3.3% (95% CI = 0.7%–5.9%) (Oberlander et al. 2006).

**Congenital Malformations**

**Tricyclic Antidepressants**

Tricyclic antidepressants (TCAs) have been marketed for many years. Therefore, they have the longest history of use during pregnancy. They are used less frequently now because of side effects including dry mouth, constipation, sedation, and orthostatic hypotension. In general, nortriptyline and desipramine are preferred tricyclics for use during pregnancy because they are least likely to cause anticholinergic effects and exacerbate the orthostatic hypotension that may occur during pregnancy (Eberhard-Gran et al. 2005).

To date, studies do not support an association between major malformations in neonates born to mothers who used TCAs during pregnancy (Alshuler et al. 1996, McElhatton et al. 1996). The European Network Teratology Service collected and evaluated prospective data on 689 pregnancies of which 330 were exposed to TCAs (McElhatton et al. 1996). Exposure in the first and second trimester occurred in 74% of the pregnancies, and 23% of women took TCAs throughout pregnancy. There was no overall increase in the rate of major malformations in the live-born infants. Similar results were found by Simon and colleagues (2002), who conducted a historical cohort study of 209 infants exposed to TCAs during the first trimester.

**Serotonin Reuptake Inhibitors**

There are conflicting reports as to the teratogenic risk associated with in utero SSRI use. A recent meta-analytic study (Einarson and Einarson 2005) compared outcomes in 830 infants exposed to SSRIs or bupropion and 934 infants not exposed to these agents. There was no increase risk of major malformations among those who were exposed. Similarly, results from a large Finnish cohort showed no increase in major malformations attendant to in utero SSRI exposure (Malm et al. 2005). Conversely, a Danish linkage study found that fetuses exposed to SSRIs during the second or third month or pregnancy were at higher risk of malformations when compared to children who were not exposed to an SSRI (6.8% vs. 3%; RR = 1.84; 95% CI = 1.25–2.71) (Wogelius et al. 2006). Offspring who were exposed during peak embryogenesis had the highest risk. Twenty-nine percent of malformations identified were cardiovascular, although the specific type was not reported.

A Swedish Medical Birth Registry (Kallen and Otterblad Olausson 2006), a study of three European Teratogen Information Services (Dian-Citrin et al. 2005b), and a historical cohort study using a large HMO database (GSK 2006) have also recently reported 1.8–2.0 higher rates of congenital heart disease among infants whose mothers received paroxetine, but not other antidepressants. Recent work finds that malformations were predominantly atrial and ventricular septal defects and were associated with use of 25 mg or more of paroxetine during the first trimester (Bérand et al. 2007). However, two case cohort studies with large sample sizes specifically tested for associations between septal defects and paroxetine and did not replicate
the previously noted relationship (Alwan et al. 2007, Louik et al. 2007).

**Bupropion**

Bupropion is an antidepressant that inhibits norepinephrine and dopamine. Results from the first prospective study of pregnancy outcomes among children exposed to bupropion for depression or smoking cessation used “another antidepressant” control group and a “no antidepressant” control group (Chun-Fai-Chan et al. 2005). Results did not show major malformations above the baseline of 1–3% among antidepressant-exposed women. Subsequent to that study, a report emerged from the GlaxoSmithKline Bupropion Pregnancy Registry, suggesting a higher-than-expected frequency of neonatal cardiac malformations. To further investigate a possible association, several large databases were analyzed although findings have not yet been published in peer-reviewed literature (GSK 2006). In one of these analyses, Cole and colleagues (2006) presented a study in which the population was drawn from the Ingenix Research Data Mart (RDM), which contains medical and pharmacy claims data from United Healthcare-affiliated health plans. They identified all women who dispensed bupropion (n = 1213) or other antidepressants who had live-born deliveries between 1995 and 2004. Two comparison cohorts were created consisting of: (1) women dispensed bupropion within 18 months before delivery or after the estimated first trimester of pregnancy and before delivery (n = 1049), (2) women dispensed antidepressants other than bupropion during the estimated first trimester or before the first trimester with days extending into the first trimester (n = 4743). There were no significant differences between groups in the rate of major malformations. All women in this analysis took an antidepressant agent, and so there were no “unexposed” infants that could be assessed. However, the general population rate for cardiac malformations is about 1%, which is slightly lower than the rate of 1.5% seen for babies that were exposed to paroxetine in utero.

**Monoamine Oxidase Inhibitors**

In a study of 21 prenatal exposures to monoamine oxidase inhibitors (MAOIs) in pregnancy, there was a relative risk of 3.4 for congenital malformations (Heinonen et al. 1999). Although this study was small, other risks associated with MAOI use, including the risk of a hypertensive crisis, contribute to recommendations that these medications should not be used in pregnancy.

**Other Antidepressants**

Other antidepressants that do not fall into either the TCA or the SSRI class, including venlafaxine (Einarson 2001), trazodone (Einarson et al. 2003), and mirtazapine (Djulus et al. 2006), have been the focus of small studies. None of these investigations reported higher rates of malformations with the various antidepressants under study.

There are limited data regarding the risks associated with atypical antipsychotics but the increasing time that these agents have been available has led to an increase in information about possible effects in pregnancy. An uncontrolled, administrative database that included outcomes to women exposed to risperidone during pregnancy showed that rates of malformations and spontaneous abortion were no higher than expected population rates (3.8% and 16.9%, respectively) (Coppola et al. 2007). However, this was based on prospective outcomes to only 68 women. Notably, the retrospectively reported cases had much higher rates of malformations, but it is difficult to interpret these findings given the risk of reporting bias.

The newer atypical antipsychotic olanzapine is used to control psychosis and mania. The pharmaceutical company registry of prospectively ascertained cases found that 13% of women experienced for spontaneous abortion, 5% had a still birth, 5% delivered preterm, and no infants exposed in utero were born with malformations (Goldstein 2000). Although these are also uncontrolled data, the rates are within the range expected for nonexposed populations. Other complications sporadically noted among pregnant women undergoing treatment with olanzapine were gestational diabetes and preeclampsia (Kirchheiner et al. 2000). Diabetes has been associated with the use of olanzapine in nonpregnant populations and may be a consequence of insulin resistance and/or weight gain (Dickson 1998, Guo et al. 2007).

**Perinatal Complications**

Other perinatal complications concurrent with late pregnancy use have been reported in association with antidepressant use. A six-fold increased risk of persistent pulmonary hypertension (PPHN) was found among newborns whose mothers were treated with SSRIs after 20 weeks of gestation compared to controls (Chambers et al. 2006). The absolute risk with exposure is 6–12 per 1000 in comparison to 1–2 per thousand and was only found for SSRI, not TCA exposure. There was no increase in risk of PPHN for babies born to women who took SSRIs prior to 20 weeks or to children born to women who took a non-SSRI medication. While this study has not been replicated, it follows up on a nonsignificantly higher rate of PPHN found by the same group in an earlier cohort study (Chambers et al. 1996). This study suggests that considerations other than malformation rates attendant upon first trimester exposure may need to be considered by patients and their clinicians. However, it should be emphasized that the absolute risk was very small and this should be weighed against the possible risk of maternal relapse into depression during pregnancy.

Respiratory distress has also been found documented by other workers who investigated the consequences of in utero exposure to SSRIs (Kallen 2004b, Costei et al. 2002) and TCAs (Kallen 2004b). Rates of respiratory distress remain higher in neonates exposed to SSRIs even after controlling for maternal depressive illness (Oberlander et al. 2006).

Other complications to neonates exposed to SSRIs antidepressants include outcomes such as low APGAR scores, and convulsions (Sanz et al. 2005) have been reported as higher in some studies evaluating the effects on neonates for women who took SSRIs (Kallen 2004b, Costei et al. 2002) or TCAs (Kallen 2004b) during the third trimester compared to controls (cf. Moses-Kolko et al. 2005 for a review). It is not clear whether these effects are due to “withdrawal” or are a type of fetal toxicity. While some have suggested that these possible complications can be obviated by tapering the medication prior to delivery, this strategy could hypothetically lead to fetal distress in utero (Moses-Kolko et al. 2005).

At this point, there is a paucity of data regarding the long-term consequences to children who are exposed to
antidepressants in utero. For infants exposed to antidepressants, mild neurocognitive effects at 6–9 months after delivery (Nulman and Koren 1996, Nulman et al. 2002) nor attention-deficit and externalizing behaviors are associated with antidepressant use (Oberlander et al. 2007).

**Electroconvulsive Therapy**

Women who are severely and acutely ill, not eating, or psychotic may require inpatient hospitalization to save the mothers’ life and the life of her baby. In such instances, electroconvulsive therapy (ECT) may provide life-saving treatment. Additionally, in a number of countries outside the United States, many psychiatrists prefer ECT, given the uncertain effects of antidepressant drugs on the health of a fetus. While there are no prospective controlled trials of ECT in pregnancy, a comprehensive review of 300 case reports is was published in 1994 (Miller 1994). Of those 300 cases, 28 cases (9%) reported complications including mild cardiac arrhythmia with no sequel in nine, three with vaginal bleeding that resolved, two with uterine contractions that resolved, four with preterm labor and five with miscarriage well after the ECT treatments, three with still births not related to ECT, and five with congenital malformations. In the later set, too little detail was available to determine the likelihood of causality in most reports although one mother received treatment with phenobarbital. The results of this qualitative review do not support a high level or risk for ECT treatment in pregnancy, a view also reflected in a second review (Stewart and Robinson 2001). Nonetheless, careful monitoring and several precautions should be used when performing ECT with pregnant women (Miller 1994, Yonkers et al. 2004). Delayed gastric emptying that often occurs in pregnancy may prompt intubation with a pediatric cuff or administration of an antacid to decrease gastric pH. Anticholinergic medication prior to ECT can lower esophageal sphincter tone and should be avoided if possible in pregnant women.

**Psychotherapy**

A 16-week controlled clinical treatment trial compared Interpersonal Psychotherapy for Antepartum Depression (IPT-P) to a Parenting Education Program (PEP) control group (Spinelli 2001). Fifty outpatient antepartum women who met DSM-IV-TR criteria for MDD were recruited to receive either the IPT-P treatment (n = 25) or the PEP control (n = 25). Thirty-eight women were included in the data analysis. Depressed mood was measured by the Edinburgh Postnatal Depression Scale (EPDS), the BDI, and the Hamilton Depression Rating Scale (HAM-D). The IPT-P treatment group showed significant improvement compared to the PEP control group on all three measures of mood at termination. The mood of the IPT-P treatment group improved significantly more than PEP control on all scores of EPDS (p = 0.005) and HAM-D (p = 0.02) and BDI (0.02). Recovery criteria was met in 60% of the IPT-P treated women according to the CGI < 2 (p = 0.011). In addition, there was a significant correlation (p = <0.05) between maternal mood and mother–infant interaction.

**Antipsychotics**

Some women with a unipolar mood disorder may express psychotic symptoms and require treatment with an antipsychotic agent. While most of the available data are derived from women who suffer from schizophrenia and bipolar disorder, a brief review is included that may be useful to managing women with a psychotic depression. A general rule to follow when using a medication to treat a pregnant woman is to use medications that have been on the market for a longer period of time and have better-known fetal safety profile (Dia-Citrin et al. 2005a). Overall, high-potency antipsychotics may be a first choice for use during pregnancy because of anticholinergic effects associated with low-potency agents. Additionally, one meta-analysis (Altshuler et al. 1996) found a small but statistically significant increase in the relative risk of congenital malformations in fetuses exposed to low-potency antipsychotics in the first trimester of pregnancy.

**Haldol**

Haloperidol is a high-potency butyrophenone with a long history of use during pregnancy. In a multicenter prospective controlled study conducted within the European Network of Teratology Information Services (ENTIS), 215 offspring were exposed to haloperidol (n = 188) and penfluridol (n = 27), including 78% in the first trimester (Dia-Citrin et al. 2005a). Children from these pregnancies were compared to 631 ENTIS controls. The rate of congenital anomalies did not differ between the exposed group and the control group. There were two cases of limb defects in the butyrophenone group (one with haloperidol and one with penfluridol), which was no higher than the expected base rate. However, babies exposed to antipsychotic agents had twice the rate of PTD (13.9% vs. 6.9%; p = 0.006) and significantly lower median birth weights compared to controls.

**Atypical Antipsychotics**

The use of atypical antipsychotics in the treatment schizophrenia has resulted in an increased number of pregnancies for these women. Unlike the older antipsychotic medications, the newer drugs do not impair fertility with the exception of risperidone, which may increase prolactin levels. Women with schizophrenia are more likely to have unplanned pregnancies, which results in delayed prenatal care and risky behaviors that may place the mother and fetus at risk. Schizophrenia itself has been known to be associated with adverse outcomes such as pregnancy and delivery complications and poor neonatal health (Yaeger et al. 2006).

The atypical antipsychotics have also gained popularity in the use of other psychiatric disorders. In the first prospective comparative study documenting pregnancy outcomes of women taking atypical antipsychotics, McKenna et al. (2005) followed patients with varying diagnoses including schizophrenia, bipolar disorder, schizoaffective disorder, psychoses, psychotic depression, obsessive compulsive disorder, posttraumatic stress disorder, and schizophreniaform disorder. They combined outcomes for women who were undergoing treatment with olanzapine (n = 60), risperidone (n = 49), quetiapine (n = 36), and clozapine (n = 6). While there was no significant difference between the rates of major malformations, prematurity, or neonatal complications, there was a nonsignificant increased rate of spontaneous abortions and elective abortions and a significant increase in the likelihood of delivering an LBW baby.
Risperidone
An uncontrolled, administrative database that included outcomes to women exposed to risperidone during pregnancy showed that rates of malformations and spontaneous abortion were no higher than expected population rates (3.8% and 16.9%, respectively) (Coppola et al. 2007). However, this was based on prospective outcomes to only 68 women. Notably, the retrospectively reported cases had much higher rates of malformations, but it is difficult to interpret these findings given the risk of reporting bias.

Olanzapine
The newer atypical antipsychotic olanzapine is used to control psychosis and mania. The pharmaceutical company registry of prospectively ascertained cases found that 13% of women experienced for spontaneous abortion, 5% had a still birth, 5% delivered preterm, and no infants exposed in utero were born with malformations (Goldstein 2000). Although these are also uncontrolled data, the rates are within the range expected for nonexposed populations. Other complications sporadically noted among pregnant women undergoing treatment with olanzapine were gestational diabetes and preeclampsia (Kirchheiner et al. 2000). Diabetes has been associated with the use of olanzapine in nonpregnant populations and may be a consequence of insulin resistance and/or weight gain (Dickson 1998, Guo et al. 2007).

Mood Stabilizers

Lithium
Lithium use in pregnancy has been comprehensively reviewed by the Institute for Evaluating Health Risks (Moore 1995). There are multiple sources of lithium exposure, including drinking water. Medicinal lithium requires much higher doses of the ion. Alarm was raised by earlier reports from the International Registry of Lithium Babies (Schou et al. 1973), a voluntary physician-reporting database, which noted a 400-fold increased rate for cardiovascular malformations. The malformation that raised the greatest concern was Ebstein’s anomaly, which is a downward displacement of the tricuspid valve along with right ventricular hypoplasia. Subsequent investigations found that 1/1000 (0.1%) to 2/1000 (0.05%) babies exposed to in utero lithium treatment will have Ebstein’s anomaly; this is 20–40 times higher than rates in the general population (Edmonds and Oakley 1990, Jacobson et al. 1992, Cohen et al. 1994). In a population-based study from a large administrative database (Kallen and Tandberg 1983) the odds ratio for any cardiac malformation was 7.7 (5% CI = 1.9–7.7), although none of these anomalies were Ebstein’s type. There was still an elevation in the odds ratio for any malformation (OR = 3.3; 95% CI = 1.2–9.2) in this study.

Other complications that have been reported among offspring exposed to medicinal lithium in utero include fetal growth restriction (Jacobson et al. 1992, Moore 1995), acute lithium toxicity in neonates (Ananth 1976, Moore 1995), and possibly neonatal mortality (Moore 1995, Stewart 1988). Long-term data are limited but available information does not support neurodevelopmental complications from medicinal in utero exposure to lithium (Jacobson et al. 1992, Schou 1976).

Valproic Acid
Valproic acid is a teratogen and its use during pregnancy is associated with neural tube defects in about 5–9% of exposed offspring (Omtzigt 1992b, Kennedy and Koren 1998). Neural tube-related teratogenicity occurs early, at 17–30 days postconception, and is worrisome because by the time women typically realize that they are pregnant their offspring may have already been exposed. The risk of neural defects is dose related (Omtzigt 1992a, Jager-Roman 1986).

As with lithium and carbamazepine (see below), fetal growth restriction (Jager-Roman 1986) has been found among babies exposed to valproic acid in utero. Additional possible complications include decelerations (Jager-Roman 1986), withdrawal symptoms of irritability, jitteriness, feeding difficulties, abnormal tone (Kennedy and Koren 1998, Felding and Rane 1984), and hypoglycemia (Thisted and Ebbesen 1993). Case reports include possible difficulties with reductions in neonatal fibrinogen levels (Majer and Green 1987) and mental retardation (DiLiberti et al. 1984).

Carbamazepine
Carbamazepine is also considered a human teratogen. As with valproic acid, neural tube defects are prominent, occurring in 0.5% and 1% of fetuses exposed in utero (Jones et al. 1989, Rosa 1991). Other anomalies that have been noted include craniofacial defects (11%), fingernail hypoplasia (26%), and developmental delay (20%) among live-born offspring (Jones et al. 1989).

The teratogenic potential of carbamazepine may be caused by the toxic epoxide metabolites (Lindhout 1992). Oxcarbazepine does not produce the epoxide metabolite, but lower teratogenic potential has not been confirmed by empirical data.

Carbamazepine exposure in pregnancy has also led to babies that are lighter (about 250 g) (Diav-Citrin et al. 2001) and have smaller head circumference (standardized for gestational age and sex) (Hillesmaa et al. 1981).

Lamotrigine
Lamotrigine is approved for treatment of bipolar depression and relapse prevention. Workers who maintain the Lamotrigine Pregnancy Registry maintained by GlaxoSmithKine presented possible consequences of lamotrigine exposure among 785 exposures with prospective follow-up data (Cunnington et al. 2005). In this data set, defects among infants exposed were similar to the base rate estimated for nonexposed populations. However, unpublished results from the North American Antiepileptic Drug Pregnancy Registry suggest a possible association in utero exposure to lamotrigine and cleft palate (Communication with GSK, July 2007). A small follow-up study of 23 infants exposed demonstrated no alterations in development at 12 months of age (Mackay et al. 1997).

Perinatal Complications
Exposure to lithium in utero increases the risk of neuromuscular complications, respiratory difficulties, cardiac arrhythmias, and renal and hepatic dysfunction among neonates (Moore 1995, Newport et al. 2005). The likelihood of complications increases as levels of exposure increase, so decreasing the dose to the lowest effective dose during pregnancy is optimal (Newport et al. 2005). Complications among
neonates exposed in utero exposure to antipsychotic agents have also been reported and include hypertonicity, motor restlessness, tremor, and difficulty with feeding (Trixler et al. 2005). Symptoms are rare and generally resolve within days.

Benzodiazepines

Benzodiazepines fall into three categories: long acting (diazepam and chlordiazepoxide), intermediate acting (clonazepam and lorazepam), and short acting (alprazolam). These are the most commonly used medications in the United States. All are assumed to be excreted into the breast milk and diffuse readily across the placenta to the fetus. The data on the use of these drugs in pregnancy are conflicting, often because of the differences in methodology. However, if administered near term they may induce sedation, fetal dependence, or withdrawal symptoms (Iqbal et al. 2002).

A meta-analysis pooled data from case–control studies (Dolovich et al. 1998). The seven cohort studies demonstrated no association between first trimester fetal exposure to benzodiazepines and major malformations (OR = 0.90; 95% CI 0.61–1.35), while four case–control studies showed that major malformations were associated with the use of benzodiazepines during pregnancy (OR = 3.01; 95% CI 1.32–6.84). Specifically, the latter association showed a relationship between oral clefts and benzodiazepine use only among case–control studies (OR 1.79 95%:1.13–2.82) (Dolovich 1998). The results from case–control studies of the relationship between benzodiazepine exposure and cleft lip or palate have suggested a risk rate of about 11:10,000, which translated into an increase of about 80% over the base risk of 6:10,000 in the general population.

Diazepam and Chlordiazepoxide

Investigations of single agents such as diazepam or chlordiazepoxide yield conflicting data for major malformations (Iqbal et al. 2002, Aarskog 1975, Saxén 1975, Rosenberg et al. 1983, Milkovich and van den Berg 1974), although an increased rate of congenital cardiac malformations with chlordiazepoxide cannot be ruled out (Czeizel et al. 2004). A case-time-control study reported (Kjaer et al. 2007) an increased risk of neural tube defects and facial clefts and limb deficiencies in mothers exposed to diazepam in the first trimester compared to later in gestation. Furthermore, the authors recommend that benzodiazepine doses should be tapered in weeks before delivery if possible to avoid potential “floppy baby,” neonatal withdrawal, or other toxic defects.

Clonazepam

While there have been various case reports of congenital malformations and other adverse effects with clonazepam (Iqbal et al. 2002), no adequate studies have determined the risk of congenital anomalies in the fetus of mothers exposed to the drug. Clonazepam is metabolized by hydroxylation, a metabolic pathway that is generally impaired in newborns, so respiratory depression must be monitored in the neonate and the nursing infant (Iqbal et al. 2002).

Lorazepam

Lorazepam is a high-potency benzodiazepine with a half-life of 12 hours in adults. Newborn elimination is slow (up to 8 days in a newborn and shorter for premature infants). Lorazepam and its pharmacologically inactive glucuronide metabolite do not cross the placenta as easily as other benzodiazepines. The metabolite does not accumulate in the tissues. Cord blood concentrations have been reported to be lower than maternal concentrations. No epidemiological studies have reported congenital anomalies in infants of mothers who were treated with lorazepam during pregnancy (Iqbal et al. 2002); however, Bonnot et al. (2001) reported data from a French registry of congenital malformations using a case–control approach. A significant association was found between lorazepam and anal atresia.

Alprazolam

Alprazolam has a shorter half-life than other benzodiazepines (10–24 hours) and readily crosses the placenta. One prospective study found no association with alprazolam and congenital anomalies (St Clair and Schirmer 1992), while other work did demonstrate congenital defects (Iqbal et al. 2002). Alprazolam is assumed to be capable of increasing the risk of various congenital abnormalities when administered during the first trimester.

Perinatal Effects

Overall, benzodiazepine use in the last month of pregnancy has been associated with CNS and respiratory depression in the newborn, particularly in long-acting benzodiazepines. Other neonatal consequences of short-acting benzodiazepines include case reports of withdrawal symptoms (Iqbal et al. 2002) including hypertonia, hyperreflexia, crying, tremors, apnea, and diarrhea and vomiting. This is particularly true for premature infants. Symptoms of higher doses during labor may induce “floppy baby syndrome” and respiratory problems (Iqbal et al. 2002).

As a general rule, exposure to benzodiazepines in the first trimester should be avoided but is not absolutely contraindicated. To avoid risk, benzodiazepines with long safety records should be prescribed as monotherapy at the lowest effective dosage for the shortest possible duration. Daily dosages should be divided into at least two doses, and tapering prior to delivery may help.

Pharmacotherapy During Lactation

Psychotropic medications are typically alkaline and, because of the need to access the central nervous system, are lipid soluble. These characteristics promote diffusion into breast milk. There may be different consequences to a baby’s exposure to a specific blood level compare to an adult because babies have immature renal and hepatic systems. Moreover, a baby’s blood-brain barrier is more permeable, and this may render the baby more vulnerable to side effects. Several excellent reviews of the use of psychotropic medications in lactating women are available (Bar-Oz et al. 2000, Burt et al. 2001, Eberhard-Gran et al. 2006, Gentile 2006, 2007).

A number of factors should be considered when discussing the possibility of psychotropic treatment for a mother who plans to nurse. Among these issues are the benefits of breastfeeding to the infant, the severity of the mother’s symptoms if left untreated, mother’s and her partner’s preference, and the potential risk to the infant should psychotropic drugs be ingested via breast milk.

There are a number of reasons that serum levels of a drug will differ from one neonate to another. If the baby was exposed to a psychotropic agent during pregnancy, he or she
will have higher neonatal levels if also given the medication only through breast milk (Wisner and Perel 1996). Genetic differences will lead to metabolic differences between mothers, and genetic differences can also influence metabolism in babies. Mothers may or may not exclusively breastfeed, and the less the total exposure to breast milk with a psychotropie, the lower the exposure in the infant. Assays of breast milk concentration may differ, depending on how soon after taking a daily dose the milk was collected, what section of the breast milk was collected (foremilk or hindmilk) (Stowe et al. 1997, 2000), and the number of days postpartum.

If a mother elects to breastfeed, the infant should be monitored for problems with sucking, fussiness, tremulousness, muscle rigidity, difficulties with arousal, failure to gain weight, and sleep and state disturbances, as well as the onset of other difficulties.

Benzodiazepines
All benzodiazepines are secreted into breast milk. For diazepam these findings have correlated with sedation and weight loss in the neonate. For drugs with a long half-life, caution should be exercised during breastfeeding and the infant monitored for sedation and respiratory depression. For short-acting benzodiazepines, caution should always be advised and the neonate monitored for drowsiness in addition to withdrawal symptoms (Iqbal et al. 2002).

Antidepressants
Elevated infant plasma levels for each drug are defined as those above 10% of the average maternal level (Weissman et al. 2004). While nortriptyline, paroxetine, and sertraline produce undetectable infant plasma levels, fluoxetine produces the highest proportion (22%) of infant levels that are elevated above 10% and citalopram produces elevated levels at 17%.

Tricyclic Antidepressants
TCAs are excreted into human breast milk in low concentrations with a wide range of reported infant serum concentrations (Whitby and Smith 2005). In one study, the authors determined that the average daily dose of the nursing infants was about 1% of the maternal dose/kg (Yoshida et al. 1997). According to a review by Misri and Kostaras (2002), no adverse events have been reported for desipramine, amitriptyline, imipramine, nortriptyline, and clomipramine. However, in two cases doxepin was found to have an active metabolite with long half-life. Exposure was associated with hypotonia, respiratory depression, and jaundice, and doxepin is generally not recommended for use in breastfeeding infants (Misri and Kostaras 2002).

Four clomipramine-treated breastfeeding mother–infant pairs were assessed for serum concentrations of clomipramine, N-desmethylclomipramine, and corresponding 8-hydroxymetabolites. Parent drug and metabolites were nondetectable or below the quantifiable limit in the sera of all infants. No adverse clinical effects were observed (Wisner et al. 1995).

Serotonin Reuptake Inhibitors
Paroxetine
The amount of paroxetine appears to be minimal with respect to the maternal drug concentrations (Gentile 2007). The relative infant dose for the suckling infant is lower than that reported for fluoxetine and citalopram, but higher than that reported for sertraline and fluvoxamine. In more than 120 case reports, three infants had adverse effects, which included one case of acute pain response; one case of lethargy, poor weight gain, and hypotonia; and one case of irritability.

Sertraline
Breastfed infants have undetectable serum concentrations of sertraline and its metabolite, and only one out of >120 cases showed a higher drug concentration. There was one case of altered acute pain response, one case of benign neonatal sleep myoclonus, and one infant with agitation, crying, insomnia, and startle (Gentile 2007).

Citalopram
In 75 mother–infant pairs who were exposed to citalopram (Gentile 2007), only one infant reported adverse effects. One case was a child who was a late walker, one case was of uneasy sleep, and one case was of colic, poor feeding, and restlessness. Franssen et al. (2006) presented a recent case of intensified therapeutic drug monitoring of citalopram in mother and newborn infant after clinically observing SSRI-associated symptoms from 2 weeks until 2 months after delivery. The SSRI-associated symptoms observed in the infant (up to 3 weeks after delivery) were irregular breathing, sleep disorders, hypotonia, and hypertonia. We conclude that the SSRI-associated symptoms in the infant represent citalopram withdrawal effects rather than side effects caused by breastfeeding.

Escitalopram
Escitalopram is excreted into breast milk. The total relative infant dose for escitalopram plus its desmethyl metabolite was 5.3% (Rampono et al. 2006). Of nine reported cases, all met developmental milestones and no adverse effects were seen. The absolute infant dose seemed to be lower than that for the equivalent antidepressant citalopram. Hence, escitalopram should be preferred over citalopram for breastfeeding women (Gentile 2007).

Fluoxetine
The concentration of fluoxetine in breast milk represents a significant predictor of the total infant serum concentration of the drug. The amount of drug transferred to an infant depends largely on the maternal drug concentration. Fluoxetine has an active metabolite norfluoxetine with a long half-life that predicts high concentrations in the neonate, and a significant number of adverse events have been reported in neonates. In over 200 case reports compiled by Gentile (2007), several adverse events have been described including elevated platelet serotonin levels, high rate of admissions to infant care units, colic, irritability, fever, and hyperactivity.

Fluvoxamine
More than 10 cases of fluvoxamine in the literature provide overall reassuring results with only one case of spontaneously resolved neonatal jaundice (Gentile 2007).

Serotonin Norepinephrine Reuptake Inhibitors
Gentile’s (2007) analysis of venlafaxine describes 15 reported cases free of adverse events. Ilett et al. (2002) evaluated six...
women and seven infants to determine plasma concentrations and effects of the drugs on the infants. Venlafaxine was detected in the plasma of one infant, while O-desmethyl venlafaxine (ODV) was detected in four infants. All infants were healthy, and mean total drug exposure was 6.4%, which was below the 10% national level for concern. Breastfed infants should be monitored carefully since ODV was detected in four infants.

**Other Antidepressants**

**Buproprion**

Buproprion accumulates in human breast milk in concentrations much higher than in maternal plasma. Two metabolites are also excreted into the milk. Neither buproprion nor its metabolites are detected in the infant’s plasma, indicating that accumulation did not occur in the infant (Briggs et al. 2002). Results from four studies indicate that the daily dose of buproprion and its metabolites delivered to an infant of a mother taking a therapeutic dose of the medication is relatively small. Thirteen of 14 infants had no adverse events, while one infant experienced a seizure (Gentile 2007).

**Mirtazapine**

Two cases of mother–infant breastfeeding pairs (Klier et al. 2007, Aichhorn et al. 2004) showed undetectable infant levels of mirtazapine. Infants had no adverse effects.

**Nefazodone**

Only four cases of reboxetine were reported with no adverse events, and three cases of nefazodone were reported with limited and conflicting data (Gentile 2007).

In summary, sertraline and paroxetine are considered as first-line medications in women who need to start medications in the postpartum period. Since citalopram and fluoxetine are associated with a relatively higher risk of adverse events, the risk and benefit of continuing these medications must be considered. The question of whether chronic exposure to low doses of antidepressant medication poses long-term neurodevelopmental risks to the infant remains unanswered. Despite the low dosage transferred to the infant through breast milk, premature infants and those with neonatal diseases may be vulnerable to such exposure (Eberhard-Gran et al. 2006). For treatment of postpartum women with a history of successfully treated depression, the most practical approach may be to continue therapy with the previously effective agent.

**Mood Stabilizers**

**Lithium**

Lithium equilibrates well in breast milk (Schou 1990), which can lead to equivalent concentrations in maternal serum and breast milk. Lithium has a narrow therapeutic and, because of this and a baby’s immature renal status, some experts recommend avoiding this agent during lactation (Eberhard-Gran et al. 2006), although the American Academy of Pediatrics does not absolutely contraindicate breastfeeding for women undergoing lithium treatment (Drugs 2001). As noted above, neonates should be monitored for complications during breastfeeding.

**Valproic Acid**

Valproic acid is secreted into breast milk but in low amounts (Bar-Oz et al. 2000). In general, the percentage baby will receive is well below 10% of the maternal level. A single case report noted difficulties with thrombocytopenia (Stahl et al. 1997). The American Academy of Pediatrics suggests that maternal treatment with valproic acid is consistent with breastfeeding (Drugs 2001).

**Carbamazepine**

The percentage of maternal carbamazepine dose that a neonate would receive from breast milk averages between 1% and 8% (Bar-Oz et al. 2000). There are generally few concerns with use of carbamazepine during pregnancy.

**Lamotrigine**

The milk:plasma ratio of lamotrigine is about 0.6, and although this is slightly higher than what is seen for valproic acid and carbamazepine (Bar-Oz et al. 2000), the plasma level of lamotrigine infants is much higher. This appears to occur because the drug’s elimination is dependent on glucuronidation, and this reaction is slowed in neonates (Liporace et al. 2004). Some neonates have achieved “therapeutic levels” of this compound but adverse effects among neonates have not been a problem.

**Atypical Antipsychotics**

It may be best to avoid breastfeeding while undergoing treatment with the typical antipsychotic, clozapine, because of the possible side effect of agranulocytosis. There is little information on the use of other newer antipsychotic agents during lactation. Case reports of risperidone, olanzapine, and quetiapine have not raised concerns (Gentile 2006).

**Typical Antipsychotics**

There is surprisingly little information on the use of typical antipsychotics in breastfeeding mothers, and information is based on case reports (Burt et al. 2001). The majority of reports have not shown adverse effects among neonates, although sedation was noted in a report of infant exposure to chlorpromazine during lactation.

**Management Recommendations**

A number of factors need to be considered when determining a treatment plan for a woman who requests consultation regarding the management of a depressive disorder during pregnancy. These factors include: (1) Is the woman contemplating pregnancy or currently pregnant? (2) If the woman is pregnant, what stage of pregnancy is she in? (3) What are the patient’s and her partner’s preferences with regard to pharmacological and nonpharmacological approaches to treatment? (4) Has she had a history of treatment and, if so, what has she received? (5) If she has discontinued treatment before, has she remained well for a period of months or longer? (6) Does the patient have evidence of psychotic or suicidal symptoms?

The ideal time to conduct a consultation is prior to conception. This affords the clinician the time to have a thoughtful discussion of the risks and benefits with the patient and her partner. It also gives the patient and her physician time to assess whether she can stay well for a period of time off medication or, if ongoing medication is required,
time to select a medication with the most reassuring safety profile. Should the patient be in the process of recovering from an episode of illness or may be improving, a preconceptional assessment will allow her a period of psychiatric stability prior to conceiving. Finally, planning for pregnancy may allow the patient an opportunity for a trial of empirically-based psychotherapy such as cognitive-behavioral therapy or interpersonal therapy if she has not previously received such treatment. For some, a behavioral therapy may help them keep stable off medication during pregnancy or may decrease symptoms.

The severity, prior clinical course, and duration of time since the most recent episode of illness should be considered when determining whether a patient can discontinue medication for her depressive disorder. Women with severe recurrent illness, suicidal ideation and attempts, as well as psychosis may not be able to safely stop pharmacotherapy (Cohen et al. 2006). Similarly, women who have just remitted from a depressive episode may relapse if they stop pharmacotherapy too soon. Many patients with these characteristics may elect to continue psychotropic medication during pregnancy. Nonetheless, a trial of a behavioral therapy, as an option, should be discussed. Documentation of discussions regarding treatment options with the patient and her partner, risks and benefits related to the various treatment options, as well as patient’s consent should be included in the medical chart. For patients who require and elect to continue pharmacotherapy, the lowest effective dose should be used. It is best to select from medications that have been on the market for a number of years, since this allows for observing outcomes from offspring intentionally or unintentionally exposed. Some recent data suggest that paroxetine should not be a first-line medication unless this is the only treatment to which a person has responded (see above). However, more recent data have failed to show an association between paroxetine and septal defects (Alwan et al. 2007, Louik et al. 2007). If a woman must continue paroxetine, keeping the dose at 25 mg daily or less may decrease the risk of cardiac malformations if such a risk exists (Bérand et al. 2007).

A similar clinical assessment is required for a woman who is pregnant and symptomatic. The severity of illness, prior clinical course, and patient and partner preference are important components of the decision to treat or not to treat with medication. Again, discussions regarding treatment with the patient and her partner should be documented along with the patient’s consent. Medications that have previously been helpful should be considered with the possible exception of paroxetine. Again, if this is the only antidepressant to which a patient has responded, this medication may be necessary.

If a patient has been undergoing pharmacological treatment for depression, current clinical status, including severity, suicidal ideation, and psychosis, are important to assess when determining if medication should be continued. Prior treatment history as well as information regarding clinical course after medication discontinuation, patient preference, and response to empiric-based psychotherapy should be elicited to determine if medication is appropriate.

Given the information about possible PPHN after later in utero exposure to SSRIs (Chambers et al. 2006), it is important for clinicians to discuss this possible adverse effect with their patient and the patients’ partners. While we await further information regarding this possible adverse effect to offspring, some patients and clinicians may prefer to switch treatment to a TCA or to a behavioral therapy. However, there is a risk of relapse with a change in treatment, and this should also be discussed with the patient and documented in her medical chart.

Summary

An increasingly large database is becoming available to assess the safety of antidepressant treatment in pregnancy. It may be that clinicians are more likely to hear about problems associated with antidepressant use than about adverse effects of discontinuing treatment. We outline information about a number of perinatal effects that have been associated with stress, depression, as well as antidepressant treatment, but a number of questions remain. Perhaps chief among these are what are the consequences of the illness and what are the results of pharmacological treatment. Thoughtful planning and a thorough discussion of risks and benefits for all approaches are important in the clinical management of pregnant or preconceptual patients, with depression and will contributing to the most optimal outcomes.

History of Combined Treatments

Whether at the beginning of a treatment or months after its initiation, psychiatrists today widely believe that more than one treatment modality—often psychotherapy and medication—is needed to optimize patient outcome. This has not always been true. When the psychoanalytic model of the mind was the major theoretical influence in the 1950s and 1960s, most American psychiatrists believed that the use of medications “reduces the motivation of the patient to pursue the psychotherapeutic work and deeper personality changes that are sought for in the psychoanalytic process” (Marmor 1981). Gradually, many psychodynamically oriented psychotherapists and psychoanalysts began to realize that the use of medication and psychotherapy could be a therapeutically powerful combination (Kubie and Margon 1945, Goldhamer 1983, Norman and Bluestone 1986, Kantor 1990) and, in fact, make patients more amenable to psychotherapeutic interventions (Cooper 1990).

As evidence for the effectiveness of medications for schizophrenia and mood disorders accumulated after 1950, some psychiatrists rejected the combination of medication and psychotherapy for the opposite reason, i.e., there was little reason to consider nonpharmacologic treatments, whose likely mechanisms were persuasion and contact with a caring doctor rather than a specific treatment.

Fortunately, most psychiatrists have shifted from dogmatic positions for or against certain treatment modalities to more inclusive views. As the literature on combined treatment has expanded, many have concluded that treatment with medication and psychotherapy may be advantageous in a number of respects. First, combining treatments may increase the magnitude of response for individual patients, resulting in fewer residual symptoms. Second, combining treatments may enhance the acceptability and effectiveness of each individual treatment—psychotherapy may help increase compliance rates and help patients tolerate side effects, while adding medication may make the problems of psychotherapy patients more tractable (Hollon et al. 2005).

It appears that combining medication and psychotherapy may enhance the strengths of each individual treatment while minimizing their respective weaknesses. For instance, the neurobiological substrate of an individual’s depression may be too severely disturbed for psychotherapy alone to be effective, and adding antidepressant medications may be more effective in reversing abnormalities such as sleep or neuroendocrine dysfunction. Patients with chronic depressive symptoms, severe psychosocial stressors, or depression in patients with personality disorders may benefit from psychotherapy in addition to medication alone (Frank et al. 2005).

Clinical Vignette

A clinical vignette helps to illustrate the possible benefits of combined treatment and potential costs of monotherapy. A, a 32-year-old woman with no history of major depression is in her third year of psychodynamic psychotherapy with Dr. B, a male psychiatrist. Her chief complaint was difficulty engaging in a committed relationship with a man. Raised primarily by her mother after a contentious divorce, A had gradually learned to trust him and to acknowledge that he was interested in her and invested in her improvement. One weekend, while shopping at the mall, A ran into Dr. B and his pregnant wife. Although she denied the importance of this event and wished the therapist well with his new baby, she became increasingly depressed in the ensuing weeks. The therapist believed that A’s depression was the result of her seeing him with his wife, confirming for her that he cared more about...
Evidence for Combined Treatments

Overview

Combined treatment with medications and psychotherapy is frequently utilized in the clinical care of patients with depression, anxiety, and other conditions (Beitman and Klerman 1991, Riba and Balon 2005). In approaching such patients, what evidence informs the clinician’s decision regarding when and how to utilize combined treatment? To address this question, this section will review the available data on the relative efficacy of medications and psychotherapy for different disorders, when medications or psychotherapy are specifically indicated for certain patient populations, and when combined treatment should be considered as opposed to monotherapy.

Randomized controlled trials (RCTs) are now the standard means for demonstrating treatment efficacy, whether of psychotherapy or of medications. Numerous studies comparing psychotherapy and medications have been conducted, and many provide significant insights. However, reviewing the literature also highlights the very limited evidence in favor of combining medications and psychotherapy and the need for more research.

Medication vs. Psychotherapy: Is One Treatment Better Than the Other?

During the 1970s and 1980s, more pharmacologic treatment options became available, and researchers systematically began to investigate the efficacy of these treatments in clinical trials. Likewise, psychotherapy researchers began to develop treatment manuals and therapist training programs so that psychotherapies could be standardized and studied systematically. These developments appeared to make possible the direct comparison of treatment with medications and psychotherapy, to determine their relative efficacy for depression, anxiety disorders, and other conditions. Therefore, the first generation of trials involving medications and psychotherapy was competitive in that they compared two treatment modalities to determine if one was superior. These trials did not usually have a combined psychotherapy and medication treatment cell, so the question of whether combined treatment offered a benefit over monotherapy was left unanswered. In addition, a serious problem facing these types of trials was the difficulty of demonstrating significant differences between two active treatments, which is much harder than demonstrating significant differences between active treatment and placebo or between posttreatment measurements and baseline.

Depressive Disorders

One of the first studies of psychotherapy and medication was carried out by Rush et al. (1977). This trial randomized 41 depressed outpatients to cognitive behavior therapy (CBT) (maximum of 20 sessions over 12 weeks) or imipramine (up to 250 mg per day for 12 weeks). Both treatment groups showed significant improvement compared to baseline, but CBT was significantly superior to imipramine in reducing depressive symptoms, as measured by the Beck Depression Inventory (BDI) and the Hamilton Rating Scale for Depression (HRSD). Of the patients receiving CBT, 79% had a final BDI < 10, compared to 23% of the patients treated with imipramine.

Perhaps the most famous trial comparing psychotherapy and medication was the National Institute of Mental Health’s (NIMH) Treatment of Depression Collaborative Research Program (TDCRP) (Elkin et al. 1985), whose results began to be published in 1989. The TDCRP was a multicenter clinical trial that randomized 250 outpatients with current major depressive disorder to 16 weeks of treatment with (1) CBT, (2) interpersonal therapy (IPT), (3) imipramine plus clinical management, or (4) pill placebo plus clinical management. The study goal was to determine the relative efficacy of two psychotherapies for depression as well as their efficacy compared to imipramine, which served as the standard reference treatment. Since it is considered to be a proven effective treatment, including an imipramine treatment condition allowed the investigators to interpret the CBT and IPT results. In case no significant differences were found between CBT and IPT, comparing each to the imipramine group would help adjudicate whether the treatments were similarly ineffective or effective. A placebo group was necessary to demonstrate that imipramine was effective in the study population.

Patients were assessed every four weeks during their treatment course, at study termination and at 6, 12, and 18 month follow-up. The primary observer-rated outcome measures were the 17-item HRSD (Hamilton 1960) and the Global Assessment of Functioning (GAS) (Endicott et al. 1976), while the primary self-report outcome measures were the BDI (Beck et al. 1961) and the Symptom Checklist-90 (SCL-90) (Derogatis 1992).

Patients enrolling in the study were 70% female, aged 35 ± 8 years, and most had recurrent depression (Elkin et al.
1989). Dropout rate was 32% in the CBT group, 23% in the IPT group, 33% in the imipramine group, and 40% in the placebo group. In the intent-to-treat analyses, patients in all four treatment conditions (including placebo) showed significant reduction in depressive symptoms over the course of the study, as measured by all four of the primary outcome measures. Few significant differences were found between the treatments: imipramine was superior to placebo on the GAS measure, and IPT as well as imipramine showed a trend for superiority to placebo on the HRSD. Significantly more patients experienced remission of their depression (as measured by HRSD < 7) in the imipramine and IPT groups compared to placebo, but CBT was not significantly different from either of the other active treatment groups or placebo. Despite the few statistically significant differences, the order of the treatments was consistent, with imipramine usually doing best, followed by IPT, CBT, and placebo.

The TDCRP was the first comparative clinical treatment trial involving psychotherapy and medication sponsored by the NIMH, and it was also the first study to compare CBT and IPT. The study benefited from a number of important methodological advances, including standardization of the treatments (by means of treatment manuals, clinician training, and monitoring of adherence), use of standard outcome measures for depression, and a multisite design permitting a larger sample to be recruited. However, questions were immediately raised about the authors’ statistical methods (Klein 1990). Reanalyses of the data showed that imipramine was significantly superior to placebo on the HRSD and the GAS, superior to IPT on the GAS, and nearly superior to CBT on the GAS (Klein and Ross 1993). CBT and IPT were not superior to placebo among patients entering the study or among completers, but CBT was inferior to IPT on the BDI among more severely depressed patients.

Continuing debate following publication of the TDCRP results made clear how dissatisfied many researchers were with the study. Pharmacologists were not satisfied with the medication treatment; e.g., imipramine at doses of 150 mg per day will not achieve a therapeutic blood level in most patients, and no blood levels were measured to guide dose adjustment. However, most did feel the inclusion of a pill placebo treatment condition was a welcome advance, since such “internal calibration” of the study was necessary to demonstrate that it took place in a drug-responsive population (Klein 1996). Psychotherapists were unhappy with potential therapist allegiance effects and lack of documentation of treatment fidelity, as recent studies have raised the possibility that the treatment administered in the IPT cell was not significantly different from CBT (Ablon and Jones 1999).

While many psychotherapy and pharmacotherapy researchers have moved on to ask whether combined treatment with medications and psychotherapy is better than monotherapy, the legacy of this first generation of competitive studies can still be seen today. First, and most directly linked to the TDCRP debate, psychotherapy researchers have continued to address the question of whether psychotherapy is as effective as antidepressant medications for severe depression. For example, DeRubeis et al. (1999) conducted a “mega analysis” of original data from four studies of combined therapy and CBT in patients with severe major depression (defined as HRSD > 20 or BDI > 30). These studies included the TDCRP, as well as an early study of imipramine vs. CBT by Rush et al. (1977), nortriptyline vs. CBT by Murphy et al. (1984), and a study of imipramine vs. CBT by Hollon et al. (1992). Adjusting for pretreatment differences in depression severity among the studies, they found no significant differences in pooled posttreatment HRSD or BDI scores of patients treated with CBT and antidepressant medication.

It should be noted that some researchers consider the definition of “severe” depression in analyses such as the above to be arbitrary. These definitions are often determined by dividing the patient sample into two groups—those having depression scores above and below the mean—and the group above the mean depression score is considered to represent severe depression. Many researchers and clinicians would object to the DeRubeis et al.’s (1999) definition of severe depression as HRSD > 20, since they would not consider patients to have severe depressions unless the HRSD is 26 or more.

More recently, Jarrett and colleagues (1999) randomized 108 patients with major depressive disorder and atypical features to treatment with CBT, phenelzine, or pill placebo. They found significantly greater response rates for CBT and phenelzine compared to placebo, but CBT and phenelzine did not significantly differ from each other. In another study, DeRubeis et al. (2005) compared CBT to antidepressant medications in 240 patients with severe major depression and found that the two treatments did not significantly differ over 16 weeks. “Severe” major depression was defined as scores of 20 or greater on the 17-item HRSD at the screening and baseline visits for the study. Response rates were 58% for both CBT and medications, while remission rates were 46% for medication and 40% for CBT. Similarly, Dimidjian et al. (2006) compared behavioral activation therapy, CBT, and antidepressant medication in 241 adults with major depressive disorder. Medications were significantly more effective than placebo in this study, and behavioral activation, as well as medications, was significantly better than CBT without being different from one another. In all of these rigorously conducted studies, therapist qualifications and training were described, treatments were manualized, and adherence and competence were assessed by blinded raters using validated rating scales.

Competitive studies continue to be performed to determine if medication or psychotherapy is more effective at achieving complete remission of depression. There has been an increasing acceptance of remission rather than response as a goal of treatment, since even depression “responders” may have a significant degree of residual illness that places them at higher risk of depression relapse, physical and functional morbidity, and suicide (Paykel 1995). Remission is defined as a state in which patients are asymptomatic or have no more than minimal symptoms and no longer meet diagnostic criteria for depression (Frank et al. 1991). Remission is often operationalized in terms of preset minimum HRSD scores, such as a measured final HRSD < 7, while response is defined as a 50% reduction in baseline depression rating score or else an “improved” or “much improved” score on the CGI.

For example, Casacalenda et al. (2002) performed a meta-analysis of six randomized, double-blind clinical trials including psychotherapy (primarily CBT and IPT) and
pharmacotherapy (mainly TCAs and phenelzine) treatment cells to determine their effects on depression remission. Remission was defined separately by each study included in the meta-analysis: three studies defined remission as HRSD < 6, two as HRSD < 7, and one as Raskin Depression Scale < 5. This meta-analysis included 883 patients having nonpsychotic major depression in both outpatient settings and psychiatric hospitals. Analyses indicated that pharmacotherapy and psychotherapy were significantly more effective than control conditions (e.g., pill placebo or treatment as usual) but not significantly different from one another (46.4% and 46.3%, respectively).

Meta-analyses have also compared psychotherapy and pharmacotherapy for the treatment of depression in older adults. Pinquart and colleagues (2006) performed a meta-analysis of 89 controlled clinical trials for depressive disorders in older adults. These trials included 57 studies of antidepressants alone, 27 studies of psychotherapy alone, and five studies of combined treatment. The 5328 patients in studies included in the analysis were 64% female, mean age 70.9 years, and represented a mix of in- and outpatients as well as patients with and without medical comorbidities. The authors found significantly larger effect sizes in psychotherapy treatment cells compared to pharmacotherapy treatment cells on clinician-rated depression scores, whereas self-rated depression scores were not significantly different between pharmacotherapy and psychotherapy treatment cells.

Results from this first phase of research studies comparing treatment for depression with psychotherapy and medications are mixed (Table 113–1). Some trials demonstrate a significant difference in favor of psychotherapy compared to medications, while others report the opposite finding. However, the result found by most of the studies cited is that no significant difference was observed between the two treatment modalities. This finding reiterates the difficulty of demonstrating significant differences between two active treatments rather than between an active treatment and baseline or a control condition. Clinically, this result also led to the consensus that either medications or psychotherapy with CBT or IPT can be a reasonable first choice for the treatment of many unipolar, nonpsychotic depressions (AHCPR 1993, APA 1993).

### Anxiety Disorders

Similar types of research studies have compared medications and psychotherapy for anxiety disorders such as panic disorder and obsessive compulsive disorder (OCD). For instance, Klosko et al. (1990) compared behavior therapy (BT), alprazolam, pill placebo, and a wait-list control in 69 patients with panic disorder. They found significantly lower clinical ratings of severity of panic disorder, lower Hamilton Anxiety Rating Scale (HARS) (Hamilton 1959) scores, and decreased subjective ratings of panic frequency and intensity in the alprazolam and BT groups compared to the placebo and wait-list control groups. No differences were observed between alprazolam and BT.

Black et al. (1993) randomized 75 outpatients with panic disorder to 8 weeks of treatment with fluvoxamine, CBT, or pill placebo. In this study, patients treated with fluvoxamine had significantly greater improvement at the study endpoint on the Clinical Anxiety Scale and the Clinical Global Impressions (CGI) Scale than patients receiving CBT or placebo. Patients receiving CBT showed significantly more

improvement on the CGI and calculation of mean weekly number of panic attacks than patients receiving placebo. Lastly, Clark et al. (1994) compared 12 weekly sessions each of CBT, applied relaxation therapy, and imipramine for patients with panic disorder. They found significantly lower scores on a panic/anxiety composite measure and higher percentages of panic-free patients in the CBT relative to the applied relaxation or imipramine groups. This difference between imipramine and CBT disappeared at 3 months follow-up, but both treatments remained superior to applied relaxation therapy.

Similar competitive studies have been performed in patients with OCD. Haan et al. (1998) compared the effectiveness of BT and clomipramine in 22 children, aged 8–18 years, with OCD. Patients were randomized to 12 weeks of BT or treatment with clomipramine at doses of 2.5 mg/kg. The authors found significant improvement of symptoms as measured by the Children’s Yale–Brown Obsessive Compulsive Scale (CY-BOCS) for both treatment conditions, but BT was significantly superior to clomipramine.

Finally, Clark et al. (2004) randomized 60 patients with generalized social phobia to cognitive therapy (CT), fluoxetine plus self-exposure (SE), or pill placebo plus SE. Patients were treated for 16 weeks, at which point the blind was broken and patients entered a 3-month booster phase. Statistically significant improvement in social phobia symptoms occurred in all three treatments, but CT was superior to fluoxetine plus SE and pill placebo plus SE at the end of acute treatment, the 3-month booster period, and a 12-month follow-up period.

Similar to the results observed in comparative trials of psychotherapy and medication for depression, those found by the above trials for anxiety disorder are mixed (Table 113–1). Some studies found psychotherapy significantly superior to medication, whereas others found medication superior to psychotherapy, but most determined both medication and psychotherapy to be effective without differing significantly. Many consensus treatment guidelines reflect these findings in recommending either an evidence-based psychotherapy or a proven effective medication for the treatment of anxiety associated with OCD, social phobia, or panic disorder (APA 2006a, 2006b).

**Combined Treatment with Medications and Psychotherapy vs. Monotherapy: Are Two Treatments Better Than One?**

The next generation of combined treatment studies was aimed less at determining which treatment was more effective, medications or psychotherapy, and more at addressing the question of whether combined treatments are superior to monotherapy.

**Depressive Disorders**

Blackburn et al. (1981) conducted one of the first studies of CBT and medication in Scotland. Sixty-four hospital outpatients and general practice patients diagnosed with recurrent depression were assigned to CBT alone, tricyclic antidepressant medication alone, or CBT plus medication. Patients received a maximum of 20 weeks’ treatment and were then followed for 2 years. There were no between-group differences among the hospital outpatients, but combined treatment and CBT both resulted in significantly higher response rates than the medication-only group. Overall in the acute study, 82% of patients receiving CBT plus medication responded, compared to 73% of patients receiving CBT and 55% of patients receiving tricyclic medication. Strikingly, after 2 years of naturalistic follow-up, significantly fewer patients in the combination treatment and CBT groups relapsed (0% and 6%, respectively), compared to 30% in the tricyclic-only group (Blackburn et al. 1986).

Other investigators found similar results. Murphy et al. (1984) randomized 87 patients with unipolar depressive disorders to CBT, nortriptyline, CBT plus nortriptyline, and CBT plus active placebo. No outcome differences were observed between groups at 12 weeks. After 1 year of follow-up, 36% of patients who responded by 12 weeks subsequently relapsed, with no differences in relapse rates between the four treatment groups. In addition, Hollon et al. (1992) randomized 107 patients with unipolar, nonpsychotic depression to pharmacotherapy with or without continuation, CBT, and combined CBT/pharmacotherapy. These authors found all three treatments effective but not significantly different from each other.

In terms of maintenance treatment, the University of Pittsburgh conducted an important study of patients with recurrent depression (Frank et al. 1990, Kupfer et al. 1992). In this study, all patients were initially treated with a combination of IPT and imipramine until their HRSD was 7 or less, which was then required to be maintained for 17 weeks. After this stabilization, the 127 eligible patients were randomized to receive combination imipramine and IPT, imipramine plus clinical management, IPT plus placebo, IPT alone, or placebo plus clinical management. Relapse was defined as an elevation in HRSD to 15 or more and the diagnosis of a new depressive episode. Followed over 3 years, patients receiving imipramine had the lowest relapse rates, with no difference between imipramine plus clinical management and imipramine plus IPT. IPT alone showed a trend toward better outcomes compared to placebo but was significantly less effective than imipramine (3-year recurrence rate of 61.5% compared to 20%).

Paykel and colleagues (1999) and Scott et al. (2000) randomized 158 patients with recent major depression that had partially remitted to antidepressant treatment after at least 8 weeks of treatment. At the beginning of the study, 60% of patients were receiving selective serotonin reuptake inhibitors (SSRIs) and 40% were receiving tricyclic antidepressants. During the treatment phase, patients received continuation antidepressants at the same dose and were randomized to receive 16 sessions of CBT and clinical management over 20 weeks or clinical management alone for 20 weeks. Patients then entered a follow-up period, during which ratings, antidepressants, and clinical management were continued, for an additional 48 weeks. The investigators found that patients receiving CBT had significantly higher remission rates at the end of 20 weeks compared to the clinical management group (25% vs. 13%, respectively). During follow-up, patients in the CBT group relapsed at significantly lower rates (29%) than did patients in the clinical management group (45%).

The results of these studies illustrate that little evidence supports the superiority of combined treatment with medications and psychotherapy over monotherapy with either medication or psychotherapy. Few studies have found
a significant benefit of combined treatment, and many more have found either no significant difference with monotherapy or even that monotherapy was significantly superior.

In response to this, some researchers have argued that the lack of evidence for superiority of combined treatment with medications and psychotherapy results from studies that were inadequately powered to detect more modest effect sizes. More recent, larger studies of combination treatment with psychotherapy and medications have found combined treatment superior to monotherapy with either treatment. In a large trial published in the *New England Journal of Medicine*, Keller and colleagues (2000) randomized nearly 700 adults with chronic major depressive disorder to 12 weeks of nefazodone, 16–20 sessions of the cognitive behavioral analysis system of psychotherapy (CBASP), or both. Combined treatment had a 73% response rate, which was significantly better than treatment with psychotherapy (48%) or medication (48%) alone. Rates of discontinuation were low and not significantly different between the treatment cells in the acute phase of the study.

Combined treatment studies of children/adolescents and the elderly are sparse. *The Treatment for Adolescents with Depression Study* (TADS), a multicenter RCT, enrolled 439 outpatients aged 12–17 years with major depressive disorder (TADS Team 2004). Subjects were randomized to receive 12 weeks of CBT alone, fluoxetine alone, combined CBT and fluoxetine, or pill placebo. Primary outcome measures were change in Children's Depression Rating Scale-Revised (CDRS-R) score and a dichotomized CGI score (responder or nonresponder). Combined treatment was superior to all other cells on the CDRS-R, while it was superior to CBT alone and placebo and not significantly different from fluoxetine alone on the CGI. Fluoxetine alone and CBT alone failed to separate from placebo on CDRS-R scores, but each was superior to placebo on dichotomized CGI score. Fluoxetine alone was significantly superior to CBT alone on both primary outcome measures. The authors concluded that “the combination of fluoxetine with CBT produced the greatest improvement in symptoms of MDD (p. 816).”

In a study enrolling 102 patients with late life depression, Thompson and colleagues (2001) compared desipramine to CBT and combined CBT/desipramine. Patients received 16–20 CBT sessions if they were assigned to one of the psychotherapy conditions, and they received a mean dose of desipramine of 90 mg, which produced therapeutic mean blood levels of 123 ng/ml. Significant improvements in HRSD scores were observed across the three treatment conditions, while improvements in BDI scores were only significant for the CBT and combined treatment conditions. Breaking down the treatment sample based on depression severity, the authors concluded that combined treatment was most effective for severely depressed patients, while CBT alone could be an effective treatment for older patients with mild-to-moderate depressions.

Additionally, Reynolds et al. (1999) compared a combination of nortriptyline and IPT, nortriptyline alone, IPT plus placebo, and placebo alone in 84 elderly outpatients with bereavement-related depression. They found a significant drug effect, with 69% of patients in the combined treatment group and 56% of nortriptyline-only patients remitting over the 16-week study. Patients treated with IPT plus placebo did not differ from patients in the placebo-only group. The rate of relapse into major depression over the 16-week follow-up period was low and not significantly different across the four treatment groups.

Another relatively understudied area regards combinations of medication and psychotherapy other than IPT or CBT. Burnand et al. (2002) randomized 74 adults with major depression to 10 weeks of clomipramine or clomipramine combined with psychodynamic psychotherapy. Both groups of patients experienced significant improvement in their depression as measured by the HRSD, with no significant differences found between the two treatment conditions. However, patients in the combined clomipramine and psychodynamic psychotherapy treatment cell had significantly higher posttreatment GAS scores, lower rates of hospitalization, and fewer lost days of work due to illness than patients treated with clomipramine alone.

Psychotherapy, medication, and their combination have been relatively less studied in dysthymia. In one notable study, Ravindran et al. (1999) compared treatment with sertraline, pill placebo, group cognitive behavior therapy (GCBT) plus placebo, and sertraline plus GCBT in adults with dysthymia. They found sertraline and combined treatment superior to GCBT plus placebo and placebo alone, but sertraline and combined treatment were not different from one another. Browne et al. (2002) compared sertraline, brief IPT, and their combination in almost 700 patients in primary care, finding that sertraline alone and combination treatment were superior to IPT alone and not significantly different from one another.

In sum, while some larger studies have succeeded in showing significant differences in favor of combined treatment compared to monootherapy, the data remain mixed (Table 113–2). Given how frequently combined treatments are advocated for the treatment of depression and the relatively greater investment of resources they require, these results compel further research in studies with sample sizes large enough to detect small-to-medium effect sizes in favor of combined treatment (APA 2006a, 2006b).

**Anxiety Disorders**

Many combination studies have been performed in panic disorder. For instance, Marks et al. (1993) compared treatment with alprazolam and exposure therapy, each alone and combined, in patients with panic disorder and agoraphobia. Relaxation treatment served as a psychological placebo, so patients were randomized to one of four groups: alprazolam plus exposure therapy, alprazolam plus relaxation, pill placebo plus exposure therapy, and pill placebo plus relaxation. Over the 8 weeks of acute treatment, patients in each treatment condition experienced significant improvement of their panic symptoms as measured by 10 separate rating scales, and there were no between-group differences observed.

In another study, Barlow et al. (2000) randomly assigned 312 patients with panic disorder to receive imipramine up to 300 mg per day, pill placebo, CBT alone, CBT plus imipramine, or CBT plus pill placebo. Patients were treated weekly for 12 weeks in the study’s acute phase, then were seen monthly in the study’s maintenance phase, and were seen 6 months after follow-up. The investigators found both imipramine alone and CBT alone were superior to placebo on the Panic Disorder Severity Scale (PDSS),
with no significant differences found between CBT alone and imipramine alone. Combined treatment with CBT and imipramine did not result in higher response rates on the PDSS compared to CBT plus placebo, CBT alone, or imipramine alone. Furthermore, combined treatment did not result in significantly lower relapse rates compared to the other treatments.

The Pediatric OCD Treatment Study (POTS) is a multicenter RCT of 112 adolescent outpatients with OCD and a CY-BOCS score of 16 or higher (POTS Team 2004). Subjects were randomized to CBT alone, sertraline alone, combined CBT and sertraline, and pill placebo, while blinded raters assessed subjects’ CY-BOCS score and remission status at 4, 8, and 12 weeks. The study investigators found combined CBT and sertraline superior to CBT alone, sertraline alone, and placebo, while CBT alone and sertraline alone were each superior to placebo but not different from one another. They concluded that “children and adolescents with OCD..."
Meta Analyses

A number of meta-analyses have combined data from individual trials to investigate combined psychotherapy and medication for depression. In one of the first such quantitative reviews, Conte et al. (1986) analyzed 17 reports of 11 studies containing a combined psychotherapy and medication treatment cell and at least one comparison group for nonpsychotic unipolar depression. They designed a rating scale for determining the quality of study design and combined disparate psychotherapies and medications for the purposes of analysis. They found that combined treatment was slightly but consistently superior to monotherapy with either psychotherapy or antidepressant medication. However, an unusual statistical method of weighting studies was employed that leads to questionable interpretation of results.

Thase et al. (1997) reanalyzed data from 595 patients with major depressive disorder enrolled in six standardized protocols between 1982 and 1992. Each individual study provided 16 weeks of treatment with CBT, IPT, or combined IPT and antidepressant treatment, and the primary outcome measure examined was remission of depression as determined by HRSD < 7 at study endpoint. They found a remission rate of 37% for psychotherapy alone compared to 48% with combined therapy, which was not a significant difference. However, in a subanalysis of severely depressed patients, combined treatment was found to be significantly more effective than psychotherapy alone (43% vs. 25%). Furthermore, combined therapy was associated with significantly shorter times to remission of depression.

Pampalona et al. (2004) reviewed the literature to find RCTs comparing antidepressant treatment alone to the combinations of antidepressants and psychotherapy for the treatment of depressive disorders. They included 16 RCTs, in which a total of 932 patients were randomized to antidepressants alone and 910 to combined treatment. Psychotherapy interventions included CBT, IPT, psychodynamic psychotherapy, marital therapy, social skills training, and problem-solving training. The authors found that combined treatment with psychotherapy and medication had a significant advantage over treatment with antidepressants alone. Patients receiving combined treatment were nearly twice as likely to experience depression response compared to antidepressants alone (odds ratio 1.86, 95% CI, 1.38–2.52).

Meta-analysts have also evaluated combined treatments for anxiety disorders, such as panic disorder. Furukawa et al. (2006) examined 23 RCTs comparing combination treatment to monotherapy with antidepressants or psychotherapy for panic disorder. For acute-phase treatment, combination therapy was more likely to produce panic response than antidepressants (relative risk of response 1.24, 95% CI, 1.02–1.52) or psychotherapy alone (relative risk of response 1.16, 95% CI, 1.03–1.30).

Van Balkom et al. (1994) examined pharmacotherapy and psychotherapy treatments for OCD and reported that serotonergic antidepressants, BT, and combination treatment were each more effective than placebo. BT and combination BT/medication were significantly more effective than medication alone, while not being different from one another. Abramowitz (1997) evaluated published reports of psychological treatments (ERP, BT, and CBT) and pharmacotherapy for OCD. ERP and CBT were found to be similarly effective and more effective than relaxation therapy in relieving the symptoms of OCD, while serotonergic medication (clomipramine most robustly) was more effective than placebo.

Augmentation Strategies for Nonresponders: Is Adding Another Treatment Modality Helpful When Patients Do Not Respond to Treatment with the First?

Depressive Disorders

In one of the earliest augmentation treatment studies, Klerman et al. (1974) randomized 150 depressed women who improved after 4–6 weeks of open treatment with 100–200 mg daily amitriptyline to weekly IPT alone, continued amitriptyline alone, combined IPT and amitriptyline, and placebo with no psychotherapy. They found similar relapse
rates of depression in all of the active treatment conditions (12% amitriptyline, 12.5% combination treatment, and 16.7% IPT alone), with placebo having the highest relapse rate (36%). The general absence of large effect sizes in favor of combined treatment observed in this study would continue in later studies of acute treatment.

A unique perspective on the use of medications and psychotherapy to treat depression has been provided by the NIMH-sponsored Sequenced Treatment Alternatives to Relieve Depression (STAR*D) study, which is the largest prospective trial for depression ever conducted. Patients presented to one of 41 sites seeking treatment, and inclusion/exclusion criteria were structured so as to promote maximum generalizability. All 3271 patients received monotherapy with citalopram in Level 1, and those whose depressions did not remit were encouraged to proceed with additional trials until remission was achieved. At Level 2, patients were allowed to express preferences for medication vs. psychotherapy and switching treatments vs. augmenting. Switch options comprised bupropion, sertraline, venlafaxine, and CBT, while augmentation options comprised adding bupropion, buspirone, or CBT to citalopram. Patients whose depressions still did not remit could be randomized at Level 3 between two switch options (nortriptyline or mirtazapine) or two augmentation options (adding lithium or T3 to whatever antidepressant they were taking). The final step, Level 4, involved randomizing patients to tranylcypromine or the combination of venlafaxine and mirtazapine.

After initial treatment with citalopram, 37% of patients were in remission from their depression (Trivedi et al. 2006b). Level 2 results for the switch (Rush et al. 2006) and augmentation (Trivedi et al. 2006a) options followed. Patients who switched medications received bupropion SR up to 400 mg daily, sertraline up to 200 mg daily, or venlafaxine XR up to 375 mg daily. Remission rates as measured by HRSD < 7 on these medications were 21.3%, 17.6%, and 24.8%, respectively, which were not significantly different from one another. Augmentation of citalopram was with bupropion SR up to 400 mg daily or buspirone up to 60 mg daily, and remission rates as measured by the HRSD were not significantly different (29.7% and 30.1%, respectively). In the Level 3 augmentation trial, 15.9% of patients achieved remission with lithium compared to 24.7% of patients receiving T3, which was not a significant difference (Nierenberg et al. 2006). However, there was a suggestion that T3 was better tolerated than lithium. Likewise, in the Level 4 trial, 6.9% of patients receiving tranylcypromine and 13.7% of patients receiving combined venlafaxine and mirtazapine remitted, which were not significantly different (McGrath et al. 2006).

Interestingly, only 26% of participants entering Level 2 found assignment to the augmentation or switch options including CBT acceptable (Thase et al. 2007). As a result, only 147 patients were assigned to CBT in Level 2. The authors found that augmentation of citalopram with CBT resulted in a depression remission rate of 23.1%, which was not significantly different from the rate observed with augmentation with bupropion or buspirone (33.3%). Switching to CBT after unsuccessful treatment with citalopram resulted in a 25.0% remission rate, compared to 27.9% after switching to sertraline, bupropion, or venlafaxine (no significant difference). However, the authors did note that pharmacologic augmentation resulted in faster speed of depression response, and patients appeared to tolerate treatment with medication or CBT equally well.

**Methodological Issues in Combined Treatment Studies**

In pharmacotherapy trials, randomized, a pill placebo comparison group, and double blinding ensure that potential confounders and nonspecific factors (such as health-care provider attention, patient expectations, and spontaneous remission) associated with every experimental treatment are equivalent between groups. These methods allow researchers to demonstrate that the effects observed are due to the specific effects of the treatment being studied rather than due to incidental factors associated with the treatment. Moreover, the inclusion of a placebo condition allows one to interpret differences observed between treatment cells, since in the absence of placebo control, one would not know whether two treatments showing similar results were equally effective or equally ineffective (Klein 1997).

A major difficulty in comparing psychotherapy, medication, and combined treatment is introduced by the absence of a psychotherapy placebo condition. Without such a placebo, it is impossible to conduct the optimal study of combined treatment, which would be a four-cell study comparing psychotherapy plus medication, psychotherapy plus pill placebo, psychotherapy placebo plus medication, and psychotherapy placebo plus pill placebo. Such a study would answer many questions, including the efficacy of medication or psychotherapy alone, the relative efficacy of the two treatments, and the value of adding one treatment to the other. Since no adequate psychotherapy placebo condition has been established, investigators have resorted to comparing placebo-controlled medication treatment to the open administration of psychotherapy.

In the TADS discussed above, adolescents with major depression were randomized to CBT alone, fluoxetine alone, combined CBT and fluoxetine, and pill placebo (TADS Team 2004). The benefit of this design is that the study can be “internally calibrated,” meaning differences between the psychotherapy and medication conditions can be more easily interpreted when it is known whether or not the medication treatment condition was effective compared to placebo. However, the study compares blinded treatments (fluoxetine or pill placebo) to unblinded treatments (CBT and combined CBT and fluoxetine). In other words, patients in the CBT-alone condition knew that they were receiving psychotherapy (active treatment), while patients taking pills did not know whether they were fluoxetine (active) or placebo (inactive). Similarly, patients in the combined cell knew that they were receiving two active treatments rather than one (CBT alone) or possibly none (fluoxetine and pill placebo).

Recent studies suggest that comparisons between unblinded and blinded treatments may be flawed. Sneed et al. (2007) recently examined how antidepressant response rates differ between placebo-controlled (i.e., active vs. inactive treatment) and comparator (i.e., active vs. active treatment) trials for late-life depression. Patients in comparator trials know that they are receiving a medication without knowing the exact agent, while patients in placebo-controlled trials do not know whether they are receiving an active
medication. Sneed et al. found that the odds of being classified as a responder in comparator trials were nearly two times the odds of responding in the placebo-controlled trials. The estimated probability of response in placebo-controlled trials was 0.46 compared to 0.63 in comparator trials.

Rutherford et al. (2007) followed up on these results in a systematic analysis of clinical trials of antidepressants for major depression in adults aged 18–65 years. Response and remission rates to antidepressant medications were compared across placebo-controlled and comparator trials. In the 48 placebo-controlled and 42 comparator trials examined, the odds of being classified as a responder to medication in comparator trials were 1.8 times the odds of being classified as a responder in placebo-controlled trials (95% CI = 1.45–2.17, p < 0.001), and the odds of being classified as a remitter to medication in comparator trials were 1.5 times the odds of being classified a remitter in placebo-controlled trials (95% CI = 1.11–2.11, p < 0.001). The estimated probability of response to medication in placebo-controlled trials was 0.52, as compared to 0.65 in comparator trials.

These results demonstrate that antidepressant response and remission rates are lower when patients do not know that they are receiving active treatment (i.e., placebo-controlled trials) vs. when they know that they are receiving medication without knowing the exact agent (i.e., comparator trials). This situation is relevant to the open and blinded administration of treatments given to patients in many combined medication and psychotherapy studies. It appears that clinical trials comparing open to blinded treatments are significantly biased against the blinded treatment (i.e., placebo-controlled medication). Since most studies comparing mediation and psychotherapy have included a placebo treatment condition (e.g., the TADS study), the possibility exists that the current literature may underestimate the effect of medications compared to psychotherapy and combined treatment. These studies need an open medication treatment cell in order to correct this bias.

Future Combined Treatment Studies
Some important questions cannot be answered from the results of studies using current clinical trials methodology. First, the efficacy of psychotherapy cannot be definitively determined, since the absence of a psychotherapy placebo rules out performing a double-blind, randomized clinical trial comparing psychotherapy to psychotherapy placebo. Rather, the effectiveness of psychotherapy and combined medication/psychotherapy can only be judged relative to comparison groups. As discussed above, one must avoid confounding such a study by comparing openly administered psychotherapy to placebo-controlled treatment with medication. Placebo-controlled treatments can only be validly compared to other placebo-controlled treatments, as occurs in a three-cell study of two medications and pill placebo with treatment allocation concealed. Known active treatments can only be compared to other active treatments, such as a study of one medication vs. another (without a placebo cell), one psychotherapy vs. another, or psychotherapy vs. medication (without a placebo cell).

For studies including medication and psychotherapy treatment cells, all treatments must be administered openly, which allows one to answer the question of whether combined treatment is superior to monotherapy with either psychotherapy or medication. There is an excellent example of such a study design, namely the three-cell design of Keller et al.’s (2000) study of combined psychotherapy/nefazodone vs. nefazodone and psychotherapy alone. Interestingly, this study has provided some of the most compelling data to date showing the value of combined treatment for depression over monotherapy, but it also took place in a special population of chronically depressed patients.

However, it is possible to determine whether adding medication to treatment with psychotherapy is beneficial. In a study comparing psychotherapy plus pill placebo, psychotherapy plus medication, medication, and pill placebo, the medication vs. pill placebo comparison allows one to determine whether the sample studied was medication responsive and supports the validity of the study’s methods. If medication is found to be superior to placebo, then the comparison of psychotherapy plus medication to psychotherapy plus pill placebo allows one to determine the value added by combined treatment relative to psychotherapy alone. An example of this study design is the Reynolds et al. (1999) study discussed above, which compared a combination of nortriptyline and IPT, nortriptyline alone, IPT plus pill placebo, and pill placebo alone in 84 elderly outpatients with bereavement-related depression. It should be apparent that the lack of a psychotherapy placebo condition makes it the case that one cannot determine whether it is helpful to add psychotherapy to treatment with medication. Additionally, fair comparisons cannot be made between the psychotherapy and medication/ placebo cells due to the problems of comparing open and placebo-controlled treatments.

Future clinical trials of medication, psychotherapy, and combined treatment must heed the limitations discussed above, in order to avoid confounding their results. Experimental treatments include factors that may affect patient outcome beyond the specific effect of the treatments under study. In order to validly compare specific treatment effects, all variables beyond these specific treatment effects must be controlled and standardized across the treatments being compared. In particular, since the open vs. placebo-controlled administration of the same treatment may affect patient outcomes, blinding (i.e., what patients, doctors, and outcome raters know about the treatment received by the patient) must be the same for all treatments in a research study.

Technical Considerations in Doing Combined Treatment
Evaluating a patient with depressive or anxiety disorders, reviewing the empirical evidence for different medication classes and psychotherapeutic modalities, and deciding to recommend combined treatment are only the beginning of the clinician’s task when treating such a patient. Clinicians must then execute the treatments recommended, which can present unique challenges due to the use of multiple treatment modalities for a single patient. How does one actually do combined treatment with medications and psychotherapy? To begin a discussion of the techniques and strategies for doing combined treatment, it is helpful to be aware of the three issues arising in nearly all combined treatments. What follows is meant to be generally applicable to all psychotherapeutic modalities and patient disorders.
Deciding Whether to Initiate Combined Treatment—the Mind of the Therapist

When conducting a diagnostic evaluation of a psychiatric patient, psychiatrists learn about the extent and development of the presenting symptoms, as well as the patient’s personal and developmental history. As yet, we do not definitively know the etiology of the symptoms—we can only know what symptoms are present and make inferences about potential etiologies. In constructing a treatment plan, we can offer the patient our expertise regarding which treatments are known to best treat the symptoms, character traits and/or interpersonal difficulties that have brought the patient to treatment.

Nevertheless, we are influenced in our treatment recommendations by our hypotheses about the etiologies of our patients’ symptoms, and these hypotheses are in turn influenced by many factors; our training, clinical and personal experiences, and exposure to research studies are all powerful influences. Being aware of these potential influences on our thinking about differential therapeutics broadens the range of potential treatment options and helps avoid clinician bias.

Deciding Whether to Initiate Combined Treatment—One or Two Disorders?

There are two different types of clinical situations for which combined treatment may be recommended:

- Combined treatment may be prescribed for a single disorder. For example, combined treatment with medication and CBT is a common treatment plan for major depressive disorder. An analogy to internal medicine might be the use of diet and blood pressure medication to control hypertension in a person at risk of myocardial infarction.
- In the second situation, two types of treatment may be used for a single individual because two different disorders are being treated. For example, a patient who is being treated with psychodynamic psychotherapy for chronic maladaptive character patterns may have generalized anxiety disorder for which medication is prescribed. In this case, two treatment modalities are being used simultaneously without being combined treatment for the same disorder, even though the disorders may be related. This is analogous to the combined use of an antihypertensive and a cholesterol-lowering agent in the treatment of two cardiac risk factors.

It is important for both the practitioner and the patient to understand whether the combined treatment is for one or two (or more) disorders, not only to best inform the patient about his/her treatment, but also because it may direct the way in which the treatment is optimally conducted. A combined treatment that has been shown to be effective for a single entity may be optimal only when the medication and psychotherapy are conducted simultaneously; on the other hand, if two disorders are being treated, sequential treatment might be optimal (see below for further discussion of simultaneous vs. sequential treatment). It is also important for the clinician to at least consider the idea that the two different disorders may ultimately be shown to be part of the same syndrome. For example, a patient who is being treated with medication for anxiety and psychotherapy for borderline personality disorder may exhibit fewer borderline traits once his/her anxiety is properly medicated.

Deciding Whether to Initiate Combined Treatment—Simultaneous or Sequential Treatment?

As discussed above, different clinical situations may call for different ways of conducting a combined treatment. One choice involves whether to administer both forms of treatment simultaneously or whether to sequence them. Again, this will depend in large part on whether it is the simultaneous administration of the psychotherapy and medication that has been shown to make the combination an effective treatment. When the two modalities are treating different disorders, sequential treatment may often be preferable. This is often true when symptoms of a severe affective or anxiety disorder may make engagement in psychotherapy difficult.

For example, a patient who presents with symptoms of major depression in the setting of a string of poor relationship choices may be best treated by sequencing the treatment. Here, pharmacologic treatment for the major depression needs to begin immediately, but the patient may be better able to engage in psychotherapy after his/her depressive symptoms have at least partially resolved. Sequencing treatments may also be helpful diagnostically. The patient who seems to have chronic self-esteem issues, who is having symptoms of a depression, may have fewer issues with esteem once out of the throes of the affective disorder, since feelings of low self-esteem can be a symptom of depression.

It should be noted that sequential treatment is often used in other areas of medicine, whether in a planned fashion (i.e., chemotherapy regimens) or due to the failure of one medication to provide the desired outcome (i.e., antibiotics). Fava (1999) has outlined four psychiatric applications of sequential treatments: (1) changing the orientation of psychotherapy when the first orientation has not achieved treatment goals, (2) switching antidepressants or augmenting treatment when the first medication has not resulted in adequate symptom relief, (3) introducing psychotherapy when medication alone has not been completely effective, (4) starting medication when psychotherapy alone has not been completely effective (Fava 1999).

Technical Considerations

Once the clinician and the patient decide together that the optimal treatment for the patient is combination treatment with psychotherapy and medication, the next question is which treatment model to use to best effect the treatment plan. There are three basic models for the use of combined treatment in clinical practice:

- The one practitioner model—one psychiatrist administers both medication and psychotherapy to the patient.
- The split treatment model—two practitioners treat the patient—one administers psychotherapy and one is the psychopharmacologist.
- The consultant model—one psychiatrist is the primary practitioner, administering both psychotherapy and medication, but a consultant is involved to add expert advice and to potentially see the patient on an as-needed basis.
Each of these models may be more or less appropriate for different clinical situations, and each has a unique profile of benefits and drawbacks. These models are applicable to any type of psychotherapy—CBT, IPT, DBT, supportive psychotherapy, behavioral therapy, and psychodynamic psychotherapy. It is important for the clinician to be well versed in the characteristics and logistics of each of these models and to have a clear sense of how to choose among them.

Choosing a Treatment Model for Combined Treatment with Medication and Psychotherapy

If the practitioner decides that combined treatment is the optimal approach, then determining which treatment model to use is an essential part of designing the treatment plan and should be an active choice on the part of the clinician and the patient. Too often, psychiatrists assume that a single clinician will administer both medication and psychotherapy, or, conversely, that the treatment will be split. While the decision is based on multiple factors, it can be carefully thought through; the following algorithm is a guide to best effect the optimal treatment plan.

What Are the Clinician’s Clinical Strengths?

In choosing the appropriate treatment model for combined treatment with medication and psychotherapy, the clinician must first assess his/her clinical strengths. Some psychiatrists feel that they are well trained in psychopharmacology but not in psychotherapy. Others may be more confident of their psychotherapy skills. Some practitioners who frequently practice combined treatment may feel that they are not knowledgeable about the particular type of psychotherapy appropriate for a specific patient. A psychiatrist who routinely prescribes medication may still recommend a medication with which he/she is relatively unfamiliar. In constructing the treatment plan that best serves the patient, the clinician will do well to be honest about his/her capacity to administer the treatment that is optimal for the patient.

Will Either Treatment Modality be Compromised if Administered by the Same Clinician?

Even if the clinician feels capable of delivering each type of treatment that is appropriate in a given clinical situation, the clinician may not feel able to administer them concomitantly to the same patient. For example, a clinician may decide that techniques that are important for good pharmacologic management, such as giving opinions, talking to family, and monitoring vital signs, would interfere with his/her ability to maintain an appropriate therapeutic stance in a psychodynamic treatment. Similarly, clinicians conducting certain manual-driven treatments, such as CBT, might decide that ongoing pharmacologic management would be to intrude unproductively on the work of the sessions. In weighing this consideration, the clinician needs to clearly delineate the optimal working conditions for helping the patient to receive the best possible psychotherapy and psychopharmacologic care.

Possibilities:

- The clinician may elect the split treatment model if the technique required for one treatment modality would render the technique for another modality suboptimal.
- The clinician may elect the consultant model if these difficulties are periodic in the treatment.

Are There Reasons Why the Treatment Should Not Be Split?

In some circumstances, the practitioner may feel that a split treatment would jeopardize the quality of the treatment. For example, patients who tend to idealize and devalue different members of the treatment team (e.g., some patients with borderline personality disorder) might be better served by having one clinician administer both the psychotherapy and the medication, since this can jeopardize the essential communicative link between clinicians and sabotage the treatment. Patients behaving in such a way are often best treated by a single clinician in order to minimize the potential for manipulation and to keep all of the information in one treatment setting. A clinician who needs assistance in this situation may seek consultation rather than splitting the treatment. Another situation might be one in which the medication has to be monitored closely, such as on a weekly basis. This might be true for any unstable patient, such as a rapidly cycling bipolar patient or a patient with affective instability and borderline personality disorder.

Does the Patient or Clinician Have Preconceptions about Combined Treatment that Should Be Addressed to Optimize Clinical Decision Making?

The clinician who is considering combination treatment with psychotherapy and psychopharmacology needs to be well versed in the myriad preconceptions that this situation engenders in both doctor and patient. These may include (but are not limited to) the following:

**Patient:**

- Since I am going to a psychiatrist, he/she should be able to administer all of the treatment.
- Psychiatrists do not know how to conduct psychotherapy.
- If my psychiatrist refers me to another clinician for part of the treatment, it is because he/she is not particularly interested in my case.

**Clinician:**

- As a psychiatrist, I should be able to administer all types of treatments to my patients without having to split the treatment.
- Administering medication to a patient in psychotherapy is no different than administering medication to a patient who is not in psychotherapy.
- My patient will think that I am not competent if I bring another clinician into the treatment plan to split the treatment or to act as a consultant.

If unaddressed, thoughts and feelings such as these can erroneously guide treatment decisions, often leading the clinician to choose a treatment model for inappropriate reasons.

What Is the Patient’s Preference?

When patient and clinician begin a treatment, both participants have opinions about how the treatment should be conducted. Aside from preconceptions about the treatment, patients may have realistic preferences about
whether the treatment should be conducted with a single practitioner or as a split treatment. If the practitioner feels that he/she does not have the skills to offer both the psychotherapy and the medication, the patient may prefer to be referred to a practitioner who is able to offer both treatments. If the practitioner thinks that the one practitioner model would be either optimal for this patient or at least equal to a split treatment, the option of referring to another practitioner should be offered as an option to the patient.

Are There Logistical and/or Financial Considerations That Need to Be Taken into Account?

Although choosing a treatment model for administering combined treatment should be based primarily on clinical considerations, there are often logistical and financial considerations that need to be taken into account. These occur in the following types of situations:

• The clinician may be the only practitioner who is geographically near the patient.
• The clinician may be working in a managed care situation.
• The patient may not be able to afford to see more than one clinician at a time.
• The patient may be more able to afford psychotherapy with a non-MD practitioner.
• The pharmacologic treatment must be affordable enough for the clinician to be able to see the patient as often as necessary.

In these situations, the clinician and the patient need to choose options for the clinical situation that optimize the treatment plan within the context of the logistical and/or financial constraints.

Summary

The clinician can use these six basic points as a simple algorithm for making decisions about which treatment model to choose for administering combined treatment with medication and psychotherapy.

Treatmen Models for Combined Treatment with Medication and Psychotherapy

Each model for combined treatment with medication and psychotherapy is uniquely suited to particular clinical situations. Each has advantages and disadvantages, as well as characteristic transfers and countertransfers that are commonly encountered. In what follows, three models for combined treatment are discussed.

The One Practitioner Model

The psychiatrist/clinician has a unique position among mental health professionals in that he/she may elect to administer combined treatment without splitting the treatment. This allows the clinician to not only construct an integrated, multimodal treatment plan, but also to conduct an ongoing treatment that includes many treatment modalities simultaneously. This can be an advantage when the clinician is trying to parse out whether a given symptom is best treated pharmacologically or psychotherapeutically. If one clinician is administering both treatments, he/she can decide on an ongoing basis about therapeutic options. Additionally, the patient in psychotherapy is generally seen on a weekly or multiple-time per week basis, which can allow the clinician to notice changes in symptomatology and medication side effects and rapidly make adjustments.

These advantages are balanced, however, by the potential pitfalls inherent in trying to “wear two hats” while treating the patient. Each treatment modality—psychotherapy and psychopharmacology—is challenging to administer and takes time. A psychopharmacologist is trained to carefully monitor both symptoms and side effects on a regular basis (often using structured interviews or scales), check vital signs, and suggest changes in the medication regimen when needed. If the visits are also devoted to psychotherapy, the clinician may be working in a managed care situation, the clinician may be the only practitioner who is geographically near the patient, the patient may not be able to afford to see more than one clinician at a time, the patient may be more able to afford psychotherapy with a non-MD practitioner, the pharmacologic treatment must be affordable enough for the clinician to be able to see the patient as often as necessary.

In these situations, the clinician and the patient need to choose options for the clinical situation that optimize the treatment plan within the context of the logistical and/or financial constraints.

Vignette

Ms. T is a 27-year-old single woman who presented to Dr. B with symptoms of anxiety and depression 3 weeks after being fired from her job. Her symptoms included insomnia, low self-esteem, difficulty concentrating, tearfulness, and occasional panic attacks triggered by things that reminded her of her boyfriend. Although she had never seen a psychiatrist before, she had been persuaded to seek a consultation by her mother, who was being successfully treated with a combination of psychotherapy and medication for an unclear affective disorder. In the initial visit, Ms. T told Dr. B about her current symptoms, as well as her lifelong history of anxiety, including childhood separation anxiety and chronic social phobia. In addition, Ms. T explained that she was in the middle of her parents’ very contentious divorce. She no longer knew which parent was right or whether either of them had her best interests at heart. In response to Dr. B’s questions about her usual patterns of adaptation, Ms. T described a life-long pattern of losing self-esteem during interpersonal crises. There was also some suggestion of chronic difficulties with anxiety and affect regulation. Dr. B both diagnosed a major depressive disorder and suspected that an anxiety disorder was present prior to the current illness. He prescribed escitalopram 10 mg per day and also suggested to Ms. T that she begin once-weekly supportive psychotherapy to address symptoms of depression as well as her chronic issues related to self-esteem management.

In the third week of treatment, when Ms. T was still on 10 mg of escitalopram, she called Dr. B saying that she was having a strange reaction to the medication. She felt that her thoughts were racing and that she could not concentrate. She also described odd sensations running through her arms. Dr. B felt that this was most likely increased anxiety after starting the SSRI; however, he was also concerned about possible hypomania. He was relieved to see her the next day, when she displayed no evidence of hypomania—her speech was normal in rate and rhythm, and she was interruptible. She did seem anxious, and on further questioning, akathisia seemed likely. Dr. B recommended low-dose clonazepam and suggested that Ms. T decrease the escitalopram and titrate up more slowly. The symptoms resolved, but Ms. T continued to have tremendous sensitivity to medication changes, which Dr. B was able to address swiftly since he was seeing her on a weekly basis. This prevented breaches in the pharmacologic treatment and helped Dr. B to diagnose the symptoms.
when does or should the pharmacologic management take place? Often, it is discussed “on the fly,” either before or after the “real” content of the session occurs. Once a satisfactory medication regimen is established, the clinician and patient may “forget” about the medication and not discuss the pharmacologic treatment, despite the fact that the clinician is still prescribing medication for the patient. This can lead to many things being overlooked, such as changes in symptoms, side effects, and opportunities to discontinue medication after an appropriate amount of time.

The clinician who elects with the patient to use the one practitioner model must be aware of these potential pitfalls and must construct ways of working with the patient that do not slight either treatment modality. It is important to remember that even though the clinician and patient may elect one model as part of the initial treatment plan, this can change during the course of the treatment. For example, if a patient’s medication management becomes very complicated, the clinician and patient may elect to switch to a split treatment so that each modality has adequate time devoted to it, or to temporarily involve a consultant until stability is once again achieved. Avoidance of one or the other treatment modality in a combined treatment should signal to the clinician that something is amiss in the balance of the treatment.

As illustrated in the above vignette, use of the one practitioner model for combined treatment may also present challenges for the delivery of psychotherapy. Time spent in medication management may detract from valuable session time that could be spent in psychotherapy. In addition, techniques used by the pharmacologist may present a challenge to the psychotherapist who is attempting to maintain technical neutrality as part of the psychotherapy, or who is trying to listen with evenly hovering attention. Good pharmacologic treatment is often quite goal-directed—the pharmacologist has specific questions that he/she needs to address at each visit and cannot simply wait to see if certain topics are brought up by the patient.

This may present a challenge for psychotherapists who also prescribe medication. Each practitioner needs to decide for him/herself how to work in both modalities if choosing the one practitioner model. Rather than practicing standard psychopharmacologic management, clinicians may modify their psychotherapeutic approach while discussing medication management. This is essential regardless of the psychotherapy type—it is as true for CBT or IPT as it is for psychodynamic or supportive psychotherapy. This type of discussion may also enhance the clinician’s understanding of the patient’s mind rather than detracting from the treatment.

The Split Treatment Model

Perhaps due to reimbursement mechanisms, much of the combined treatment that is currently practiced today occurs in the split treatment model. Treatments may be split for many reasons including the following:

- The patient’s therapist is not an MD.
- The practitioner may not feel competent in both treatment modalities.
- The practitioner may feel that one or the other treatment would be compromised if they were administered by a single practitioner.
- Logistical and/or financial considerations (such as payment by a managed care company) may dictate that the psychiatrist can only be paid for part of the treatment.

Splitting the treatment can often free up each practitioner to concentrate solely on one treatment modality. Unlike the practitioner in the one practitioner model, the therapist or pharmacologist need only focus on that treatment modality when meeting with the patient. However, effective split treatment necessitates that both practitioners consider the ways in which things that the patient reports might be related to the other treatment modality. For example, a patient’s worsening symptoms reported to a psychopharmacologist might be related to something that is happening in the patient’s psychotherapy, while increased irritability or anxiety reported to a therapist might be best treated with a medication.

Communication between the clinician prescribing medication and undertaking a patient’s psychotherapy is essential, especially since these clinicians may have different professional backgrounds. Most frequently, psychiatrists serve the pharmacologic role, while psychologists, social workers, or licensed therapists serve as the patient’s psychotherapist, but many more arrangements are possible. For instance, psychiatrists treating patients with psychotherapy or psychiatric consultation may also elect to have their patients’ pharmacologic treatment managed by another psychiatrist. Additionally, primary-care physicians are now prescribing psychotropic medications with increasing frequency. In such a situation, it is important for the mental health professional undertaking psychotherapy to communicate with the internal medicine

**Vignette**

Mr. R is a 55-year-old man who entered psychotherapy after the death of his mother prompted him to think about his goals for the rest of his life. Having chronically denied himself pleasure, he had worked hard to support his family and now felt “cheated” out of many things that he had wanted to accomplish. His work in psychodynamic psychotherapy with Dr. F helped to clarify many masochistic patterns that had led him to chronically make choices with which he was no longer happy. Approximately 1 year into the treatment, Mr. R began to experience low energy, early morning awakening, poor appetite, and passive suicidal ideation. After a few weeks, Dr. F diagnosed major depressive disorder and suggested treatment with sertraline, which Mr. R accepted.

After 5 weeks of treatment produced no improvement, Dr. F decided to switch to venlafaxine. Again, 5 weeks later, after appropriate increases in the medication, there was only moderate improvement. In addition, the patient had severe gastrointestinal symptoms. At this point, Mr. R began to come late to psychotherapy sessions for the first time in the course of the treatment. When Dr. F discussed this with the patient, it became clear that Mr. R felt that he was being cheated in his psychotherapy because his sessions were being exclusively taken up with questions about dosages and side effects. At this point, Dr. F suggested to Mr. R that he consult a psychopharmacologist to continue the pharmacologic treatment so that the psychotherapy could proceed.
physician about psychiatric illness and the medical ramifications of treatment.

When a patient comes for an evaluation with a psychiatrist, he/she may hope that the psychiatrist can administer all aspects of the treatment. Referral to a second practitioner for either psychotherapy or psychopharmacology may prompt the patient to feel rejected or think less of the evaluating psychiatrist. These reactions are best handled via straightforward discussions of the reasons for referral and the patients’ thoughts and feelings. Once the split treatment is underway, the patient may feel more comfortable with one practitioner or another and is likely to discuss each treatment with the other practitioner. A patient may value the psychopharmacologist more because of the “rapid help” that comes from medication or may value the psychotherapist more, complaining that the psychopharmacologist “never asks about my life.” Sometimes, a session in which both practitioners are present can be helpful to ensure that all three people involved in the treatment are “on the same page.”

Psychiatrists who are trained in both psychotherapy and psychopharmacology may feel like failures if they are unable to offer both treatments to the patient. This may lead them to underestimate themselves or to join with their patients in the devaluation of nonmedical therapists. As above, communication between the two practitioners involved in a case is critical to avoid problems like those mentioned above. In addition, developing ongoing relationships with practitioners with whom one frequently splits treatment helps to develop trust between practitioners. Mutual respect between the practitioners in a split treatment is essential for the development of a good working relationship in which undermining can be minimized. This type of ongoing communication can also result in mutual learning, as the two practitioners share their perspectives about patients over time.

The Consultation Model

Usually, combination treatment with medication and psychotherapy takes the form of the one practitioner model or the split treatment model. However, a third model, the consultation model, is also important. In this model, the patient’s primary clinician enlists the help of a consultant, who is usually an expert in one or the other treatment modality. This may be helpful during diagnostic situations, such as when a patient in an ongoing psychotherapy has worsening symptoms of depression that might require the addition of a medication. In this situation, the primary practitioner may feel hampered in his/her ability to objectively evaluate the diagnostic situation, given the close work in which he/she is engaged with the patient.

Here a consultant may be called upon to join the treatment for some period of time. For example, he/she could see the patient and the patient’s family for a diagnostic consultation. In another situation, a psychotherapist may call a consultation when the psychopharmacologic management of a patient becomes so complex that session time is exclusively devoted to medication management questions. Also, clinicians may find themselves needing help with a pharmacologic situation with which they are unfamiliar—such as the need to use a medication that they have never used or in the case of a particularly refractory mood disorder. In these situations, the consultant can either interact with the therapist only or serve to temporarily split the treatment. If the treatment is temporarily split, open lines of communication are as important to this success of this model as they are to the split treatment model.

Conclusions

The empirical study of medications and psychotherapy for depression and anxiety started with competitive trials of medication vs. psychotherapy, progressed to studies comparing combined treatment and monotherapy, and has most recently focused on augmentation studies of medication and psychotherapy. Most early studies comparing antidepressant medications and psychotherapy for depression did not show clear superiority of one treatment modality over the other. Therefore, as an initial treatment strategy for mild-to-moderate, unipolar, nonpsychotic depression, it appears that either antidepressant medication or an evidence-based psychotherapy such as IPT or CBT would be reasonable choices.

In light of the frequency with which combined treatment with psychotherapy and antidepressant medication appears to be prescribed, the dearth of evidence demonstrating superiority of combined treatment vs. monotherapy as an acute treatment for depression and anxiety disorders is surprising. Many early studies comparing combined treatment to psychotherapy or medication alone did not find improved outcomes, although meta-analyses of these treatments have generally found small but consistent results in favor of combined treatment. These early studies may not have been adequately powered to detect these small differences, and as discussed, comparisons of combined treatment to monotherapy can be flawed when they are made between open and blinded treatments. Nonetheless, while combined treatment may not be appropriate as an initial treatment for all patients, there are some data to support its use in cases of more severe or chronic depression, or where noncompliance, comorbidities, and treatment refractoriness have complicated the initial presentation.

The most important clinical question may relate to the sequencing of treatment with psychotherapy and medications, as well as the augmenting of one treatment modality with the other. As results from the STAR*D study indicate, less than 40% of patients are likely to experience remission with the first treatment prescribed. This makes it critical to study augmentation and switching strategies for those patients not experiencing remission, and combining treatment modalities is one strategy that should be considered.

The decision to recommend combined treatment with psychotherapy and medications is only the first step. Executing this recommendation requires serious consideration of the preconceptions doctor and patient bring to the treatment, logistical realities of the clinician’s credentials and the patient’s resources, and the nature of the illness or illnesses under treatment. There are few empirical data to guide clinicians deciding between the various models of combined treatment. The most that can be recommended at present is candid discussion with the patient of the benefits and disadvantages of various treatment strategies and awareness of the difficulties of combined treatment in the mind of the clinician.

**Introduction**

Epidemiological research suggests that one-half to two-thirds of persons with psychiatric disabilities that may benefit from treatment either fail to seek help; or, when they do, are noncompliant with treatment (Kessler et al. 2001, Regier et al. 1993).

In the past 15 years the number of psychiatric medications has increased to well over 200 actively used medications; yet, in order to be effective, these medications must be taken by the patient. Medication should be prescribed according to a rational regimen that is based on integration of general pharmacokinetic and pharmacodynamic principles with “real-life” variables. Medication regimens should be both efficacious and feasible (Katzung 2007, Haynes et al. 1979).

Poor compliance can adversely affect medical decisions. Physicians, unaware of compliance problems, may incorrectly assume that poor therapeutic outcomes are due to failure of the prescribed treatment and increase the dose, add medication, or prescribe medication with potentially more serious adverse reactions (Katzung 2007).

Although thousands of studies have been published regarding medication noncompliance, interventions developed to date have had only limited impact on the problem (Sackett and Snow 1979, Haynes et al. 2005). Compliance to psychiatric medication poses special challenges, due to many factors—some related to medications in general and some specific to psychiatric medications. Psychiatric illness has a direct impact on the ability and motivation of patients to take the very medications that have been prescribed to treat their symptoms. In addition, a growing body of literature suggests that mental illness stigma and ubiquitous fears about psychiatric medications may be of particular significance in determining compliance to psychiatric medications (Sirey et al. 2001, Corrigan and Watson 2006).

This chapter details the complexity of medication compliance and the impact of noncompliance on treatment of psychiatric disorders. Methods for quantifying medication compliance are reviewed. Risk factors for medication noncompliance are discussed, including lack of perceived necessity for medication, cognitive deficits, medication side effects, financial burden (e.g., poverty, lack of insurance, insurance nonparity), mental illness stigma, poor doctor–patient relationship, and negative patient/family beliefs about medication. This chapter also reviews emerging strategies that providers can use to maximize patient compliance to psychiatric medication. Practical and specific suggestions are given with clinical examples.

**Definition: “Compliance” versus “Adherence”**

Haynes (1979) defined compliance as the “extent to which a person’s behavior coincides with medical advice,” e.g., taking medication or engaging in other prescribed treatments. Patients who are noncompliant to prescribed treatment are often seen as derelict. Because of the pejorative connotation of the term compliance, many researchers have adopted the use of adherence. In his thoughtful and comprehensive analysis of current medical paradigms for medication treatment, Trostle (2000) argues from an anthropological perspective, that discussing patients’ “compliance” or “adherence” to treatment is tantamount to discussing “the authority of medical professionals.”

When viewed through the eyes of physicians, patient noncompliance to prescribed medication may seem irrational. In reality, patient compliance to any treatment recommendation is a complex behavior related to many factors that are patient, provider, and disease based. In addition, there are contextual factors that influence patients’ compliance to prescribed medication, such as the increasing influence of managed care, pharmaceutical direct-marketing strategies, and societal stigma of psychiatric medication. Adequate medication compliance is achieved by agreement between the doctor and patient, rather than a unilateral decision by either.

Understanding treatment compliance is more problematic in pediatric and adolescent patients, and can present psychodynamic and ethical challenges. Assumptions about patient responsibility, rationality, and control do not apply with pediatric patients who generally have neither the cognitive nor legal ability to consent or refuse to take psychiatric medication. There is considerable state-to-state and national variation regarding consent for, right to, and confidentiality regarding psychiatric treatment in minors. Readers are encouraged to refer to their local mental health codes to familiarize themselves with local legislation.
Treatment Refusal
Grossly categorized, patients may be classified into:

- Those who overtly refuse medication treatment(s)
- Those who ostensibly accept medication treatment but never fill their prescription(s)
- Those who are poorly compliant with the prescribed medication regimen(s)
- Those who adequately comply with the prescribed medication regimen(s)

Patients who are adamantly opposed to psychiatric medication may not (voluntarily) present to a psychiatrist. A substantial percentage of those patients who are evaluated by psychiatrists still refuse treatment with psychiatric medication.

Refusal of psychiatric medication can be viewed from a legal perspective. The legal right to refuse treatment varies by jurisdiction. Most psychiatrists recognize clinical situations in which it is reasonable to pursue involuntary treatment (e.g., patients who are a danger to themselves or others). However, short of life-threatening situations and/or cases of patient incompetence, it is advisable to consider that forced treatment may severely compromise future therapeutic efforts with the patient. Rather than immediately attempting to override a patient’s refusal, it behooves the physician to examine the factors underlying the refusal, with the aim of resolving the issue within the framework of the therapeutic alliance. Relevant factors may include reality-based concerns (e.g., potential side effects), idiosyncratic meanings of treatment (e.g., if I take medication I am crazy), primary and secondary gains, transference effects, and familial and cultural factors (Appelbaum and Gutheil 1982).

Overview of Theoretical Models
Various conceptual models have been developed to describe patients’ health behavior during treatment of chronic conditions (Leventhal and Cameron 1987, Conrad 1985). Major models of health behavior that have been developed from social cognitive theory include: (1) Health Belief Model; (2) Theory of Reasoned Action and Theory of Planned Behavior; (3) Stages of Change Theory; and (4) Protection Motivation Theory. Although these models differ in important ways, they all assume that medication compliance can be predicted by patients’ perceptions of threat from the medical condition and their expectancy regarding the consequences of medication compliance.

The Health Belief Model (HBM) assumes that medication-taking is a rational decision made by the patient based on a cost–benefit analysis (Janz and Becker 1984, Rosenstock 1988). Regardless of the “objective” view of the prescribing physician, it is the patient’s perception of the benefits and risks of medication that determines their compliance behavior.

The HBM has been demonstrated to have predictive value with regard to medication compliance in a variety of chronic medical conditions, including tuberculosis, diabetes, and hypertension (Becker and Maiman 1975, Becker 1985). More recently, the HBM has been used in studies of medication compliance in psychiatric disorders (Budd et al. 1996). Lingam and Scott (2002) conducted a review of research (1976–2001) on treatment noncompliance in adults with affective disorders. They concluded that patients’ attitudes and beliefs are at least as important as side effects in predicting compliance with medication for affective disorders and that the HBM is a promising tool for identification of individuals at risk for noncompliance.

Bush and Iannotti (1988, 1990) adapted the Health Belief Model for use in children and adolescents. They added key developmental and contextual components to the model, including caretaker attitudes (perceived threat to child from illness, perceived benefit of medication), parent–child interactions, level of child/adolescent autonomy, and child readiness factors (illness concern, expectancy for efficacy of medication treatment). Their model, called the Children’s Health Belief Model, was based on data from 420 elementary age children and tested the model with a sample of 270 adolescents. The model accounted for 64% of the variance in adolescents’ behavioral response to illness. Based on these findings, the best predictors of adolescent compliance to treatment were their perception of the severity of the illness and the predicted/perceived benefit of the medication. They found that primary caretaker’s attitudes influenced their adolescents’ readiness and expectancies regarding medications, but that the adolescents’ own cognitions and attitudes were most important in determining compliance to medication. Bush and Iannotti (1988, 1990) concluded that while parents do influence their children’s health beliefs and health behavior, these influences are small when compared to other developmental influences on children’s attitudes and behaviors.

The Theory of Reasoned Action (TRA) by Ajzen and Fishbein (1980) and its more recent extension the Theory of Planned Behavior (TPB) by Ajzen (1988) resemble the HBM in the assumption that people make rational decisions (i.e., cost–benefit analyses) about their behavior based on information and beliefs about the behavior, and that health behaviors are under volitional control. The TRA and TPB differ from the HBM in two major ways. TRA and TPB assert that patient intentions are the most important determinant of their behavior. Furthermore, they state that intentions are a function of a person’s attitude toward the behavior and the person’s perceptions of social norms regarding the behavior. When applied to patient compliance to psychiatric medication, a patient’s attitude toward medication compliance is based on their predicted consequences of taking medication and the value (costs and benefits) they attribute to these consequences. For example, if a person believes that a medication is effective in the treatment of a particular symptom/illness, then they may believe that the consequence of not taking the medication will be persistence or return of the symptom/illness. If so, depending on the degree of distress from the symptom/illness, they may see a benefit in taking the medication; however, the “cost” of taking the medication may outweigh this benefit. According to TRA/TPB theory, however, an important factor influencing their decision is a person’s expectation of whether significant others in their life (i.e., family and friends) will support their taking psychiatric medication. Of course, the person’s motivation to comply with the preferences of their significant others, will determine the impact of perceived social norms on predicting their medication compliance.

Stages of change theory is based on the premise that behavior change occurs in stages or phases and the
factors that influence behavior may change from one stage to another. Implicit in stage models is the assumption that, initially, behavior change is largely under the control of deliberate cognitive processes. As the new behavior is repeated over time, situational cues to decisions begin to elicit the cognitive processes that result in decisions and intentions. Over time actions may come to be performed automatically in response to situational cues such that they are no longer under volitional control (Prochaska et al. 1994).

Protection Motivation Theory (PMT) was originally proposed to provide conceptual clarity to the understanding of fear appeals. It was later extended to a theory of persuasive communication, with an emphasis on the cognitive processes mediating behavioral change. According to the theory, appraisal of a health threat and appraisal of possible coping responses result in the intention to perform adaptive responses (protection motivation). The intention to protect oneself depends upon four factors: (1) perceived severity of the threat; (2) perceived vulnerability; (3) perceived response efficacy—expectancy that carrying out recommendations can remove the threat; and (4) perceived self-efficacy—the belief in one's ability to execute the recommended courses of action successfully (Rogers 1983).

Prevalence of Medication Noncompliance

Rates of medication compliance/noncompliance depend on many factors, e.g., whether the prescribed regimen is short term or long term, whether the medication is for prophylaxis or for treatment of disease. Based on their comprehensive literature review, Sackett and Snow (1979) approximated that the average compliance for short-term regimens is 62% versus a range of 33–94% (mean 57%) for long-term preventive regimens and 41–69% (mean 54%) for long-term treatment regimens. Patients prescribed medications for long periods of time, for prophylaxis, or for chronic diseases appear to be less compliant.

The large variation in reported rates speaks to the complexity of the behavior. Rates vary substantially depending on the method of measurement. Medication-taking varies according to many other factors, even when considering the behavior of only one patient. A patient may be more or less compliant to a prescribed medication depending on the complexity of the regimen, the severity and type of illness, side effects, past experience with medication, and trust in their physician.

The specific type of medication prescribed may also be important. Psychiatrists have observed that some patients appear to be more apprehensive about taking psychiatric than nonpsychiatric medications. The explanation undoubtedly varies from patient to patient. Available research suggests that both societal stigma of mental illness and psychiatric medication, and fears specific to psychiatric medications, contribute to this phenomenon. An individual's fear of psychiatric medication may be influenced by current and past experience with mental illness and psychiatric medication. This frequently includes input from family and friends regarding psychiatric medication. Individuals' attitudes about mental illness and psychiatric medication are highly influenced by societal lore based on actual history of treatment of the mentally ill, cinematic portrayals of psychiatry, media reports, and information on the Internet.

Patterns of Medication Noncompliance

There are many patterns of medication noncompliance. Despite its apparent simplicity, taking medication as prescribed is a complex and dynamic behavior. Empirical evidence demonstrates that noncompliance is best understood as a variable behavior, rather than a trait characteristic. Rudd et al. (1989) reported marked inter- and intra-subject variability in medication compliance on a week-to-week basis. Patients may continue to keep appointments, while not taking prescribed medications, so attendance at appointments should not be overly reassuring. Patients prescribed more than one medication may take one medication but not others. Patients also may initially adhere to medication recommendations, but later may discontinue their medication without informing their physician. Based on a comprehensive review of reported rates, patterns, and correlates of medication noncompliance, the following have been observed:

1. Medication compliance tends to decline over time
2. Baseline compliance is the strongest predictor of long-term compliance to medication
3. Patients who have been poorly compliant in the past are more likely to be noncompliant in the future

Many studies treat compliance as dichotomous and univariate, rather than as a continuous phenomenon with multiple dimensions. A patient may adhere to one part of treatment recommendations but not to others (Fotheringham and Sawyer 1995; Orme and Binik 1989). Failure to comply with medication-taking may include omissions of doses, taking more than the prescribed dose, errors in dosage or prescribed frequency of doses, taking medication for the wrong reason, taking medication as needed rather than on a regular schedule, and discontinuing medication early.

Both the pattern and rate of missed medication doses are important. Converging evidence suggests that we view medication compliance on a continuum with many different patterns of partial compliance, but 100% compliance is abnormal. Bachmann et al. (1999) studied methods to achieve high therapeutic success despite less than perfect compliance. They suggest this may be achieved by selection of an agent that, based on its pharmacological properties, is “more forgiving” of delayed or omitted doses, such as fluoxetine. Forgiveness is defined as the drug’s post-dose duration of action minus the prescribed interval between doses.

Delays and omissions in dose administration are the predominant medication errors. Electronic monitoring shows a skew toward dose omission, with widely variable intervals between doses, though dosing in the day or two prior to scheduled visits is usually correct (Feinstein 1990). Appropriate administration of the medication for the few days preceding an appointment, the so-called “white coat” compliance, does not reflect long-term compliance. One in six patients is very punctual in the timing of prescribed doses. Three in six make minor errors in timing that are too small to reduce the full-dose action of any but the least forgiving medications (Urquhart 1995, 1997).

Medication errors can be further classified according to whether the error was unintentional (forgetting or misunderstanding the dose or frequency) versus intentional (conscious decision to modify medication dose/frequency for any reason). There is a substantial difference between
forgetting to take a pill despite knowing the proper regimen, and believing, incorrectly, that only three pills are needed daily and adjusting the regimen without consulting the doctor (Rudd 1993). Patients may alter their dose of medication(s) without consulting their physician, or may take medication only “as needed.” Lapses between prescribed doses of three or more days are called “drug holidays.” Drug holidays occur monthly to quarterly in two-thirds of patients (Urquhart 1995, 1997). If patients have protracted or more frequent drug holidays, not only will the medication likely be ineffective, but patients may experience side effects due to the recurrent rebound and/or first-dose effects. These side effects may, in turn, contribute to persistent or worsened compliance to the medication regimen.

**Measurement of Medication Compliance**

Measurement of medication compliance is difficult. Physician estimate is a poor measure of compliance and more experienced clinicians do no better than trainees. Faithfully attending appointments does not ensure compliance with prescribed treatment, although compliance is much worse in those who fail to keep appointments. Rudd (1993) demonstrated that physicians’ estimated rate of compliance is only weakly correlated to rates obtained by objective measurement or electronic monitoring. Mushlin and Appel (1978) reported that physicians correctly identify less than one half of noncompliant patients.

Although there are hundreds of studies debating the merits of different measurement methods, no existing measure is entirely fool proof. In general, measures of compliance to medication treatment can be classified as direct or indirect:

**Direct Measures**

**Supervised Doses**

This is impractical and often unreliable. Even under direct observation by trained staff on an inpatient psychiatric unit, patients can feign medication ingestion. For adolescent patients, direct observation, particularly by parents, may provoke negative emotions in the adolescent struggling for autonomy.

**Blood Levels**

Blood levels of drugs and/or their metabolites are only useful when accurate measurements of all significant active metabolites of the drug are available and there is a known relationship between the clinical effects of the drug and blood/serum concentration (Morselli and Bianchetti 1983, Gualtieri and Golden 1984). In general, blood levels are clinically useful for lithium carbonate, tricyclic antidepressants, and certain mood stabilizer medications. None of the SSRIs have serum levels that are sufficiently reliable to warrant the cost, inconvenience, and pain of blood draws. When obtained, typically the only useful information derived from an SSRI level is the gross presence or absence of the medication at the time of the blood draw (Ducan 1998, Green 1995). Even for medications with reliable pharmacokinetic information, many drugs achieve target levels after a few doses so that appropriate administration for a few days before a blood draw (“white coat” compliance) could result in normal levels. Although a concentration of zero shows no recent medication ingestion, “spot concentrations” are of limited use.

**Indirect Measures**

**Patient/Other Self-Report**

Patient self-report is the most widely used method of measuring compliance to prescribed treatment. In usual practice, clinicians do not use standardized methods; instead questions regarding compliance, if asked, are often closed and leading: e.g., “are you taking your medication?” One difficulty of self-report data is the risk of misreporting. Cramer (1995) concluded that direct questioning during a patient interview has been proven inadequate to evaluate medication compliance because patients tend to tell doctors what they think the doctor wants to hear. A second limitation is lack of reliability of patient recall. Daily diaries have been used to circumvent this problem; however, few data are available on their utility or acceptability to patients. Parents or other caregivers can be asked whether the adolescent is taking his/her medication as prescribed; however, unless these individuals are present for administration of the medication, their report is presumptive. To increase the reliability and validity of self-report data, a number of researchers have attempted to develop and use structured tools for gathering patient self-report information (Morisky et al. 1986, Svarstad et al. 1999).

**Pill Count**

This refers to counting tablets returned in bottles at scheduled appointments. This method has been shown by many studies to be inadequate in measuring actual medication compliance (Pullar and Feely 1990, Cramer 1989, Rudd et al. 1989, Kruse et al. 1993, Urquhart 1995). Patients often forget or are reluctant to bring bottles to appointments. Some patients put their medication in other containers. Patients, perhaps in an attempt to please their doctor, may discard or hoard remaining tablets and bring the empty bottle.

**Pharmacy Records**

Prescription renewals can be used to monitor the frequency of refills. This method has been demonstrated by numerous studies to be inadequate in measuring actual usage of medication. Patients sometimes obtain medications from more than one pharmacy, more than one doctor, or from friends or family. HMOs and insurance plans may require patients to refill their medication quarterly. Patients may accept unneeded prescriptions because they are embarrassed to admit that they are not taking the medication as prescribed (Rudd et al. 1989).

**Electronic Monitoring (EM)**

Available since 1986, EM is now considered to be nearly a “gold standard” for measuring compliance to prescribed medication (Cramer 1989, Riekert and Rand 2002). Medication is dispensed from a container that has a microprocessor (usually in the cap) that records the date, time, and duration of each container opening. Connecting to a computer using commercially available software retrieves data. Using EM, the variability of dosing in ambulatory trials practice has been shown to be far greater than previously indicated by other methods (Feinstein 1990b, Pullar and Feely 1990,
Factors Associated with Poor Medication Compliance

EM provides more complete longitudinal information than any other currently available method and it does not rely on the memory of patients or doctors. EM has also been demonstrated to be superior to other methods in demonstrating important findings. For example, in their study comparing SSRIs to TCA antidepressants, Thompson (2000) found that only electronic monitoring allowed collection of data sufficiently complete to measure prolonged periods of noncompliance. Using pill count and patient questionnaires, they found no significant differences in compliance to SSRI versus TCA medication, despite marked differences in side effect profile and dose regimen. However, using survival analysis of data from electronic monitoring, they found an association between compliance and efficacy and showed superior compliance and efficacy of SSRIs versus tricycles.

There are also potential disadvantages of electronic monitoring. EM is not completely accurate—opening the EM cap does not correlate one-to-one medication ingestion. EM is expensive—the substantial minimum investment needed to purchase sufficient devices for simultaneous patients is compounded because patients may lose or damage the devices (Riekert and Rand 2002).

Risk Factors for Noncompliance

Commonly reported reasons for medication discontinuation include side effects, low perceived need for medication, feeling better, and perceived medication ineffectiveness. Refer to Table 114–1 for more factors commonly associated with poor medication compliance.

Just as individual patients’ medication compliance pattern may vary over the course of treatment, the relative significance of specific barriers to compliance vary greatly between patients. Based on their review of pediatric literature, Logan et al. (2003) identified the most important correlates of noncompliance: (1) disease and regimen factors (duration and course of illness, symptom severity, type and complexity of regimen, efficacy, and side effects); (2) patient factors (developmental characteristics such as cognitive developmental level, level of autonomy); (3) interpersonal or attributional tendencies (depression, psychological coping strategies, self-efficacy); (4) peer/family influences (stigma of disease/regimen, perceived need for secrecy, family cohesion/conflict, parental support, shared responsibility for regimen); (5) relationship with medical team. Using these a priori factors, they developed the Illness Management Survey, which is a self-report measure designed to identify the relative importance of common compliance barriers for individuals patients. Their results were striking; they discovered that four of the five most important barriers to compliance cited by adolescents could be classified as due to internal processes (cognitive ability, perceived support from their family and doctor, and perceived stigma of disease/treatment). Adolescents’ perceived burden of the disease/treatment (complexity of regimen, interference with normal life, unpleasantness of side effects) was also an important factor. Refer to Figure 114–1 for an integrated model of factors that influence patients’ compliance to medication.

Demographic Factors

Converging data suggests that no single demographic variable (with the exception of age) predisposes an individual to noncompliance (Haynes et al. 1979, Jay et al. 1984). Studies have failed to identify differences in patient compliance to treatment based on race, gender, religion, educational level, or socioeconomic status (Horne and Weinman 1999).

Medication compliance does appear to be influenced by age/developmental level. Past research has shown that compliance to medication in children is related to the mother’s perception of the severity of her child’s illness, but not to the physician’s estimate of severity of the child’s illness. Data also suggests that adolescents are less compliant to medical recommendations than younger children or adults, which may be due to developmental factors (Cromer and Tarnowski 1989, Riekert 2002). Developmental factors that may influence compliance (see Table 114–2) in adolescents (and developmentally delayed adults) include: (1) Brain Maturation & Development of Cognitive Processes; (2) Psychological Development (see Table 114–2).

Adolescence is characterized by experimentation and risk-taking, limited insight, a sense of invulnerability, increased influence of peers, and lack of future orientation. Although a sense of autonomy is a positive developmental milestone, a child who feels autonomous may view health-promoting influences as a restriction to autonomy.

Only a small percent of mental health treatment in adolescents is self-initiated. Compliance to medication among children and adolescents requires the consent and cooperation of a parent as well as the assent and cooperation of the youth. The involvement of adults may create conflict for teens because help-seeking and utilization of adult-provided services is inconsistent with their desire for autonomy, privacy, and independence.

Patient-Related Factors

Pragmatics

Some examples of pragmatic barriers to improved medication compliance include income, stability/stress in home life, homelessness, transportation, phone service, medical and prescription coverage, travel time to doctor’s office, waiting times to see physicians, access to prescription
refills, access to nurse/physician to answer questions, practices of third-party payers, and national health care policies.

**Ability**
A patient’s ability to take medications as prescribed is influenced by the patient’s cognitive functioning, motor functioning, and knowledge about the medication. Their cognitive functioning is determined by level of alertness, orientation to person/place/time, sustained attention, memory, ability to use a calendar/reminders/organizers, thought processes, processing speed, problem-solving skills, capacity for logical operations (understanding of cause and effect), intelligence, literacy, math skills, executive functioning, and impulse control. A patient’s motor functioning consists of fine motor control, physical mobility, ability to drive or obtain transportation, ability to swallow medication and can affect physical ability to obtain and take medication. Finally, a patient’s knowledge about medication influences their compliance to medication. A number of studies have examined the impact of patient knowledge about their illness and treatment on medication compliance. Most studies have concluded that while patient instruction is an important component of treatment and may improve compliance to short-term medication treatment, patient education alone does not assure compliance to long-term medication treatment (Morris and Halperin 1979). Sackett and Snow (1979) showed that even “mastery learning” about medication treatment does not necessarily improve medication-taking behavior.

**Motivation**
A patient’s motivation to take prescribed medication is influenced by many complex and interrelated factors:

Patient Beliefs/Attitudes about Medication

In a landmark publication, Frank (1973) described the close association between beliefs and attitudes toward treatment-seeking, expectancies of change, and actual illness outcome. Subsequent research supports the importance of medication beliefs in determining patient compliance to medication recommendations. For example, Lingam and Scott (2002) conducted a review of research from 1976 to 2001 on treatment noncompliance in affective disorders and reported that attitudes and beliefs are at least as important as side effects in predicting noncompliance to antidepressant treatment. Research in patients with chronic medical illness suggests that how patients understand their illness has a significant impact on treatment compliance (Leventhal et al. 1992). Horne and Weinman (1999) proposed a theoretical model for the relationship between patient beliefs about medication and compliance to medication treatment in adults with chronic illness. In their study of 324 patients with chronic illness (asthma, renal, cardiac, and cancer), they found that patient beliefs about medication were more powerful predictors of compliance than clinical or demographic factors. Based on their findings, the authors concluded that patients’ general beliefs about medication influenced their initial orientation toward prescribed medication, but it was patients’ specific beliefs about their prescribed medication that is most strongly related to their medication compliance.

Studies have documented the resistance of adolescents to psychiatric medication. Scott et al. (1992) found that 58% of mentally ill adolescents (with diagnosed schizophrenia, unipolar depression, and bipolar depression) disagreed with the need to take prescribed medication. Williams and Hollis (1998) report that 61% of adolescents with various psychiatric diagnoses had a bias against taking medication and a lack of positive expectancy for effect of medication.

Noncompliant patients can be classified into subgroups based on their particular risk factors or barriers to compliance (Conrad 1985):

• Testing—The patient stops medication in order to “test” whether it is needed and/or effective
• Control of dependency—The fear that medication is a crutch; fear of dependency on medication; medication becomes a symbol of the dependence created by a chronic illness and is a constant reminder of the illness
• Destigmatization—The fear of societal stigma of illness and “flight to health”; avoiding medication is a way to avoid the stigma of the illness

• Practical considerations—e.g., expense and/or burden of the regimen; wish to avoid problems that might occur by mixing alcohol or illicit drugs with the medication

Patient Concerns about Medication

Many patients have substantial suspicions about prescribed medication and these beliefs may influence how information about medication is interpreted and acted upon. Certain beliefs about medication are highly prevalent across diverse populations, e.g., medications are addictive and accumulate in the body to produce adverse long-term effects.

Williams et al. (1998) studied attitudes about psychiatric medications among incarcerated female adolescents. The most common concerns reported by this sample were: (1) “Medicine might be hard to swallow or taste bad,” 44.4%; (2) “I feel strongly that people should solve problems on their own—medicines are a crutch,” 33.2%; and (3) “Medicine might change my personality or not let me be myself,” 30.8%. Other concerns included: “I wouldn’t want others to know I was taking medication to help with my feelings or behavior—I might get teased by my peers’ and “Medicine might cost too much for my family to afford.”

Patient Concerns about Mental Illness Stigma

The word stigma literally means “mark of shame.” Link and Phelan (2001) defined stigma as any trait of an individual or group that evokes a negative or punitive social response. In common parlance, people refer to the stigma associated with individual traits (e.g., skin color, obesity), events (e.g., personal history of psychiatric hospitalization, incarceration, or substance abuse), or groups (e.g., persons with mental illness, persons who are HIV+). Mental illness stigma specifically refers to status loss and discrimination due to negative stereotypes about people labeled with mental illness.

The mentally ill are one of the most stigmatized social groups (Sayre 2000, Link et al. 2004). Derogatory messages about mental illness are ubiquitous in society, seen in colloquial expressions, cartoon characters, and mass advertisement (Philo 1996, Wahl 1995, Wilson et al. 2000). Link (1987) found that people learn negative stereotypes long before they themselves become patients and that the experience of illness triggers internalized negative beliefs.

The 1999 Surgeon General’s Report on Mental Health cited stigma as a powerful obstacle to seeking care (Satcher 1999). Jorm and Korten (1997) found that the public more often perceives psychiatric medication as more harmful than helpful. Studies of stigma and compliance to depression treatment have found that perceived stigma predicts treatment discontinuation (Lai et al. 1997, Sirey et al. 2001). If a person believes that the mentally ill are less competent than other people, it is not surprising that they may wish to distance themselves from such a label. Taking psychiatric medication implies mental illness; noncompliance with prescribed medication can reflect denial or ambivalence.

Perceived Necessity for Medication Treatment

Studies across medical conditions show that people prescribed the same medication for the same condition differ in their perceptions of personal need for medication (Horne and Weinman 1999). The factors determining perceived necessity for medication in depression are not fully
understood. According to the common sense model of self-regulation, patients do not blindly follow medical advice, but assess the threat posed by their illness to determine whether treatment is needed, and if so, what treatment is appropriate (Leventhal et al. 1992). A number of factors may contribute to perceived need for medication, including perceived severity of illness, level of distress/impact of illness, understanding of illness (e.g., beliefs about causation, expected duration, beliefs about amenability to treatment), perceived efficacy of medication, and perceptions of personal resilience (Horne 2006).

Adams and Scott (2000) found that perceived benefit of treatment and perceived severity of illness, together, accounted for 43% of variance in compliance. Using the Health Belief Model, Budd et al. (1996) found that perceived severity of symptoms was associated with greater medication compliance.

Perceived Efficacy of Medication Treatment
Patients’ perceptions of the efficacy of medication may not be the same as those of their doctors. An individual’s perception of the effectiveness of a treatment depends on whether the outcome of treatment matches their expectations. For example, a patient who believes that effective treatment of depression means that they will be “happy” after taking medication for one week is likely to be disappointed.

Perceived efficacy of prescribed medication has a complex relationship to perceived necessity for medication and compliance to prescribed medication. In their study of depressed adults in primary care, Brown et al. (2001) found that, although most patients acknowledged the negative impact of depression on their lives, less than 40% viewed antidepressants as effective in treating their symptoms. Moreover, clinical experience and published data suggest that regardless of their clinical response to medication treatment, patients commonly have attitudes and beliefs about psychiatric medication that are inconsistent with medication compliance (Williams et al. 1998).

Physicians often assume that if a medication produces significant reduction in a patient’s symptoms, then the medication is “necessary”; however, it is not uncommon for patients who have experienced some benefit from medication to discontinue medication prematurely, stating “I feel better so I don’t need to take the medication anymore.”

Provider-Related Factors

Pragmatics
Some examples of pragmatic barriers to improved medication compliance include the quality/quantity of office staff; location of practice, practices of third-party payers, national health care policies, continuity of care, and communication between various medication providers. Goldfinger et al. (1984) examine the role of service systems breakdown in patients whose treatment fails.

Ability
A physician’s ability to facilitate patient compliance with medication is influenced by innate talents, interpersonal skills, empathy, psychological mindedness, confidence, openness, quality of training, and clinical experience.

Motivation
A physician’s motivation to improve their patients’ medication compliance is influenced by personal history of mental illness, personal beliefs (especially about the stigma of mental illness and beliefs about medication efficacy and safety), family and/or friends with mental illness, ethical principles, perceived professional mission—and; on the darker side, perhaps avoidance of legal liability and high malpractice rates.

Therapeutic Alliance
Patients’ medication compliance is substantially influenced by perceived support from their physician. Doctors and patients develop a relationship that is based on communication that includes information, affect, and social learning. Therapeutic alliance is as important for success in psychopharmacology as it is for psychotherapy. With increasing pressure from all sides for doctors to perform “medication checks,” the interpersonal aspects of the doctor–patient relationship are dismissed. Optimal therapeutic alliance depends on mutual trust, respect, honesty, openness, and comfort between doctor and patient, all of which take time.

Based on their study of compliance with medication treatment for tuberculosis, Sumartijo (1993) concluded that poor performance by the health team often was responsible for poor compliance to medication (Sumartijo 1993). Medication compliance is affected by continuity of care. Charney et al. (1967) demonstrated that compliance was worse when patients saw the partner of their regular physician than when they saw their regular physician (Charney et al. 1967). Other factors that contribute to the quality of the doctor–patient relationship include: (1) availability of the physician (or appropriate medical staff) between appointments; (2) length, frequency, and quality of appointments; (3) waiting times to see the doctor. Finally, the quality of office support staff can have a significant impact on patient care.

Patients who are poorly compliant with treatment frequently elicit strong countertransference responses in their providers. Doctors may experience feelings of disappointment, anger, and/or defensiveness. They may blame the patient, as exemplified by the statement; the patient is “resistant” or “doesn’t want to get better.” These responses are counterproductive and serve only to further erode the therapeutic alliance. In this light, medication noncompliance can be seen as a failure of the relationship, rather than as a failure of the patient (Weiden and Rao 2005).

Contextual Factors

Family Factors
Chesla (1989) and Rose (1983) reported an association between relatives’ beliefs about illness and their beliefs about treatment and found evidence that family beliefs influence patient compliance. They observed that family members who consider mental illness caused by a chemical imbalance strongly reinforced the use of medication in the patient. In a cross-cultural study sponsored by the World Health Organization, Bush and Hardon (1990) found that medication use, family beliefs, and health-related practices are instilled in children by school age and influence their readiness to take prescribed medication.

Stine (1994) reported several reasons for noncompliance to psychiatric medication in children and adolescents
despite clinical improvement and absence of side effects, including parental discomfort with the idea of psychiatric medication, patient fear of stigma, and child refusal and resistance. Public awareness of the controversy regarding efficacy and safety of SSRIs in children and adolescents may impact parent/family concerns about medications. Prescribing providers need to be sensitive to concerns about medication safety.

**Financial Factors**
For patients without health insurance and/or prescription coverage, the cost of medication and medical care may be a significant barrier to medication compliance. Patients with health insurance may still sustain significant medical costs that effect medication compliance. Many health insurance plans do not include prescription coverage or have restricted formularies. Managed care formularies increasingly restrict medication choices. These restrictions are especially severe for psychiatric medications due to nonparity of coverage for mental health problems. More patients are required to pay deductibles and co-pays, which vary in amount, but can be as high as 20–80% of the actual cost of the prescription or service. Some patients are required to obtain prescriptions for a 3-month quantity of medication and receive their medications by mail. Patients with Medicaid and Medicare insurance are now required to enroll in a managed care plan that regulates prescription benefits. These plans have restricted formularies and require prior authorization for all nonformulary medications (Kilkstrom 1998). Although co-pays for patients on Medicaid are much lower than those with private insurance plans, they can still pose a substantial financial burden for patients living on severely restricted incomes, particularly if they are on multiple medications (as is frequently the case).

**Clinical Factors**

**Medication Regimen**
Studies of the number, type, dose, frequency, and time of medication prescribed in relationship to medication adherence have revealed variable results. In a review of studies using electronic monitoring to measure adherence, Claxton et al. (2001) found an inverse relationship between number of daily doses and adherence. Kruse et al. (1993) report higher patient compliance with twice daily (85%) versus four times daily regimens (65%), and that evening doses are omitted twice as often as morning doses. Horne and Weinman (1998) found no relationship between the total number of prescribed medications and compliance.

**Severity of Illness/Level of Distress**
Multiple studies of patient medication compliance, across a range of chronic illnesses, have shown that physicians’ assessments of medication necessity or illness severity often have little correlation with patients’ level of medication compliance (Kiley et al. 1993, Phipps and Decuir-Whalley 1990, Lemanek 1990). Even when the patient’s reported symptoms underlie the physician’s assessment (e.g., using the Beck’s Depression Inventory (Beck et al. 1961) to assess severity of depression), this may not predict patient compliance to prescribed medication.

One predictor of medication noncompliance is the absence of patient distress (Ellison 2000). Without the motivation provided by distress, taking medication may seem pointless and not worth the side effects. Even patients who are sufficiently motivated by distress to schedule an evaluation with a psychiatrist may, in a “flight to health,” experience relief prior to starting medication. Many patients, after taking medications and experiencing relief from symptoms, may discontinue medication prematurely—with or without the physician’s knowledge. Other patients, perhaps pressured into seeing a psychiatrist, may not acknowledge the distress observed by others for a number of reasons (e.g., denial of illness, lack of insight).

Finally, depending on the type of disorder and severity of symptoms, psychiatric illness itself may interfere with patients’ willingness and/or ability to comply with medication (Chen 1991). These factors will be discussed at length below under “Specific Populations,” e.g., schizophrenia, bipolar disorder, attention deficit disorder.

**Side Effects**
It is a mistake to ignore the possibility that a patient’s noncompliance to medication is based on concerns about current or potential side effects of treatment. Side effects to prescribed medication, even if considered “mild” by the medical provider, may have a significant impact on medication compliance. Patients may discontinue medication that has been effective if the side effect is sufficiently noxious, e.g., nausea, sexual dysfunction. Patients’ concerns about the possibility of side effects or adverse events (even in the absence of past or current problems) may also be a significant factor in compliance to prescribed medication. For example, fear of severe adverse events (potentially fatal or causing disability, e.g., hepatotoxicity, cardiac arrhythmia, tardive dyskinesia), even if rare, may be a significant deterrent to patient compliance.

Even when a patient offers no reason for not taking the medication, or points to some other cause; the physician should make specific inquiries about embarrassing (e.g., sexual dysfunction) or difficult to describe side effects (e.g., akathesia). If no current side effects can be elicited, past experiences with medications should be reviewed, as well as whether patients have witnessed or heard reports of bad experiences with psychiatric medications from family, friends, the media, or internet reports (Appelbaum and Gutheil 1982).

Side effects are associated with noncompliance to medication, but to a lesser extent than initially believed. Prevalence of antidepressant noncompliance has not substantially changed with the advent of new medications (Lingam and Scott 2002). In their study of medication noncompliance in severe affective disorders, Adams and Scott (2000) reported that side effect fears were more predictive of noncompliance than actual side effects. It is important to remember that it is subjective distress about the side effect, rather than the side effect itself, that is most linked to medication noncompliance.

**Specific Patient Populations**
Psychiatric diagnoses are associated with poorer medication compliance than are nonpsychiatric illnesses (Litt and Cuskey 1980, Haynes et al. 1979). Psychiatric illness, by
virtue of impact on patient ability and motivation, presents particular challenges for compliance with medication treatment. While it is beyond the scope of this chapter to address compliance issues related to every psychiatric disorder, factors unique to a few specific diagnostic groups are outlined below.

**Depression**

Approximately 8–10% of patients never fill their antidepressant prescription (Rashid 1982). Subsequent antidepressant compliance decays over time and medication discontinuation is greatest within the first month of treatment. Johnson (1981) reported antidepressant discontinuation rates of 16% within the first week, 41% within two weeks, 59% within three weeks, and 68% within four weeks. In their meta-analysis of discontinuation of SSRIs and tricyclic antidepressants, Hotopf et al. (1997) found 30% of patients stopped taking their antidepressant within one month and 45–60% stop by 3 months.

Rapid cessation of selective serotonin reuptake inhibitors (SSRIs) can produce a discontinuation syndrome consisting of somatic and psychological symptoms. In some situations, symptoms related to medication discontinuation may re-enforce the need for compliance to medication; however, if these symptoms are attributed to the medication itself, they may serve as a barrier to future compliance.

Depression has been shown to independently predict noncompliance. Depression-specific factors in noncompliance include reduced motivation, reduced task initiation, and cognitive impairment (slowed processing speed, poor concentration, and impaired executive functioning). The severely depressed patient may lack the energy and motivation to participate in treatment of any kind. Feelings of hopelessness or frank suicidal ideation related to depression may prevent patients from complying with medication or other treatments prescribed for co-morbid medical illnesses. This phenomenon can be particularly devastating to the treatment of patients with chronic or potentially fatal illness (diabetes, end-stage renal disease, cancer, transplant patients).

**Bipolar Disorder**

The problem of medication noncompliance in treatment of bipolar disorder has likely been experienced by many readers. Barriers to compliance in bipolar disorder can be classified as: (1) Pragmatic/ability to take medication—In both the manic and depressed phases of the illness, there are a number of core symptoms that can decrease the patient’s ability to take the medication as prescribed: impaired concentration/memory, disorganization, anergia, and altered sleep cycle; (2) Willingness—Patients with bipolar disorder may be hesitant to take medication that reduces hypomanic periods that they associate with exuberance, peaks of creativity, periods of increased goal-directed behavior, and decreased need for sleep. The manic phase of bipolar disorder is characterized by grandiosity, and occasionally frank psychosis, both of which impact the patient’s insight and willingness to comply with treatment; (3) Aversive nature of treatment—Medications typically used to treat bipolar disorder (i.e., mood stabilizers, antipsychotics) commonly have odious side effects (e.g., weight gain, sedation, movement disorders) or require frequent blood levels which can be a roadblock for some.

Rates of medication noncompliance among patients with bipolar disorder range from 18 to 52% (Scott and Pope 2002, Rosa et al. 2007, Keck et al. 1998). In a study of patients prescribed mood stabilizers, 50% of subjects admitted to some degree of medication noncompliance (Scott and Pope 2002). Scott and Pope (2002) report 32% of patients admitted to only partial compliance to medication which was defined as missing 30% or more of their medication. Factors associated with noncompliance were greater length of time on mood stabilizers, past history of noncompliance, denial of the severity of the illness, fear of side effects (not actual side effects), and negative attitudes toward medication (Rosa et al. 2007, Scott and Pope 2002). Gitlin et al. (1989) reported increased medication noncompliance in patients reporting coordination problems and/or cognitive side effects in response to lithium. In their study of medication compliance in patients with bipolar disorder, Keck et al. (1989) reported increased medication noncompliance in patients with comorbid substance abuse disorders.

**Schizophrenia**

Results from the CATIE study (the largest clinical trial of schizophrenia) indicate that 74% of patients with schizophrenia discontinued their medication treatment within 18 months (Lieberman et al. 2005). A number of other studies report noncompliance rates in excess of 50% (Valenstein et al. 2006, Rettenbacher et al. 2004, Novak-Grubic and Tavcar 2002). Valenstein et al. (2006) found that poor compliance was associated with young age, nonwhite race, substance abuse diagnosis, psychiatric hospitalization, and predominant treatment with first generation antipsychotics. Rettenbacher et al. (2004) found compliance positively associated with patients’ feelings of a positive effect of the drug on the illness, and greater negative symptoms.

In addition to deficits in judgment and insight present during active psychosis, persons suffering from schizophrenia have a number of cognitive deficits which are present not only in acute phases of illness, but also during periods of remission (Gold and Harvey 1993). Specific areas of impairment include attention, memory, and executive function. Similar to patients with other mental disorders (e.g., major depression, bipolar disorder), patients with schizophrenia often have irregular sleep and meal patterns and/or chaotic lives, making taking medications on a regular schedule very challenging.

Olsson et al. (2000) found that schizophrenic patients with substance use, difficulty recognizing their own symptoms, a weak alliance with inpatient staff, or poor family support were at increased risk for noncompliance following discharge from inpatient treatment.

**Attention Deficit Hyperactivity Disorder (ADHD)**

The characteristic features of ADHD, such as inattention, disorganization, and distractibility, can all contribute to noncompliance to medication. Since ADHD is a chronic illness with significant morbidity, it requires compliance to a medication regimen for many years. Due to the strong genetic etiology, parents of children with ADHD frequently have ADHD themselves and suffer from cognitive and temperamental characteristics similar to their children which can contribute to noncompliance (Stine 1994).
One study examined the length of time children with ADHD were compliant to stimulant treatment over a 3-year period. The authors reported 81% compliance rate at 1 year, but only 52% at 3 years (Thiruchelvam et al. 2001). Children who were compliant were younger, tended to have more severe symptoms of ADHD, but no oppositional/defiant symptoms. Children who were compliant to medication had more improvement in teacher-rated symptoms at 5-year follow-up (Charach et al. 2004). In an older study of compliance to ADHD medications, Firestone (1982) found that 26% of participants refused medication at the start of the study. Of those who accepted medication, 20% stopped their medication after 4 months, and 55% stopped after 10 months (Firestone 1982). Even more striking, less than 10% of families talked to their physician prior to discontinuing medication.

The reasons for noncompliance among patients with ADHD are multiple. Thiruchelvam et al. (2001) reported greater rates of noncompliance in older children and children with ODD symptoms. This suggests that older and more defiant children may resist and ultimately stop taking medication. Reported side effects were not related to compliance in this study.

Stine (1994) published an eloquent discussion of psychodynamic and psychosocial factors related to psychiatric medication compliance in the treatment of ADHD. The most commonly reported reasons for medication discontinuation were: (1) the child’s impression that the medication makes them feel strange or uneasy; (2) the belief that the medication makes the child less popular or entertaining when they take it; (3) the difficulty of having to take the medication at school; (4) the belief that taking medication makes the child different from friends or that friends will treat them differently because of their medication; (5) desire to disavow symptoms or the need for treatment; and (6) beliefs about the dangers of drugs (these fears are sometimes extreme; e.g., “medications are poisonous”).

Substance Abuse Disorders

It is not in the scope of this chapter to discuss specific treatment regimens for the various substance abuse disorders. The key point is that co-morbid substance abuse (in addition to any other medical or psychiatric disorder) increases the risk of medication noncompliance with prescribed medications, either psychiatric or nonpsychiatric. A number of factors likely contribute. Patients who are actively using alcohol and/or illicit drugs are often fearful that the prescribed medication(s), particularly psychiatric medications, will interact dangerously with alcohol or other substances. Unfortunately, physicians, family, and friends, frequently reinforce many of these beliefs, regardless of scientific evidence—perhaps hoping to “be careful” or that the patient will be “forced into quitting.” In long-term medication regimens, one must consider whether such advice is necessary or realistic. Many patients, especially when feeling a bit better, will simply stop their prescribed medication(s), or take them irregularly or as needed, in order to “safely” use alcohol or other substances. Data support an increased risk of secondary depression/anxiety/insomnia in patients with significant alcohol or cannabis abuse; however, alcohol does not directly interact with many of the newer generation antidepressants. While, as physicians, we need to assess the degree of the substance abuse openly with the patient, monitor for abuse of prescription medications as well as signs of CNS toxicity/oversedation, and collaborate with the patient—initially to provide nonjudgmental guidance and education, and later, to explore the patient’s motivation to engage in treatment for substance abuse, generally while continuing medication for the patient’s psychiatric disorder.

Developmentally Disabled/Cognitively Impaired

Cognitive developmental level affects the capacity and motivation for treatment compliance in a number of ways, including through memory, perception of time, and understanding of causality and consequences. Patients may not comply with physician’s recommendations because of physicians’ use of abstract rather than concrete reasoning in education about the illness and treatment required. Complex cognitive processes are required to understand the varied presentation of psychiatric symptoms, the multiple causes of mental illness, and the factors that contribute to severity of symptoms. Patients must have an adequate understanding of causality to understand how compliance (or noncompliance) affects the course of illness. They must have adequate perception of time to understand the short- and long-term consequences of depression and to understand the need to take medication regularly despite the delayed time to effect of medications. They must possess the ability for formal operations to fully understand the multiple abstract causes and consequences involved in illness and treatment of depression. Pediatric patients differ considerably in these cognitive skills.

In early adolescence, youth are able to think about illness in increasingly complex ways. By later adolescents, most youth have the capacity for somewhat scientific understanding of illness and treatment. Even adult patients may not have the health knowledge or logical operations necessary to understand the necessity to fully understand various components of treatment. Bush and Iannotti (1990), using their Children’s Health Belief Model, found that adolescents’ perceptions of the severity of illness and benefit of medication were the most important factors contributing to their compliance to medication. Both these factors require the understanding of causality and consequences. It is clear that efforts to enhance treatment compliance should match the intervention with the cognitive level of the patient.

Intervention Strategies

In an early publication, Haynes et al. (1976) identified six major strategies to improve medication compliance:

1. Informational and instructional
2. Reduction of barriers to compliance
3. Behavior modification approaches—problem solving, skills training
4. Increased patient supervision
5. Medication reminders and cues
6. Pharmacy interventions
7. Increasing resources/supports
8. Collaborative treatment teams
Much later, in a systematic review of interventions for enhancing medication compliance, Haynes et al. (2005) concluded that improving short-term compliance is relatively successful with a variety of simple interventions; however, interventions for enhancing long-term compliance in chronic health problems have been more complex and not very effective. Unfortunately, many medication regimens in psychiatry are long term.

Given the number of past intervention trials which have failed or produced results of marginal clinical utility for chronic medication regimens, it seems probable that past paradigms must be examined. The limited success of past interventions may be due to attempts to address unintentional but not intentional noncompliance. The simple strategies listed above fail to consider the power of psychosocial factors, such as patient beliefs, therapeutic alliance, and the influence of family, friends, and the community.

Selected Promising Intervention Strategies

Patient Self-Regulation of Medication
For some patients, self-regulation of dosage can be beneficial (Epstein and Cluss 1982). Nesson et al. (1980) utilized a self-control package that included self-monitoring of blood pressure and self-selection of dose regimen. Patients with insulin-dependent diabetes mellitus have long used the “sliding scale” method for fine tuning blood sugar control to avoid dangerous highs and lows (Epstein and Al. 1981). In pediatrics and child psychiatry, parents are commonly trained to administer “as needed” doses of medication (e.g., use of nebulized medication treatments as needed in asthma, use of anxiolytic or antipsychotic medication as needed for acute agitation in severely behaviorally disturbed patients).

Motivational Interviewing
Motivational interviewing uses a collaborative style of interaction between patient and provider to assess patient motivation to change. Over 70 clinical trials have established motivational interviewing as an effective method to promote behavioral change, including increasing treatment compliance. Miller and Rollnick (2002) demonstrated that adding even one motivational interviewing session in early treatment can improve patient retention, increase compliance, and improve outcome. The three principles of motivational interviewing are the use of collaboration between the physician and the patient, evocation of patient responses, and autonomy for the patient.

Tailoring Medication Regimens: Using Pharmacokinetics to Optimize Medication Compliance
What is good enough compliance? Unfortunately, the overwhelming majority of published studies set an arbitrary cutoff point for what constitutes compliance. Many studies even treat compliance as a dichotomous construct (e.g., compliant versus noncompliant). Even those studies that begin with a continuous measure of compliance (e.g., percent of doses taken as prescribed) generally set an arbitrary cutoff point for satisfactory compliance (e.g., 80%). In reality, the minimal level of compliance necessary to achieve the desired clinical outcome (e.g., remission of depression symptoms) depends on many factors, including the pharmacokinetic properties of the medication, individual differences in drug absorption and metabolism, individual variations in response to medication, with respect to efficacy and side effects (Epstein and Cluss 1982). For some conditions/medications, 50% compliance may be sufficient; whereas, for others, 80% or more may be necessary.

The pharmacokinetic (absorption, distribution, elimination) and pharmacodynamic (pharmacological effect, clinical response, toxicity, efficacy) profile of any medication varies across patients and can vary within the same patient due to many factors, e.g., age, race, gender, organ functioning due to maturation/disease, disease severity and comorbidity, and pregnancy (Katzung 2007).

Individual patterns of drug taking (“medication compliance”) influence the pharmacokinetics and pharmacodynamics of a medication; known pharmacokinetic properties of medications can be used to select more feasible, “forgiving,” medication regimens that can be tailored to individual patients (Rudd and Lenert 1995, Urquhart 1992, Levy 1993).

Weiden and Rao (2005) propose using a mnemonic of the “four Fs” to guide psychopharmacological treatment to increase medication compliance: (1) effectiveness, (2) flexibility, (3) forgiveness, and (4) user-friendly (Weiden and Rao 2005).

1. Effectiveness: Not only can noncompliance lead to relapse, but relapse can lead to noncompliance. One of the most commonly given explanations for medication discontinuation is that “the medication wasn’t working.” Systematically reviewing symptoms periodically during treatment can be helpful for both the doctor and patient in determining whether the medication is effective. Efficacy of psychiatric medication is especially important, as psychiatric symptoms themselves may interfere with compliance behavior (e.g., by preventing patients from learning from experience, interfering with ability to understand psychoeducation, and decreasing ability to remember the medication schedule).

2. Flexibility: Flexibility refers to considering as many pharmacological options as possible and actively collaborating with the patient to select medication. This approach allows the physician to tailor the medication regimen to target symptoms based on the patient’s priorities, while minimizing side effects that are most distressing to the patient.

3. Forgiveness: Because less than perfect compliance is the norm rather than the exception, medications that are forgiving of dosage irregularities should be selected.

4. User-friendly: Consideration should be given to ease of administration (number and time of daily doses; route of administration), number of medications, cost of medication, difficulty of obtaining the medication, and burden of side effects.

Treatment Concordance/Shared Decision Making
Many researchers now argue that only through increased collaboration with patients, can physicians determine the optimal medication regimen for any given patient (e.g., a regimen that is both feasible and effective for that patient). Using the paradigm of treatment concordance, physicians actively collaborate with patients to identify patients’
priorities and select medication regimens that target as many of the patient’s goals as possible. The model of shared decision making is illustrated in Table 114–3.

This method of prescribing medication utilizes evidence-based practices for selecting a range of medication regimens, all of which have sufficient empirical and/or clinical data support and then integrates known pharmacokinetic properties of medications, awareness of risk factors for noncompliance, and substantive understanding of the individual patient’s goals and priorities to compare the ability of the selected medication regimens to minimize barriers to medication compliance and compensate for imperfect patient behaviors. This process is tailored to individual patients and must be dynamic and interactive, just as medication compliance is a dynamic process, influenced by many factors.

Examples: If a depressed patient is bothered by insomnia and weight loss, mirtazapine or paroxetine might be reasonable choices. For patients who are obese and/or at risk for diabetes or elevated cholesterol, the physician should avoid medications that are apt to increase weight, glucose, cholesterol, and/or glucose (e.g., second generation antipsychotic agents). Optimally, through the use of patient education regarding symptom targets and potential side effects, several potential medication regimens can be identified and the physician can collaborate with the patient to select the regimen that best suits that individual.

### Conclusions
Given the preponderance of data supporting the high prevalence of medication noncompliance across all age, racial, and disease groups, physicians must accept the reality that perfect medication compliance is unattainable. In addition, given the number of past intervention trials which have failed or which have produced results of marginal clinical utility, it seems probable that past paradigms must be re-examined. Some of the more recent efforts appear promising, e.g., training providers to take more responsibility, and to take a more proactive role in tailoring medication regimens to better fit the needs of patients. Physicians must allow patients to speak freely about real-life barriers to medication compliance as well as their feelings, beliefs, and attitudes regarding medication, all of which can contribute to both unintentional and intentional noncompliance.

Disaster Psychiatry
Disaster is defined in the Oxford English Dictionary as “[a]nything . . . of ruinous or distressing nature; [a] sudden, great misfortune” (Oxford English Dictionary Online 2006). This definition captures both the catastrophe and the human tragedy that characterizes all disaster events. Disasters occur abruptly, and often with little predictability. Their destructive force can destroy communities, or even nations. Physical destruction (e.g., bodily integrity or health, homes or other cherished possessions, loved ones, and pets) and equally important emotional disruption and impairment (e.g., sense of safety, trust in government, questioning of spirituality, and connection to community) are expected with disasters. Although individuals and communities may grow from such experiences, disasters, by their ruinous and distressing nature, are costly, and always reason for anxiety, fear, and at times horror. Disasters vary in type, duration, and intensity (see below). Most if not all members of communities exposed to disaster will experience some degree of emotional distress. Depending on degree of personal exposure and loss, a disaster may precipitate mental disorders in some individuals and can lead to health-risk behaviors, such as increased smoking and alcohol consumption. Large-scale disasters create challenges for recovery amongst individuals and their communities (e.g., evacuation, loss of workplaces, disruption of the physical and interpersonal community, and social infrastructures).

Disasters differ from other types of traumatic events, as they strike across all strata of society (North 2003). Those who are most poor and disadvantaged, however, often bear the largest burden (Lima et al. 1989) because of where they build homes, the vulnerability of their home structures, and the lack of resources for recovery. An estimated 162 million people were affected by disasters in 2005. Nearly 105,000 people died and damages totaled over 176 billion dollars (World Health Organization, Collaborating Center for Research on the Epidemiology of Disasters 2006). Weather-related disasters (such as hurricanes and tsunamis) have received increased interest over the past decade. Historically, pandemic influenza has resulted in tremendous worldwide morbidity and mortality. The 1918 flu is said to have killed from 20 to 50 million people worldwide. The potential for the emergence of another pandemic influenza looms once again with the concerns of mass casualties around the globe. Current planning for a pandemic suggests that efforts to implement health-protective behaviors (e.g., adherence to medical recommendations, social distancing, quarantine, and travel restrictions) will present a significant challenge in a free and mobile society.

Disasters involving intentional mass violence, such as terrorism and war, have gained increased recognition in recent years. The Oklahoma City bombing, the World Trade Center attacks in 1993 and 2001, the anthrax attacks in the U.S., train bombings in Madrid, London tube attacks, sarin attacks in Tokyo, and ongoing terrorist attacks in the Middle East demonstrate the breadth and scope of intentionally caused disasters. Terrorist acts, by definition, target the very sense of safety and cohesion of society.

Demands produced by disasters overload community resources (e.g., health, law enforcement, and public works). The supply–demand mismatch hits directly at community weaknesses and vulnerabilities. Basic needs, such as water, food, and shelter, may be in short supply. Conflicts in responsibilities (e.g., family care vs. professional duties) can also contribute to further stress and emotional and behavioral changes in community members, including emergency first responders and community leaders.

As the immediate impact of a disaster subsides, survivors are confronted with the challenge of rebuilding their lives and sustaining their families. As they strive to return to...
a sense of “normalcy,” energy, money, and time are devoted to rebuilding lives, routines, jobs, and structures. This often overlooked (and often prolonged) period of rebuilding exacts an emotional toll on disaster-affected communities. From a disaster mental health management perspective, mitigating the psychological and behavioral effects of disaster requires an appreciation of both the types of disasters and the range of distress-related pathology in individuals and communities.

This chapter describes the types of disasters and their potential effects. Mental health response must be based on an action plan that effectively utilizes available resources (e.g., material, monetary, and personnel) and balances individual and community-based (or public health) approaches to treatment and the identification of at-risk groups. A public health approach addresses both individual and population care needs. This perspective targets those most severely affected, provides guidance and assistance for all who experience distress, and facilitates effective community leadership. Public health focus on mental and behavioral responses to disaster can provide for the public’s health and foster the resilience of disaster-exposed individuals and communities.

**Types of Disasters**

Disasters can be broadly divided into two types: human-made and natural disasters (Figure 115-1). Natural disasters (e.g., hurricanes, floods, tsunamis, and earthquakes) are considered by some to be “acts of God,” or result from the destructive forces of nature. Present science provides little an individual and community can do to prevent the most destructive natural disasters. Advances in science and technology have afforded increasing degrees of warning for some natural disasters. However, there is little that can be done to alter its occurrence or course.

Human-made disasters (e.g., transportation accidents, building collapses, nuclear and industrial accidents, and acts of mass violence, such as terrorism) make up the other category of disaster. Human actions contribute to the creation of this type of disaster and, to a certain extent, develop from human technology and engineering advancement. These types of disasters include structural failure, the failure of safety mechanisms, or intentionally caused destruction.

There is evidence that human-made disasters precipitate a more prolonged and difficult recovery for affected populations (Norris et al. 2002a). In human-made disasters, the belief (real or otherwise) that the event was preventable may contribute to the emotional sequelae. In some cases, a source of human error or oversight contributing to the event is readily identifiable.

The distinction between human-made and natural disasters is less clear in some cases. For example, an earthquake may cause initial damage and loss. However, the losses and damages may be more pronounced if preventable structural flaws in buildings lead to the collapse of additional structures. In the case of floods, if dams or other structures meant to divert water are not effectively located or structurally intact, their failure will make a natural disaster more widespread.

Terrorism is a special category of human-made disasters. Unlike other human-made disasters, terrorist acts are conducted with the purposes of causing fear (terror). Terrorist acts are implemented by those who wish to coerce societies and who believe that inducing fear, shock, horror, and revulsion will prompt societal change. These acts are often motivated by ideological, religious, and political agendas. Terrorist acts can lead to death, injury, property damage, and evacuation of communities. However, the main aim of these acts is to challenge a society’s sense of well-being, cohesion, and security.

The effects of terrorism can be magnified with the use of CBRNE (chemical, biological, nuclear, radiological, and high-yield explosive) agents. These mechanisms are well suited to causing terror (Holloway et al. 1997, Ursano et al. 2003b). The infectiousness and insidiousness of biological agents, the persistence and disfiguring effects of chemical weapons, and the delayed and uncertain effects of radiological agents, in particular, perpetuate fear and induce terror. Use of such agents on a large scale may not only result in injury and death upon immediate deployment but may complicate an otherwise already-prolonged recovery process.

**Types of Responses**

Disasters evoke a variety of immediate reactions at the individual and community level; grief, dismay, shock, disassociation, and other manifestations of distress may occur among the vast majority of community members. Some persons will experience exacerbations of preexistent mental

![Types of disasters](image-url)
disorders and still others may develop new mental disorders. At the individual level, response depends on a number of variables. The severity of response is greatest in those with high perceived threat to life, low controllability (e.g., those who feel powerless to alter the course of their own problems), high loss, injury, threat of disaster recurring, and exposure to death and the dead (Boudreaux et al. 1998, Epstein et al. 1997, Green et al. 1985, North et al. 1999, Schuster et al. 2001, Ursano et al. 2007, Wain et al. 2006, Zatzick et al. 2001). It is noteworthy that despite the universality of distress-related experiences, resilience and recovery after disaster are the rule. Most victims will not develop chronic problems. This tendency toward recovery is often termed resilience, a dynamic process of health recovery and coping in the face of adversity (Bonanno 2004). Optimism, intelligence, humor, creativity, and active coping are related to resilience and positive outcomes after crises (Charney 2004). Through active coping individuals accept the impact of a traumatic event (such as a disaster) and implement attainable, concrete measures to improve things.

Even in resilient populations, acute behavioral and emotional manifestations of distress (e.g., problems with sleep, transient worry, and anxiety) are common. Most of these psychological reactions to disasters may be considered ordinary or adaptive responses to stress (IOM 2003). For most, these symptoms will abate and do not require formal treatment. However, their resolution may be sped by educational outreach and community-wide supportive interventions (IOM 2003). Distress may also present as somatic symptoms represented by a myriad of physical complaints, including headaches, stomachaches, unexplained pain, and fatigue (Engel 2001). Somatic symptoms are frequently associated with anxiety or depression, and patients with these symptoms often seek care in a primary care clinic. Collaborative care between psychiatry and primary care is of particular importance after disaster for health surveillance, early detection, and treatment of stress-related physical symptoms.

**Health-risk behaviors** (Table 115–2) are those actions made in response to experiencing a disaster. In some cases these behaviors aim to reduce perceived risk of harm (e.g., changing travel route or mode of travel). They may reflect efforts to reduce or “self-medicate” distress (e.g., increase in smoking or alcohol consumption). Increased smoking and drinking has been reported after disaster (Norris et al. 2002a, Shalev et al. 1990). Increased substance use does not necessarily lead to substance-use disorders (Katz et al. 2002). Other health-risk behaviors may result from a necessary or excessive focus on meeting basic needs (e.g., failure to maintain sleep pattern or exercise regimen).

Increases in domestic violence and family relationship problems after a disaster (Adams and Adams 1984) represent another form of health-risk behavior after disaster. Effects of disaster on parenting have not been well studied; however, some data suggest increases in child abuse following disasters (Keenan et al. 2004).

For community leaders and disaster responders, over-education is a disaster behavior that may initially extend, but ultimately diminish one’s capacity to contribute to disaster recovery. Voluntary and altruistic assumption of long work hours, limited sleep, and decreased intake of food and water may be undertaken to benefit others, but the resultant cognitive and performance errors may put others at risk (Norwood et al. 2000). Evacuation behavior is a disaster behavior with implications for morbidity and mortality. After the First World Trade bombing in 1993 many persons either did not evacuate or took significantly longer to do so than necessary, as they sought to quell their anxiety by leaving the building with familiar peers (Aguirre et al. 1998). After the 9/11 attacks, those who evacuated from buildings in New York City tended to congregate near the site of the disaster (Gershon et al. 2004). These seemingly innocuous behaviors may result in increased casualties in cases of secondary building collapse.

The third interrelated psychological consequence of disasters is psychiatric illness. This category includes posttraumatic stress disorder, acute stress disorder, depression, and other anxiety disorders (Table 115–3).

**PTSD** is a frequent subject of study following disasters (for review, see Breslau et al. 2005, Saigh and Bremmer 1999). This disorder is relatively common in the aftermath of large-scale disasters, with prevalence ranging from 10 to 40% in various studies (David et al. 1996, Galea et al. 2002, Green et al. 1991, Ironson et al. 1997, North et al. 1999, Schlenger et al. 2002). Individuals with PTSD experience symptomatology in a number of domains that lead to functional impairment. These domains include hyperarousal symptoms (e.g., problems with sleep, easy startle, and irritability), avoidance (e.g., numbing, not recalling important aspects of the trauma, and sense of foreshortened future), and recollections (e.g., nightmares, reliving the event, and having physiological response to reminders of the event).

The National Comorbidity Study found rates of PTSD to be 7.8% (Kessler et al. 1995), while the National Women's Study found rates to be 12.3% (Resnick et al. 1993). Following the Katrina hurricane, the disaster region had approximately 30% incidence of PTSD (Ursano 2006). In its acute and milder forms, PTSD may be more analogous to the common cold and experienced by nearly everyone at some point in their lives. Like a common cold that becomes pneumonia, it is when it persists that it can be debilitating and require more formalized (and possibly) prolonged intervention.

**Acute stress disorder (ASD)** is a disorder similar to PTSD but persists for a minimum of 2 days to a maximum duration of 4 weeks. (If it persists longer, then PTSD is the appropriate diagnosis.) The diagnostic criteria for ASD include the symptoms of PTSD with the additional requirement for peritraumatic dissociative symptoms. Dissociative experiences are quite common in the immediate aftermath of trauma (Fullerton et al. 2004).

PTSD and ASD are by no means the only trauma-related psychiatric disorders and may not even be the most common (Fullerton and Ursano 1997, Norris et al. 2002b, North et al. 1999). Exposure to disaster has been associated with increased risk for depression (Miguel-Tobal et al. 2006), generalized anxiety disorder, panic disorder, and increased substance-use disorders (Breslau et al. 1991, Kessler et al. 1995, North et al. 2002, Vlahov et al. 2002). There is suggestion that these disorders occur at higher than average rates (Galea et al. 2002, Kessler et al. 1999, Miguel-Tobal et al. 2006) and may be relatively common in the 6- to 12-month period after a disaster.

Bereavement and grief associated with traumatic loss pose special challenges to survivors of disasters and other traumatic events. Even when not directly witnessing death, family members may develop intrusive images based on information from authorities or the media. A syndrome related to PTSD, with excessive yearning for, and intrusive recollections surrounding the death of a significant other is termed complicated grief. Complicated grief has been proposed for addition to the DSM. Whether or not it is formally recognized complicated grief represents a distinct subset of disaster-related psychopathology for which prevention, recognition, and treatment approaches are being developed.

At the community level, effective leadership after disaster includes “grief leadership,” an important aspect of giving permission for, and teaching and showing communities how to grieve (Ursano and Fullerton 1990).

Community Response
Just as individuals are affected by disaster, so are the communities to which they belong. The community response to disaster often runs a predictable and, at times, paradoxical course. Communities temporarily coalesce immediately after a traumatic event, in a phase referred to as the “honeymoon period.” Groups and individuals work together under a common, altruistic cause. Accounts of heroism are reported and a sense of “we will survive” pervades the community (Zunin and Myers 2000).

As time evolves, the sense of optimism turns to disillusionment and anger. Scaregiving often occurs and the search for accountability often ensues. Mayors, police chiefs, politicians, and community leaders are often targets. The search for blame often exposes the social fault lines of conflict and suspicion that present along racial, ethnic, economic, and religious divides. Communities encompass not only geographical areas in which disaster victims reside but also the less tangible groups with which individuals share a “sense of belonging.” Communities may include workplaces, neighborhoods, churches, schools, ethnic groups, families, and other circumscribed populations with which individuals may choose to associate or find membership.

Communities serve as important physical and emotional support systems that individuals can look to after a disaster. Disasters, however, may impair a given community’s ability to function, self-sustain, and provide safety for its members. In disasters that cause widespread destruction and evacuation, jobs, friends, schools, and areas of worship may be destroyed or displaced. The recovery environment may not be intact or be able to support its members (Hobfoll and Jackson 1991, Noji 1997).

There is ample evidence that available social support after disaster can affect outcome and that the perception of available resources can increase feelings of safety (Norris et al. 2002a). Replacing lost resources as quickly as possible is one of the most useful interventions in the immediate aftermath of disaster (Hobfoll and Lilly 1993). Organizations within the community including churches, schools, and employers may be well positioned to provide support and information to individuals with specific concerns and/or needs. Individuals naturally look to these community resources as providers of such support. Recent studies suggest that businesses vary significantly in their human capital continuity resources and preparedness to offer assistance to employees and their families after disaster (Ursano et al. 2007).

One aspect of community response to disaster is community-related grief or bereavement. Gestures of sympathy for the injured, dead, and missing as well as their families are common. Observed rituals, such as burials and funerals, are observed. As times passes, the creation of memorials—both formal (such as structures and monuments) and informal ones (wreaths, candles, and pictures)—often occurs. Memorials may assist some in recovery and remembrance, while others may see these as constant and intrusive reminders. Anniversaries of the disaster additionally stir memories and renew the grieving process (Ursano et al. 2003a).

At-Risk Groups
Protecting those who are at risk from disasters is critical. Studies are now only beginning to explore why some people exposed to disasters develop posttraumatic pathology and others do not. This research has generally demonstrated particular at-risk groups. Persons most directly exposed to trauma, physically injured persons, women, those with pre-existing psychiatric conditions, children, refugees, other displaced persons, and those with ongoing negative life events may be at increased risk for psychological problems following a disaster (Table 115–4).

In general, women appear to be at greater risk for PTSD and major depression, while men are at greater risk for substance abuse after disasters (Kasl et al. 1981a, 1981b, Lopez-Ibor et al. 1985, Maes et al. 1998, North et al. 1999, Weissaeth 1985). These gender-related distinctions diminish in military populations engaged in combat (Hoge et al. 2004) perhaps as a result of selection, specific training or the nature of war-related trauma. Other demographic factors from disaster literature, such as age, race, and socioeconomic status, present either mixed finding or insufficient evidence to conclude consistent association as they apply to postdisaster outcome.

Those directly exposed are at greatest risk for psychiatric disorders after the disaster. The directly exposed group usually includes individuals most proximal to the disaster (Galea et al. 2002, North et al. 2002), those who were in physical danger, and those who directly witnessed traumatic events. In addition, individuals who have attachments with primary victims, first responders, and support providers are at greater risk (Wright and Bartone 1994) than “detached” bystanders.

veterans demonstrated a higher rate of PTSD in the wounded soldier cohort (Helzer et al. 1987). Also, high levels of physical problems early after injury were predictive of the subsequent development of PTSD and depression in injured U.S. soldiers (Grieger et al. 2006). In addition, psychiatric symptoms are frequently seen in injured survivors dealing with the stress and extent of injury (Brandt et al. 1997, North et al. 1999, Shore et al. 1989, Zatzick et al. 2001).

First responders (e.g., fireman, police, and emergency medical technicians) are an at-risk population by virtue of their job and degree of exposure (Duckworth 1986, Fullerton et al. 2004, Jones 1985, Weiss et al. 1995). Well-trained individuals can develop persistent problems as a consequence of frequency and degree of exposure, particularly to the disfigurement and grotesquery of the immediate post-disaster scene. First responders must also contend with their own safety as well as that of others at the disaster scene. First responders may “identify” with victims and think “it could have been me,” or be reminded of their own (and their family’s) vulnerability. This phenomenon has been particularly associated with increased rates of psychopathology in handlers of human remains (McCarroll et al. 2001, 2002, Ursano et al. 1999).

First responders may also include bystanders in the vicinity when a disaster occurs. It is estimated that 50% of those who initially report to assist after a disaster are these types of bystanders. These individuals may be at particular risk, as they are exposed to tasks and scenes for which they have little training or previous experience in handling.

Preexistent psychiatric conditions are not necessary for psychiatric morbidity after a disaster and they are not sufficient to account for it (Goldberg et al. 1990, McFarlane 1989, Ursano et al. 1981). Those with preexisting psychiatric conditions are at increased risk of psychiatric illness after a disaster (Bromet et al. 1982, McFarlane 1989, North et al. 1989, 1994, 1999, Ramsay 1990, Smith et al. 1990, Weissah 1985). In addition to psychiatric illness, personality features have been shown to be associated with development of psychopathology (including PTSD) after a disaster (Chen et al. 2001).

Children are a population of concern after all disasters (Cohen et al. 2006, Pfefferbaum et al. 2005, Pynoos et al. 1997). Limited cognitive level and maturity to understand, displacement, experiences of altered parenting and observation of parental distress (Michael and Julia 2006), loss of parental figure, and injury are all thought to contribute to their risk. Overt manifestations of distress may include lability, problems falling asleep, frequent crying, fear, and anniversary grief. Alternatively, presentations may also be more subtle, such as manifesting in multiple, medically unexplained somatic complaints (Michael and Julia 2006).

Depression, anxiety, and PTSD in children of disaster have been well characterized. The prevalence of PTSD symptoms 2 months after the Asian tsunami in children aged 7–14 was 13% (children in camps), 11% (children affected in villages), and 6% (children in unaffected villages) (Thienkrua et al. 2006). In New York public schools after the 9/11 attacks, 28.6% of children in grades 4 through 12 had one or more of six probable anxiety/depressive disorders (Hoven et al. 2005) and were largely represented by probable diagnoses of agoraphobia, separation anxiety, and PTSD. Comorbidity is not uncommon in adolescents after disasters. One recent study (Kar and Bastia 2006) noted comorbidity in 39% of adolescents with psychiatric diagnoses. Distress without psychiatric disorder has also been demonstrated. A significant proportion of children also worry about the future and the potential to be victims of terrorism (Schuster et al. 2001).

Refugees/displacement. Being displaced (e.g., evacuated to a refugee camp) is associated with elevated rates of depression and anxiety (Thapa and Hauff 2005), PTSD (Bland et al. 2005), and—for children—insecure attachment style in their adult years (Foster et al. 2003). The refugee population encounters many problems (such as loss of job, loss of home, and loss of community) that are associated with issues of attachment, familiarity, and identity (Fullilove 1996).

Ongoing negative life events. Research has also focused on those who experience further negative life events after a disaster. These negative life events are usually brought upon by the disaster and its subsequent effects, such as loss of community employer that in turn produces loss of job, financial constraints, relationship difficulties, etc. These contribute to increased likelihood of PTSD (Adams and Boscariino 2006), PTSD severity (Maes et al. 2001), and depression (Person et al. 2006). Negative life events have also been linked to an increase in workdays lost (Boscariino et al. 2006) as well as poorer mental health outcome (Adams et al. 2006). Long-standing psychosocial and personality issues that predate the disaster may confound the risk for experiencing negative life events after a disaster (North 2003).

Mitigating Disaster-Related Distress and Dysfunction

During a disaster, mental health providers must anticipate and respond to a range of emotional and behavioral demands from those affected. In the case of disasters involving epidemics or bioterrorism, stressors include quarantine, shelter in place, and travel restrictions. The public health system must address mental health care across the dimensions of distress, disorder, and behavior.

Mental health professionals are an essential part of planning for and responding to disasters. Mental health disaster response includes the identification and treatment of those who need immediate psychiatric care as well as interventions for those populations that will benefit from support, guidance, and the provision psychological health-related information. Public education, consultation to leadership, and schools are important tools for mitigating community-wide distress and facilitating early identification of those in need of treatment.

The range of responses for which mental health disaster planners must account requires that new models of monitoring community health care needs in real time (i.e., mental health surveillance) as well as innovative models for delivering care are developed (Bryant 2006). The mental health care system, as part of the medical care system, must join with the public health and emergency response system to address the needs for triage, surge capacity, and health surveillance in order to best provide care for communities exposed to a disaster (Raphael 2006). The knowledge base from a variety of disciplines including sociology, risk communication, education, and disaster mental health can contribute to the development of effective response plans (Litz et al. 2002). This knowledge can provide guidance for
community leaders, local emergency planners, health and mental health planners, and health care providers in order to create an informed and well-prepared plan for psychological and behavioral consequences of disasters (Litz et al. 2002). Therefore accurate assessment, and appreciation and proper use of community resources can help mitigate the effects of disaster and its responses (Table 115–6).

**Planning and Preparation**

Planning is the first and most important step in forming an effective and coordinated response. It is often difficult to obtain resources for planning, as these needs must be balanced against resources utilized for more immediate needs. Disasters are often unexpected and, although there is very little that can be done to control the timing and occurrence of such events, the effects can be mitigated with a considerate and well-formed plan. In preparation for disasters, leaders of the community response need to be identified. Elected officials, religious leaders, educators, and military leaders provide a pool of appropriate candidates. This cross section should include those who provide expertise in essential human needs during a disaster, such as communications, security, and aid assistance. Leaders are in the best position to know of the resources in the community and its present need. Knowing the most efficient way of reaching those who require assistance is also a function of leadership identification.

Leaders are often looked upon as the “voice” and the communicators of the community. In times of crises, this is an expectation. Clear, concise, and accurate updates from community leaders can help inform and calm a populace looking for answers. Thus, for leaders, training in the principles of good risk communication and public education may prove invaluable. Risk communication is a scientifically informed approach to communicating in stressful situations. Principles of good risk communication enable leaders to inform and direct diverse populations (Table 115–6).

**Planning**

Leadership should be identified in order to

- perform accurate assessment of resources in community
- identify at-risk populations within the community
- determine the best way to assist community in culturally acceptable ways
- be trained in the principle of good risk communication
- prepare populace (i.e., having emergency provisions and plans)

**During Event**

After a disaster

- Most important initial need is to address the medical and emergent needs of those affected
- Psychological first aid may be of benefit
- Those least injured will present for evaluation first
- Medical assets will be overwhelmed
- Large numbers of presenters will be distressed and will seek reassurance
- A side area by the emergency room should be established for those who are not reassured and need time to reconstitute
- A volunteer registry for subsequent contact can be established for subsequent follow-up (health surveillance)

Individuals in the community look to their leaders for information, inspiration, a sense of control, optimism, and help during a period of grief (Barbera et al. 2001). Effective risk communication helps to provide these by delivering frequent information from credible and consistent sources. This information should avoid speculation, outline specific steps people can do to protect themselves, and inform when the next messages will be delivered; this can assist in reducing negative psychological responses, encourage safe and responsible behaviors, build trust, and minimize misinformation (Aakko 2004, Covello et al. 2001, Glik 2007). Leaders must also understand what is culturally and socially appropriate in terms of aid, timing, and assistance measures.

Being aware of the presence and needs of at-risk groups is an important function of leaders. This is especially true in the diverse and multicultural communities. Different cultures may have markedly different responses as a result of past experiences with disasters, with government’s aid and assistance, and with security forces, police, or other first responders. Many immigrant groups and individuals have limited proficiency in the language of their current homelands and have previous experience with torture or abuse by authorities, multiple losses, minimal resources, and limited access to care. Any of these may place them at greater risk. In the planning phase for disaster response, awareness and information must be culturally sensitive and accessible.

Leaders must be aware of their community’s inherent strengths. Fostering resilience is a primary goal of preparedness. Resilience represents both decreased adverse responses and more rapid recovery. Town meetings that occur prior to crises may foster community efficacy by enabling community networks to work together in order to anticipate “cracks” in the support network. For example, these meetings can set forth plans, such as who will watch children on the block if a mother or father is not home. Such cohesion efforts can develop community efficacy (Sampson 2003, Sampson et al. 1997) and channel fear into a flow of constructive action instead of community chaos.

Efforts to promote individual and family pre-event preparation are vitally important to minimizing the psychological consequences of disaster. In surveys conducted after hurricanes Katrina and Rita, less than half of respondents reported having a family emergency plan familiar to all members. In addition, less than a third had emergency provisions (e.g., 2 days of food and water, flashlight, radio, spare batteries, emergency phone numbers, and a preplanned emergency meeting place) (Redlener and Berman 2006). Forming a communication plan with loved ones (in the case of separation), establishing and mapping out of evacuation routes, having extra medication supplies, developing care plans for

Early Intervention at the Community Level

Identifying vulnerable populations, providing psychoeducational support, assessing population needs, and providing access to care are areas of emphasis when managing disaster mental health. Referred to as Critical Incident Needs Assessment Teams (CINAT), these multidisciplinary teams are formed from the community and workplaces from which they live and serve (Hamaoka et al. 2007). Team membership may include not only mental health authorities, but also others such as leaders, information specialists, and security specialists. These teams provide a vehicle for the delivery of psychological first aid (PFA), leadership consultation on grief leadership and other behavioral issues, and health surveillance.

PFA may be helpful and appropriate in the immediate aftermath (hours to days) of disaster (CSTS 2005, Parker et al. 2006, Watson and Shalev 2005, Weisaeth 2004). This evidenced-informed interventional structure aims to reduce distress by using several principles (Table 115–7) and is best thought of as a flexible, supportive, population-based approach to distressed persons. Since outcome studies are lacking, intervention should be considered as “likely to be helpful.” Its main objectives are to limit distress, emphasize healthy behaviors, and minimize negative health behaviors. PFA is an intervention that can be accomplished by anyone who had been trained. (That is, it does not have to be accomplished by a mental health provider.) In addition, this training does not require formal mental health training.

Principles of PFA include promoting safety, calm, connectedness, self-efficacy, and hopefulness.

receiving assistance. In the same way, promoting calm is another tenant of PFA. Promoting calm may seem to be a challenge in the chaotic environment after a disaster, but providing accurate information about the disaster and relief efforts so that they are apprised of the situation can assist in producing calm. Another example would allow for victims to share their stories and emotions if they choose. Providing and maintaining a friendly and compassionate stance even if others are being difficult is another way to promote calm.

By remembering to promote connectedness, PFA helps providers remember that family and loved ones are important and that helping them connect with them is important. Even if the disaster makes it physically prohibitive for family members to meet, promoting connectedness can even include telephonic communication or information from separated family members about their location and status. In promoting connectedness, it is also important to remember that, if at all possible, family members should remain together. Connectedness both increases emotional support and provides opportunities to obtain practical help and information.

Finding and sharing the types and locations of available services can assist in instilling hopefulness. If one knows that more help and services are on the way, reminding people of this can be helpful when they experience fear or worry. In addition, recognizing and reminding people that “things will get better” is an important clinical task in most settings where the clinician may be able to see further ahead than the patient in distress. Promoting self-efficacy enables victims to help themselves in the aftermath of a disaster and to believe that they have the skills to survive and move forward. Ways to help promote this tenant are providing suggestions that steer people toward helping themselves, thereby helping them meet their own needs. This helps victims take control in their environment and empowers them.

Brief simple conversations and informal on-site talks with survivors can be of great assistance. This early “walk-around” intervention offers support and education, avoids mental health labeling, and makes possible early assessment of those in most need. Mental disorders that occur in response to disasters appear to respond to the same therapeutic approaches as disorders observed in traditional treatment environments. Psychotherapy (e.g., cognitive therapy, cognitive–behavioral therapy, and interpersonal therapy) and medication (e.g., selective serotonin reuptake inhibitors, selective norepinephrine-serotonin reuptake inhibitors, and dopamine-norepinephrine reuptake inhibitors) are evidenced-based treatments for depression (APA 2000). Treatment guidelines for ASD and PTSD have also been established (Ursano et al. 2004). Evidence-based treatments for PTSD include medications (e.g., selective serotonin reuptake inhibitors, such as paroxetine and sertraline) as well as therapies (e.g., cognitive–behavioral therapy) (Bryant et al. 1998, 2003). Other medications may improve sleep or reduce posttraumatic nightmares. Combinations of psychotherapy and medication may promote maximal response. One well-publicized disaster intervention known as “psychological debriefing” has not been shown to prevent PTSD and may be harmful in certain circumstances (Rose et al. 2002).

Sustaining Recovery
The longer term morbidity associated with disasters has not been well studied. However, the prevalence of psychiatric disorder in refugee populations, war veterans, and holocaust survivors and the chronic and recurrent nature of depression, anxiety disorders, and substance-related pathology suggests that the long-term emotional and behavioral consequences of disaster are substantial. The institution of new health programs and resources and public health awareness campaigns in rebuilding communities may result in persons with illness that predated the disaster seeking adding to the burden of those affected “purely” by the disaster. Traditional psychopharmacological and psychotherapeutic approaches may serve these populations (if resources are sufficient) but vulnerable populations (the elderly, the chronically mentally ill, and the poor) may continue to require targeted interventions for years after a large-scale disaster.

Pandemic Flu: A Case Example

Pandemic flu is a present-day concern that highlights the need for planning and attention. It is estimated that the next influenza pandemic may result in millions of casualties and substantial morbidity associated. A response plan for a disaster of such magnitude will require leaders and communities to work together. Obstacles to such a coordinated international response include cultural differences, geographical and political boundaries, and the willingness of those affected to respond and adhere to recommendations from various sources of authority.

There have not recently been large enough infectious outbreaks to fully inform a consensus response to a potential pandemic flu. Recent data and observations on infectious disease outbreak and mental health responses provided by SARS (Des Jarlais et al. 2006, Hawryluck et al. 2005, Ko et al. 2006, Ursano 2005) and contained outbreaks of influenza in the far east suggest that planning must include the notion that care providers will be reduced in number and effectiveness by the outbreak itself (Chong et al. 2004, Lin et al. 2007).

Although much of the initial attention will focus on the contagion and casualties, planners need to remain cognizant of distress behaviors, health-risk behaviors, and psychiatric illness. The attention to such issues can influence the adherence to recommendations to help control the outbreak. The scope of this potential disaster has widespread implications and special considerations. This pertinent example reinforces the content of this chapter and discusses some special considerations of this disaster.

General responses (and special considerations for each stage) can be divided into three parts: preparedness, early response, and later response and recovery (Table 115–8).
Preparedness
Public education must begin immediately and embed into existing disaster public education campaigns and initiatives. Such education should focus on facts, to include what is known, what is not known, and how individuals, communities, and organizations can prepare. This public education should be inclusive of the varying degrees of threats, to include those of reasonably low threat potential to those with the highest potential. This can provide usable information on which to base choices (Morse et al. 2006).

Leadership serves a critical function in the preparation phase. Leaders are valuable in identifying those groups who may be at the greatest risk for problems related to the contagion, such as those with psychiatric illness, children, elderly, homeless, and those with losses. They also serve to affect communities and influence individual behaviors; these can be especially helpful in the endorsing and modeling of proper protective health behaviors. Special attention to the workplace is imperative (as this venue can potentially reach large audiences), as well as enlisting the media as partners.

Early Pandemic Response
There will likely be widespread morbidity and mortality. In the midst of such event and ongoing loss, there will also be the challenge of sustaining community and function in the midst of a restrictive environment (e.g., shelter in place, contact precautions, and treatment adherence).

In the early pandemic response, the role of communication will be of utmost importance. Dissemination of uncomplicated and empathically informed information on normal stress reactions can help to normalize reactions and emphasize hope, resilience, and natural recovery. This will be essential as recommendations to prevent exposure, infection, and halting of the disease process will be met in a variety of ways: hope, skepticism, and fear. Compliance with vaccinations and medication regimen will vary greatly and will not be complete. The public must be clearly and repeatedly informed about the rationale and mechanism for distribution of limited supplies of medication and resources. Likewise, leadership must adhere to policies regarding such distribution, as abuses of policy will undercut the public safety and adherence to other recommendations.

Certain events, known as “tipping points,” will occur that can dramatically increase or decrease fear and health-risk behaviors. Events that present tipping points are the death of important figures, deaths of the particularly vulnerable (e.g., children), new unexpected or unknown risk factors, and treatment shortages. Such events can present widespread distress in individuals and communities already weathering a great deal of stress and fear. Anticipation of the effect of these events may help inform a response to address these.

Those who believe they have been exposed (but have actually not been) will outnumber those exposed and may quickly overwhelm a community’s medical response capacity. Planning for the psychological and behavioral responses of the health demand surge and responses to shortages should be anticipated.

Later Response and Recovery
Maintenance of community and its social supports will be important. These may be diminished because of movement restrictions due to concerns of contagion. Virtual contacts, via Internet, telephone, television, and radio, will be increasingly important at these times. At other times, local gathering places—religious places, schools, post office, and grocery stores—are points of access for education, training, and distribution.

Instilling a sense of normalcy, in as much as is allowed, may be effective in fostering resilience. Observing rituals and engaging in regular activities (such as school and work) can help manage the community and organizational distress into constructive behaviors. Providing tasks for community action can supplement needed functions, decrease helplessness, and instill optimism.

Under conditions of continuing threat, the management of ongoing racial and social conflicts in the immediate period and during recovery takes on added significance. Stigma and discrimination may marginalize and isolate groups, thereby impeding recovery.

In the later phases, the management of bodies and the community response to losses will be significant. Containment measures related to bodies and contagion may conflict with religious ritual of burial and therefore have the potential to complicate bereavement. In a pandemic, funeral resources will be overwhelmed. In addition, careful identification of bodies must be ensured and appropriate, accurate records maintained.

Conclusion
Disasters are ubiquitous; they affect individuals, families, workplaces, and communities. Whether from natural or human-made causes, disasters will continue to be a primary cause of mental health need. Proper preparation, effective leadership, attention to community and individual needs, and well-placed interventions can help mitigate the distress produced by disasters and help maximize community restoration.

Introduction
Management of the suicidal patient is one of the most challenging clinical tasks faced by the clinician. A clear and thorough approach to risk assessment and a comprehensive, yet focused management plan is required. Accurately predicting which patients will eventually commit suicide is not currently possible. However, factors that raise and protect against risk have been identified. This chapter provides a guide for the clinician managing the suicidal patient. The risk and protective factors for suicide are presented, as well as suggested assessment and treatment approaches for suicidality.

What is Suicidal Ideation and Behavior?
While the field is troubled by the use of inconsistent terminology for suicidal ideation and behavior (O’Carroll et al. 1996, Andriessen 2006), the following definitions, previously used in recent research (e.g., Posner et al. 2004, Hammad et al. 2006) will be used for suicidal ideation, suicide attempt, completed suicide, and nonsuicidal self-injurious behavior in this chapter.

Suicidal ideation is the occurrence of passive thoughts about wanting to be dead or active thoughts about killing oneself (Posner et al. 2007). Suicidal thoughts may range from the occasional and fleeting to the ruminative and omnipresent. Typically, they fluctuate and are ambivalent, countered by the will to live.

A suicide attempt is defined as a potentially self-injurious behavior with at least some intent to die as a consequence of the act (O’Carroll et al. 1996, Oquendo et al. 2003). The intention of suicidal behavior is to end one’s own life. Suicidal intent is necessary for a potentially self-injurious behavior to be labeled an attempt; however other motivations may also be present, for example, to influence another. Attempting suicide may or may not cause actual injury. Self-injurious behavior without suicidal intent is engaged in for purposes other than death, such as communicating distress and stimulating or coping with strong emotions. Self-harm behavior that is undertaken without at least some intent to die is not classified as suicidal. Populations with suicidal behavior and self-injurious behavior without suicidal intent can be meaningfully distinguished by these behaviors (Nock and Kessler 2006), although the overlap between these populations is not small. Completed suicide is a self-injurious behavior that has the consequence of death which must be accompanied by at least some intent to die as result of the behavior (O’Carroll et al. 1996, Oquendo et al. 2003).

Scope of The Problem of Suicidal Behavior: Mortality and Morbidity
In 2000, suicide accounted for up to 1 million deaths worldwide including approximately 30,000 in the US (World Health Organization 2007, Centers for Disease Control and Prevention, National Center for Injury Prevention and Control 2007). Globally, suicide is among the top three leading causes of death for ages 15–44 years (World Health Organization 2007). Suicide rates vary by country with high rates recently reported in the Baltic States, Russia and some Eastern and Northern European countries (World Health Organization 2007). Rates also vary over time, for example, rates of youth suicide rose in many countries between the 1960s and 1990s (Gunnell 2000, Cantor et al. 1996) and have declined or stabilized in some countries since the 1990s and early 2000s (Gunnell 2000, Lester and Yang 2005, Bridge et al. 2005). National rates may be influenced by factors including, religion, socioeconomic factors, access to means, and mental illness (Levi et al. 2003). In addition, the quality and type of data collection and classification varies between countries and limits the utility of this data.

The burden of suicide has come to governmental attention with the development of strategy and policy to combat
the problem (e.g., the US Surgeon General’s Call to Action to Prevent Suicide; U.S. Public Health Service 1999). The UK aims to cut suicide by 25% by 2010 (Robinson et al. 2006), given both its enormous human cost for surviving family (Mitchell et al. 2005) plus economic cost (Clayton and Barceló 1999). But the burden is not limited to the costs of completed suicide alone. In a large US national survey, 4.6% of respondents admitted to attempting suicide, 13.5% reported lifetime suicidal ideation, and 3.9% admitted to ideation with a plan during their lifetime (Kessler et al. 1999). In the US, suicidal and nonsuicidal self-injury requiring hospitalization numbered more than 154,000 in 2005 (Centers for Disease Control and Prevention, National Center for Injury Prevention and Control 2007) and account for 0.4% of all emergency department visits (Doshi et al. 2005). Moreover, a sizeable proportion of suicide attempters do not attend emergency departments or receive medical or psychiatric care (Suominen et al. 1998). Thus, the problem of suicidal behaviors is significant.

Risk and Protective Factors

While suicide is responsible for a substantial number of preventable deaths, it accounts for only a small percentage of all deaths. The relatively infrequent nature of suicide and the complex etiology of suicide contribute to the difficulty in identifying predictors of attempted and completed suicide that possess reasonable levels of sensitivity and specificity. Typically, risk factors have a low level of specificity, in that they produce a high proportion of false positives. For example, psychiatric diagnosis is highly associated with suicide but the majority of people with a psychiatric diagnosis do not attempt suicide (Mann and Currier 2006). Factors that protect against suicidal behavior have also been identified. Like risk factors, knowledge of protective factors, such as employment and social support, in some cases, can provide targets for treatment. Knowledge of risk and protective factors for suicidality are therefore important for the clinician managing a suicidal patient. The following is a summary of those factors.

Demographic Risk and Protective Factors

Gender

Males are almost four times as likely to die by suicide as females (Centers for Disease Control and Prevention, National Center for Injury Prevention and Control 2007). Females are twice to three times more likely to think about suicide (Kessler et al. 1999, De Leo et al. 2005) and almost twice as likely to attempt (Kessler et al. 1999). These differences may be explained in terms of an unequal distribution of risk factors. For example, while females experience greater levels of depression (Kessler et al. 2005) which raises risk, they typically use less lethal means when attempting (Hawton 2000), and are less likely to experience substance abuse or impulse control disorders (Kessler et al. 2005) than males, which reduce risk.

Age

In the US, completed suicide increases markedly from childhood, where it is a very rare event (6–11 years, 0.13/100,000), to early adolescence (1.34/100,000) and mid-late adolescence (8.2/100,000), before stabilizing in early adulthood (20–24 years 12.47/100,000) to adult levels (Centers for Disease Control and Prevention, National Center for Injury Prevention and Control 2007). While frequency of completed suicide is generally stable throughout adult life, there is a sharp, dramatic increase in completed suicide in elderly populations (Conwell 2001). In contrast, suicidal ideation and attempts have been noted to decline with age (De Leo et al. 2005, Kuo et al. 2001, Kessler et al. 2005). Apart from the possibility that risk of suicidal ideation indeed decreases with age, this could imply that attempts become more lethal and/or better planned resulting in fewer remaining ideators or that as the population ages, more of the at-risk individuals have died by suicide or other causes.

Religiosity

Religious belief or affiliation is associated with a reduced risk of suicide (Anglin et al. 2004, Dervic et al. 2004, Eagles et al. 2003, Hilton et al. 2002). The protective effect of religion may be due to the deterrent effect of religious beliefs, such as suicide is a sin or is morally wrong or social support from family (Dervic et al. 2004) or a religious group (Neelcman et al. 1997). The protective effect of religion may not be universal, however, with some religions having beliefs that are congruent with suicide, for example, condoning suicide as an honorable way of dealing with problems or that death may be a way of being reunited with loved ones (American Psychiatric Association 2003). Considering this variability, clinicians ought to query patients about their religiosity and the likely impact of religious beliefs on suicidality.

Family and Social Factors

Separated, divorced, and widowed individuals have been found to be at twice the risk of attempted suicide (Kessler et al. 1999, 2005). Another study has shown that risk varies with gender and is only elevated in divorced males (Kposowa 2000). The relative protective effects of marriage may be gained from companionship, social support and a sense of responsibility (American Psychiatric Association 2003). Having children appears to attenuate risk (Clark and Fawcett 1994) and number of children has been negatively associated with suicide risk in women (Hoyer and Lund 1993). Heikkinen et al. (1994) found social support to be lacking prior to suicide, while others found adequate self-reported social support in European suicide attempters, however, lower support predicted future attempts (Bille-Brahe et al. 1999, Bille-Brahe and Jensen 2004). Suicidal patients may require encouragement and assistance in establishing or connecting with their social network, particularly given the impact of psychiatric disorders on social functioning.

Familial Association

A family history of suicide raises the risk of suicidal behavior (Jeglic et al. 2005, Mann et al. 2005). Brent et al. (2002) found suicide attempt to be six times more likely in the offspring of depressed suicide attempters compared with depressed nonattempters. Further, suicide attempters with a family history of suicide were more likely to have made multiple attempts than those without a family history (Jeglic et al. 2005). Evidence suggests that risk is transmitted via an impulsive-aggressive trait (Roy 2006, Brent et al. 2002,
Mann et al. 2005), experience of child sexual abuse in parents and offspring (Brent et al. 2002, Miltz et al. 2005) and early onset of depression in offspring (Mann et al. 2005). Jeglic et al. (2005) proposed that learning of negative problem solving after exposure to a suicidal parent could contribute to the transmission of risk. Collectively, these findings suggest that a family history of suicidality should be taken during the assessment of an individual for suicide risk.

**Employment**

Suicide attempts (Beautrais et al. 1998, Kessler et al. 1999) and completed suicide (Kposowa 2001, Brown et al. 2000) are more prevalent in unemployed compared with employed populations. Unemployment has been found to place women at greater risk of suicide relative to males (Kposowa 2001). Unemployment may not have a direct causal effect on suicidality. When Beautrais et al. (1998) adjusted for confounding factors (psychiatric diagnosis and childhood, family, and educational factors) the relationship between unemployment and suicide was no longer significantly related to serious suicide attempt confirming previous hypotheses about its role. (Jones et al. 1991). In particular, unemployment may be a consequence of psychiatric morbidity, as psychiatric disorders are known to have an impact on workplace performance, productivity, and absenteeism (e.g., Olsson et al. 1997, Kessler et al. 2006, Lim et al. 2000). Employed patients may need support to protect their position such as, additional sick leave, reduced duties, and time for attending treatment appointments. Referral of unemployed patients appropriate for employment to rehabilitation services is worth consideration. In particular, supported employment programs have been found to be efficacious (e.g., Crowther et al. 2001).

**Clinical Risk and Protective Factors**

**Past Suicidality**

A history of suicidal ideation and behavior are consistently identified as predicting further suicidality and completed suicide. Suicidal ideation prospectively predicts completed suicide (Brown et al. 2000, Beck et al. 1999) and suicide attempt (Kuo et al. 2001) while ideation with a plan was found to be a stronger predictor of suicide attempt than ideation without (Kessler et al. 1999). Suicide attempts have been found to be a marker of future suicidal acts (Mann et al. 1999b, Oquendo et al. 2004) and completed suicide (Beck and Steer 1989, Brown et al. 2000, Nordström et al. 1995). Thus a thorough assessment of the patient's past history of suicidal behavior or ideation is critical.

**Psychiatric Disorder**

Prevalence of psychiatric diagnosis in completed suicide populations is as high as 90% in both child and adolescent (Shaffer et al. 1996) and adult samples (Conwell et al. 1996), as determined by psychological autopsy. This rate is similar to that found in attempters who make medically serious attempts (Beautrais et al. 1996). Increasing comorbidity has been associated with increasing risk of suicide attempt in clinical (Beautrais et al. 1996) and general population samples (Kessler et al. 1999). Kessler et al. (1999) found that those with more disorders, regardless of type of disorder, were more likely to attempt suicide. For all age groups, the presence and number of psychiatric disorders should be considered when estimating risk.

**Mood Disorders**

Suicidal ideation is a symptom of a major depressive episode; hence it is predictable that a substantial and widely replicated increased risk of suicide will be evident in those with a mood disorder (Beautrais et al. 1996, Baxter and Appleby 1999, Conwell et al. 1996, Harris and Barraclough 1997, Kessler et al. 1999). A 20-fold increased risk of completed suicide has been estimated for major depressive disorder and a 12-fold increased risk for dysthymic disorder (Harris and Barraclough 1997). The odds of lifetime attempt are 12 times higher in those with major depressive disorder and eight times higher with dysthymic disorder (Kessler et al. 1999). Similarly, bipolar disorder has been consistently found to be a risk factor for suicide (Brown et al. 2000, Harris and Barraclough 1997) with an estimated 15-fold increased risk of completed suicide (Harris and Barraclough 1997). The depressive phase of the illness has been shown to be the time of greatest risk, but suicide may also occur in a mixed state and very rarely in a purely manic state (Isometsä et al. 1994, Simpson and Jamison 1999). Given the risk afforded by mood disorders and the lifetime community prevalence of about 20% (Kessler et al. 2005), management of suicidality becomes a common task for the clinician working with this population.

**Schizophrenia**

Individuals with schizophrenia are at high risk of suicide attempt and completion. A recent estimate suggests that the lifetime suicide rate for individuals with schizophrenia is 5% (Palmer et al. 2005). Younger age and the initial years after onset of illness have been identified as the times of greatest risk (Nordentoft et al. 2004, Hunt et al. 2006, Harkavy-Friedman et al. 1999). Others have identified depressive disorder, drug misuse and poor treatment compliance (Hawton et al. 2005, Hunt et al. 2006) as risk factors for completed suicide in populations with schizophrenia. In those with chronic schizophrenia, hopelessness, insight into illness and higher cognitive function show an association with greater suicidality, with hopelessness affording the greatest risk (Kim et al. 2003). Others have found that self-insight into schizophrenia may precipitate depression and hopelessness but might also have a beneficial effect on treatment adherence (Bourgeois et al. 2004). While most of these identified risk factors are evident in other suicidal populations, a number provide targets for treatment strategies (e.g., management of depression, strategies to improve treatment adherence, and increasing risk surveillance).

**Anxiety Disorders**

Anxiety disorders have been suggested to increase risk of suicidal ideation and attempt (Simon et al. 2007, Kessler et al. 1999, Sareen et al. 2005). Sareen et al. (2005) suggested that most anxiety disorders (social phobia, simple phobia, generalized anxiety disorder, panic disorder, agoraphobia, and obsessive compulsive disorder) independently and significantly elevated risk of future suicidal ideation and attempt. While some have found panic disorder to independently increase risk of suicide attempts (Weissman et al. 1989), others have found that increased risk is only
evident when comorbid disorders, including depression and substance abuse are present (Friedman et al. 1999, Vickers and McNally 2004, Warshaw et al. 2000). Further, Placidi et al. (2000) found that a lifetime history of suicide attempts was unrelated to panic disorder comorbid with major depressive episode and that higher anxiety was evident in those without a suicide attempt. These findings were interpreted as suggesting that another factor(s) may explain the elevations in suicide attempts associated with panic disorder or that anxiety in some cases might even be protective. Post-traumatic stress disorder has been associated with increased risk of suicide attempt of up to eight times greater than non-PTSD populations (Davidson et al. 1991, Tarrier and Gregg 2004) while even subthreshold PTSD raised risk of suicidal ideation while controlling for depression (Marshall et al. 2001). However, there is at least some data that suggests that the association between PTSD and suicidal behavior is mediated by the presence of comorbid borderline personality disorder (Oquendo et al. 2005). Thus, although some evidence suggests that an anxiety disorder in combination with a mood disorder is associated with greater risk of suicidality than that of a mood disorder alone (Simon et al. 2007, Sareen et al. 2005), the mediating role of other comorbidities has not yet been adequately addressed. Nonetheless, while suicidality is not a symptom of any anxiety disorder, attention must be paid to assessment of anxiety disorders when completing a risk assessment given the evidence that supports their contribution to risk.

Alcohol and Substance Use Disorders
Alcohol and substance use disorders raise risk of suicide attempts (Landheim et al. 2006, Kessler et al. 1999) and completed suicide (Wilcox et al. 2004, Borges et al. 2000, Beck and Steer 1989). Psychological autopsy studies have detected alcohol use disorder in approximately 50% of completed suicides (Conwell et al. 1996, Kolves et al. 2006) while toxicological testing has found one third of completed suicides tested positive for alcohol at time of death (Centers for Disease Control and Prevention 2006). Alcohol use disorders are less common in females (Grant et al. 2004) but have been shown to be more highly associated with suicide attempts in females compared with males (Wilcox et al. 2004). Comorbidity between alcohol use disorders and other psychiatric disorders, depression in particular, raises risk of suicide (Wilcox et al. 2004, Preuss et al. 2003). Further, Borges et al. (2000) has found that substance abusing suicide ideators are at significant risk of an unplanned attempt. Risk of suicide associated with opiate and mixed substance abuse has been associated with even greater risk of suicide than alcohol (Wilcox et al. 2004). Others have found that the number rather than type of substances is more important for predicting suicide attempts (Borges et al. 2000). Given the common comorbidity and increased risk, it is essential that patients are screened for the presence of alcohol and substance use disorders (Sher 2006).

Borderline Personality Disorder
The diagnostic criteria for borderline personality disorder include multiple risk factors for suicide including recurrent suicidal behavior, gestures, or threats, or self-mutilating behavior as well as impulsivity (American Psychiatric Association 2005). In clinical populations, it is estimated that up to 10% of those with borderline personality disorder complete suicide (Black et al. 2004) and approximately 75% attempt suicide (Black et al. 2004, Soloff et al. 1994). Presence of comorbid depressive and drug and alcohol disorders, hopelessness, and childhood sexual and physical abuse also independently contribute to the risk of suicide in those with borderline personality disorder (Brodsky et al. 1997, Isometsä et al. 1996a, Soloff et al. 2000, 2002). In assessing the borderline patient for suicide risk, it is important to distinguish between self-injury with suicidal intent from self-injury without suicidal intent. While both behaviors elevate risk of suicide, self-injury with intent to die suggests a greater risk; however self-harm with low lethality remains an important risk factor not to be ignored. In addition, the borderline patient may underestimate the lethality of self-injury made without suicidal intent (Stanley et al. 2001).

Hopelessness
A sense of hopelessness within the context of a psychiatric illness can make current problems seem untenable and make suicide seem like a reasonable solution (Beck et al. 1990). Hopelessness is considered a risk factor for suicidal ideation (Kuo et al. 2004, Beck et al. 1993), attempt (Beautrais et al. 1999, Kuo et al. 2004), and completed suicide (Kuo et al. 2004, Beck et al. 1985, Beck et al. 1990, Brown et al. 2000). This association has been replicated in both clinical (Beck et al. 1990, Beautrais et al. 1999) and normal populations (Kuo et al. 2004). Moreover, a recent study demonstrated that improvement in hopelessness and depression preceded reduction in suicidal ideation (Sokero et al. 2006). In sum, hopelessness elevates risk of suicidality independent of psychiatric illness and is often stable over time (Haahtainen et al. 2003) making it an important factor to assess.

Impulsivity and Aggression
Impulsivity has been linked with suicide attempts in a variety of psychiatric populations (Corryble et al. 1999, Brodsky et al. 1997, Swann et al. 2005). Impulsivity may relate to behavioral disinhibition and therefore increase risk of suicidal behavior. However, impulsive suicide attempts might be less lethal (Baca-Garcia et al. 2001, 2005) than those that are carefully and deliberately planned. Aggressive behavior comorbid with a mood disorders has been found to be associated with greater risk of suicide attempt (Malone et al. 1995, Oquendo et al. 2000) and completion (Dumais et al. 2005)．A trait impulsivity/aggression factor was found to be more predictive of a lifetime attempt (Odds Ratio: 3.3) than depression or psychosis in a psychiatric sample (Mann et al. 1999b) highlighting the importance of this troubling trait. A patient's history of impulsivity and aggression should be assessed and might be elucidated by enquiring about previous trouble with the police for assault or violence, fighting, hostile behavior, agitation, conflict in relationships, domestic violence, actions lacking forethought and disinhibited behavior.

Abuse
Physically abused children were found to be more likely to exhibit suicidality and depressive symptoms than children who had experienced neglect or those who experienced neither abuse nor neglect (Finzi et al. 2001). Molnar et al.
the sessions with the patient.

Neurobiological
The functioning of the serotonergic and the hypothalamic-pituitary-adrenal axis has been implicated in the search for biological risk factors for suicide (Arango et al. 1995; Mann et al. 2000). Serotonin (5-HT) dysregulation in suicide victims and attempters is the most robust neurobiological finding. Autopsy studies have found that suicide victims have fewer presynaptic serotonin transporter sites in the hypothalamus, occipital cortex and brainstem (Mann 2003). Greater blunting in response to the fenfluramine challenge (a test that causes the release of serotonin and while preventing its reuptake) is associated with a history of more lethal suicidal behavior (Mann et al. 1999a). Cerebrospinal fluid (CSF) concentrations of hydroxyindole acetic acid (5-HIAA), a metabolite of serotonin have been found to predict suicide risk in the one–two year period following an index attempt (Nordström et al. 1994, Samuelsson et al. 2006). Some evidence suggests that suicidal behavior may be associated with an abnormal physiological stress response given findings from studies of the HPA axis, the neuroendocrine system that regulates stress responses (Carballo et al., in press). While biological markers of suicidal risk show promise, at present they do not have any clinical application in the management of the suicidal patient. A comprehensive review of prospective studies of biologic predictors of suicidal behavior in mood disorders can be found in Mann and Currier (2007).

Management of the Suicidal Patient

Engaging the Suicidal Patient
Establishing a therapeutic relationship is the first task for the clinician managing the suicidal patient and comes before assessing risk (Meichenbaum 2005). Engaging the suicidal patient may be a challenging task given ambivalence about life, possible previous negative experiences in therapy, severity of illness, and the clinician's competing need to establish an assessment of risk. The therapeutic relationship, however, is particularly important given the high proportion of suicidal patients who discontinue treatment early (Dahlsgaard et al. 1998) and that risk of suicide remains high after a suicide attempt (Nordström et al. 1995). A variety of techniques can be used to establish a therapeutic relationship for example, empathic listening of the patient's concerns, validation of their feelings to ensure that the patient feels heard and understood and taking a collaborative approach to the sessions with the patient.

Assessment
The aim of the assessment of a suicidal patient is to evaluate the patient's current suicidal risk by determining diagnosis as well as demographic and clinical suicide risk and protective factors. Although there are no definitive empirically based approaches to predicting suicide risk, in this section, we suggest clinical approaches that may be of utility in delineating risk for suicidal behaviors in general. Ideally, assessment provides a diagnostic profile and an estimate about current level of suicidal risk which informs the type and intensity of intervention required. Suicide risk is known to fluctuate; therefore risk assessment should be updated regularly. Unfortunately, there is no empirically derived information regarding the frequency of these assessments. Of note, the limits of confidentiality and the circumstances in which the clinician is ethically required to breach the confidence are best discussed at the first interview.

Interviewing a patient about current suicidality requires the asking of direct questions about thoughts and behaviors in a sensitive manner. Clinicians may opt to begin with querying passive thoughts of suicide (e.g., Have you had any thoughts of wanting to be dead or of ending your life?) followed by enquiring about active thoughts of killing oneself (Has it gotten more serious, where you had thought about killing yourself?). While lowest on the suicidality spectrum, passive thoughts are an important risk factor for completed suicide (Brown et al. 2000). Determine whether the patient has a plan for how they would kill themselves (Have you thought about how you would kill yourself? Do you have a plan?) and whether they intend to act upon the
plan (When having these thoughts, have you had an intention to act upon them?). Suicidal ideators without a plan were found to be at greater risk than ideators without a plan (Kessler et al. 1999). A profile of suicidal ideation should be determined including the following information: duration and frequency of thoughts, ability to cope with the thoughts, adaptive and maladaptive coping strategies, and deterrents to completed suicide.

Beyond ideation, the clinician next asks about suicidal behavior including preparation for a suicidal attempt, for example, stockpiling of pills, acquisition of a firearm, poison or rope. Questioning about previous self-injurious behavior and its intent then follows (Have you ever hurt yourself in any way on purpose? What did you intend to happen? Did you intend to kill yourself?). The intention of self-harming behavior may be suicidal or for other purposes or a combination of both.

Valuable details about suicidality include time of onset, course (e.g., episodic, escalating), levels of suicidal intent associated with attempts, precipitants (e.g., conflict with spouse, isolation, unemployment, command hallucinations), probability of rescue from attempt (i.e., remote location with low chance of rescue versus in a populated or public area), medical seriousness, need for medical attention, actual lethality of the attempt, and the patient’s understanding of lethality. These details may provide insight into the risk of future attempts and provide information about targets for intervention. A brief tool to assess and track both suicidal ideation and behavior during management of a patient, such as the Columbia Suicide Severity Rating Scale (C-SSRS; Posner et al. 2007) may enhance clinical practice. The C-SSRS is the prospective counterpart to the suicide classification system developed for the Food and Drug Administration (FDA) safety analyses of antidepressants (Posner et al., 2007).

If permission is granted by the patient, consulting other informants (e.g., family, general practitioner) may provide important information about the patient’s behavior. This contact may provide an opportunity to discuss and clarify the various roles of those involved in the patient’s care, for example, psychotherapy from the psychologist, transport to appointments from a relative.

Interviewing the patient or involved family members about family history of mental illness (particularly depression, bipolar disorder, schizophrenia, alcohol, and substance abuse) is indicated. While knowledge of relatives’ illnesses may be nonspecific (e.g., grandparent with “nervous breakdown”) further clues might be gained by asking about use of psychopharmacological treatment, impact on functioning and hospitalization.

Upon the completion of a risk assessment a clinician is not expected to be able to predict the future, but will develop a judgment about a patient’s current level of risk and respond accordingly in the interest of the patient’s safety. This may include referral for inpatient treatment, increased monitoring as an outpatient, engagement of the support group or family to provide more intensive supervision of the patient, development of a plan regarding procedures to institute if the patient becomes more suicidal (e.g., go to the local emergency department, contact the clinician, etc.) (see description of safety plan in Section “Treatment”)

**Treatment**

There are two common approaches to treating the suicidal patient. The primary approach is to address the disorder underlying the suicidality. The second approach is to directly treat the suicidality, as is the focus of some psychotherapeutic approaches. Treatment might also be useful to stabilize additional risk factors for suicide while enhancing any protective factors (American Psychiatric Association 2003). Treatment planning should be informed by results of risk assessment, while also considering the patient’s capacity to self-care particularly in a crisis and understanding of treatment options (American Psychiatric Association 2003). If consent is granted by the patient, useful information about the management may come from their previous treatment and interactions with clinicians, for example, previous hospitalization for suicide attempt is a risk factor for future attempt. Evaluation of the patient’s expectations of treatment may reveal a sense of hopelessness and futility in commencing or continuing treatment that may require addressing. Provision of psychoeducation about mental illness being a disease rather than a personal flaw or inadequacy and suicidal behavior as being related to mental illness may reduce self-blame and misperceptions within the family. Treatment options and setting should be discussed with the patient and family, where appropriate, and written consent gained.

When risk of suicide attempt is highly elevated or considered imminent, and/or confidence in a patient’s ability to refrain from acting on suicidal thoughts is low, inpatient hospitalization may be required on a voluntary or involuntary basis. The decision to hospitalize can be complex. Hospitalization offers the opportunity to closely monitor a patient’s behavior, restrict access to suicidal means and stabilize medication. However, hospitalization may interrupt employment, disrupt the family, reduce contact with supports and may foster dependency (American Psychiatric Association 2003).

Suicide risk is highest during the first week of an inpatient stay and in the week after discharge (Qin and Nordentoft 2005) suggesting the need for close monitoring on the ward and follow-up after discharge during these periods. Long-term inpatient treatment may not be indicated for those with borderline personality disorder (Paris 2004). However, a short-term admission may be required when risk is elevated, and particularly in the presence of a comorbid axis I disorder (Oldham 2006).

Risk of self-harm may be reduced during treatment by the development of a ‘safety plan’ for the patient. Safety plans are typically multifaceted and may include detecting triggers to suicidality and methods of avoiding or addressing them, removal of materials used for self-harm, scheduling regular appointments and arranging plans for transport, organization of a support team that the patient can contact for support in case of a suicidal crisis whatever the time (e.g., clinician, family, friends, emergency department, mobile crisis team). A safety plan differs from a “no-harm contract” which is an agreement to contact someone before self-harming (discussed in Subsection “No-harm Contracts”).

Treating suicidal patients for modifiable risk factors, such as depression, anxiety, and unemployment can present challenges for the clinician. Suicide attempters frequently do not follow through with referral for treatment (Jauregui...
et al. 1999) and discontinue treatment early (Dahlsgaard et al. 1998). This indicates a need for strategies to increase treatment engagement and compliance. Programs designed to extend the length of treatment have had limited success. Van Heerening et al. (1995) found that home visits improved attendance but did not reduce suicidality. A related problem is the generally inadequate levels of treatment received by individuals with mental illness (Oquendo et al. 2002, Wang et al. 2005, Fernández et al. 2007).

**Treatment Modality**

Both psychopharmacological and psychosocial treatments have a role in the management of the suicidal patient. The few treatments that have empirical support specifically for suicidality are reviewed below. In the absence of comprehensive efficacy evidence for the treatment of suicidality, clinicians are advised to aggressively treat the underlying psychopathology following current treatment guidelines (e.g., American Psychiatric Association Practice Guidelines; American Psychiatric Association 2006).

**Pharmacological Treatment**

**Lithium**

The prophylactic property of lithium in protecting against suicidality in major affective disorders (bipolar I and II disorder, recurrent major depressive disorder) has often been reported (American Psychiatric Association 2003, Baldessarini et al. 2001, Cipriani et al. 2005, Jamison 2000, Kallner et al. 2000, Bowden 2000). Baldessarini et al. (2001, 2003) reviews concluded that the rate of completed and attempted suicide during long-term lithium treatment reduced by 13–15-fold in comparison with no lithium or discontinuation. The protective effect is possibly strongest in those with recurrent major depression followed, by bipolar II disorder and bipolar I disorder (Baldessarini et al. 2003). In a recent 10-year follow-up of bipolar I disorder adults, those noncompliant with lithium maintenance were not only at greater risk of suicidal behavior but also were more severely ill (greater substance abuse and more hospitalizations) (Gonzalez-Pinto et al. 2006). These findings are made all the more noteworthy given the potential lethality of lithium in overdose (Zetin 2004). Prospective randomized controlled clinical studies investigating lithium as a treatment to protect against suicidality are currently underway in adults but lacking for youth.

**Antidepressants**

Antidepressant medications have established efficacy in the treatment of depressive disorders (Rush et al. 2006)—the most common diagnosis experienced by those who complete suicide. In the last few years, debate has re-emerged about the impact of antidepressants on suicidality. While the efficacy of antidepressants in reducing risk of suicide has not been demonstrated in clinical trials or meta-analyses of these data, these trials were not typically designed to address this question. Other studies of large databases have shown a reduction of risk associated with antidepressant treatment.

Recently, the FDA has conducted analyses with both pediatric (N=4582) and adult (N=99 839) samples from randomized clinical trials to examine links between suicidality and antidepressant use compared to placebo (Hammad et al. 2006, Stone and Jones 2006). Put together, the results suggest an age effect in which risk of suicidality is increased for children, adolescents, and young adults up to 25 years who were treated with antidepressants, no different for adults aged over 25 years and less than 65 years treated with either placebo or antidepressants and reduced for those over 65 years treated with antidepressants, suggesting a protective effect (Stone and Jones 2006). These findings initially led to the implementation of a black box warning on all antidepressants warning of a 4% vs. 2% risk of suicidality in children and adolescents taking antidepressant medication versus placebo, which is soon to be extended to include young adults. While the FDA analyses were conducted with the best data available, that is, spontaneously generated adverse events from clinical trials, concerns have been raised about the validity of using randomized controlled trial (RCT) data that lacked prospective, standardized assessment of suicidality. Alternative explanations for the association include the ascertainment bias, in that those who were treated with an active drug might be more likely to discuss suicidal thoughts or those treated with the active drug and experienced some improvement might be more prone to discussing their suicidality for the first time (Posner et al. 2007).

Meanwhile, analyses using alternate data sources have failed to demonstrate the risk of antidepressants, in fact, evidence suggesting a protective effect has been found. Lower youth suicide rates were found in the US counties with higher selective serotonin reuptake inhibitor (SSRI) prescription rates (Gibbons et al. 2006). Greater risk of suicide has been found in the month prior to commencement of antidepressant treatment compared with during treatment (Simon et al. 2006). Further, autopsy studies have found that SSRI use is very rarely evident at time of death in youth who commit suicide (Gray et al. 2003, Leon et al. 2004).

Recent studies have examined the impact of antidepressant safety warnings on physician behavior. The US pediatric antidepressant prescriptions have declined since the introduction of the warnings in 2003 (Nemeroff et al. 2007), meaning that fewer youths are likely to be receiving treatment for depression. Meanwhile, suicide in 10–19-year olds increased by 13.3% (between 2003 and 2004) following a decline in rates over the previous four years (Centers for Disease Control and Prevention, National Center for Injury Prevention and Control 2007). This pattern was also found in the Netherlands where a 22% decrease in youth SSRI prescriptions occurred between 2003 and 2005 at the same time as a 49% increase in youth suicide (Gibbons 2006). The increase in suicide may represent a fluctuation in rates or be explained by other causes. However, further investigation of this potential relationship is warranted, as it is feared that declining prescription of antidepressants may be responsible for rising suicide rates amongst youth.

Antidepressants may have a role to play in the prevention of suicide in youth and young adults as well as adults due to their ability to successfully treat depressive disorders—a major risk factor for suicide. It is considered that untreated depression portends a far greater risk of suicidality than that of antidepressant medication. Commencement of antidepressant treatment should include regular and careful monitoring to assist with achieving optimal dose and the management of possible side effects. For youth, parents...
should be recruited to assist with monitoring for side effects and therapeutic response. A baseline of suicidal ideation and behavior should be taken to assist with the detection of treatment emergent suicidality versus that which is a part of the illness (American Psychiatric Association 2003). Patients should be clearly informed about the likelihood of side effects and their types, and the likely latency before onset of therapeutic effect. While the SSRIs are relatively safe in overdose (Whyte et al. 2003) care should be taken in amount prescribed to avoid stockpiling.

**Antipsychotics**

The current first line treatment for schizophrenia and schizoaffective disorder are the second-generation antipsychotics. However, most lack empirical evidence supporting their efficacy reducing suicide risk and rate with the exception of clozapine (Meltzer and Okayli 1995, Walker et al. 1997, Reid et al. 1998, Modestin et al. 2005). As clozapine patients are required to have weekly to biweekly hemato logical monitoring for early detection of the very rare but potentially fatal side effect agranulocytosis (Lieberman 1998), it was originally thought that the additional clinical monitoring might be responsible for the decline in suicidality (Kerwin and Bolonna 2004). The clinical attention may result in a more rapid detection and treatment of suicidality. However, the most compelling evidence of the benefits of clozapine on suicidality came from a two-year study of 980 patients with schizophrenia or schizoaffective disorder randomized to either clozapine or olanzapine which controlled for clinical attention (Glick et al. 2004). The clozapine group was found to have fewer suicide attempts and hospitalizations to prevent suicide. The olanzapine group also used significantly more concomitant psychotropic medications. However, this did not improve the group’s performance (Glick et al. 2004). The strength of this evidence led to the FDA’s approval of clozapine for suicidality in schizophrenia in the late 2002. While persuasive evidence exists supporting its use, it is not widely used probably given the chance of agranulocytosis which occurs in less than .5% (Honigfeld et al. 1998) other adverse events (Lieberman and Safferman 1992) and cost (Sernyak et al. 2001).

**Psychosocial Treatments**

**Cognitive Behavioral Therapy**

Cognitive behavioral therapy (CBT) is an established treatment for a number of psychiatric disorders that are suicide risk factors including unipolar depressive disorders and anxiety disorders (Butler et al. 2006) and is used as an adjunctive treatment in the treatment of schizophrenia (Bechdolf et al. 2005, Sensky et al. 2000, Turkington et al. 2006) and bipolar disorder (Lam et al. 2005, Ball et al. 2006). However, the following two treatments differ in that they aim to directly treat suicidality rather than a diagnosis underlying the behavior.

Building on the efficacy of cognitive therapy for depression, Brown et al. (2005) modified cognitive therapy for the treatment of suicidal patients regardless of diagnosis. The manualized cognitive therapy focused on proximal thoughts, images, and core beliefs that were activated prior to the suicide attempt. Cognitive and behavioral strategies were used to modify suicidal thoughts and beliefs and to develop adaptive ways of coping with stressors that might precipitate an attempt. Hopelessness, poor problem solving, impaired impulse control, treatment noncompliance and social isolation, notable risk factors for suicide were also targeted in the treatment. After 18 months, significantly fewer suicide attempts were made by the cognitive therapy group (24%) compared with treatment as usual (42%) (Brown et al. 2005). This program has been modified for use with adolescent and young adult suicide attempters (Henriques et al. 2003) but not yet evaluated.

**Dialectical Behavior Therapy**

Dialectical behavior therapy (DBT) is a combination of change focused cognitive–behavioral type strategies and acceptance and validation techniques (Stanley and Brodsky 2005). This manualized treatment was developed to address suicidality and self-harming behavior in borderline personality disorder. The key goal of DBT is to reduce life-threatening behaviors, followed by therapy interfering-behaviors and quality-of-life-threatening behaviors. DBT consists of two treatment components. Treatment includes one or two weekly individual sessions, supplemented by group skills training (Linehan 1993). Group treatment modules include mindfulness, distress tolerance, emotion regulation and interpersonal effectiveness. DBT has been demonstrated to be superior to nonbehavioral expert therapy (Linehan et al. 2006) and treatment as usual (Linehan et al. 1991, Verheul et al. 2003) in reducing self-harming and suicidal behavior and increasing treatment retention in the treatment of borderline personality disorder.

**Family Treatments**

A number of findings point to the importance of involving family in the treatment of suicidality. Suicidal individuals often come from poorly functioning family environments (McDermut et al. 2001). Family members are regularly called upon to help maintain safety of a suicidal individual, involvement in treatment could provide them with skills to aid problem solving and other crisis strategies. To date, few studies have evaluated the anti-suicidal effects of family intervention. Family intervention targeting problem solving and communication skills for young people who had deliberately self-poisoned has been found to be no better than treatment as usual in reducing suicidality (Harrington et al. 1998). The association between poor family environment and the course of bipolar disorder led to the development of family-focused treatment (Miklowitz et al. 2000). The approach is comprised of 21 outpatient sessions that address psychoeducation, communication skills training and problem solving components conducted over 9 months. The approach has been found to be a useful adjunctive treatment to pharmacotherapy for bipolar disorder, with studies demonstrating its advantages over crisis management (Miklowitz et al. 2000) and individual treatment (Rea et al. 2003). The treatment has been adapted for suicidal bipolar disorder (Miklowitz and Taylor 2006), but has not yet been evaluated.

**No-harm Contracts**

A “no-harm” contract is a written or verbal agreement by a patient to contact a health care provider, friend or relative for assistance before engaging in any self-injurious behavior. The contract will typically have a specified time frame, for
example, until next treatment session. While the no-harm or no-suicide contracts were first introduced more than 30 years ago, empirical investigation of the benefits of this technique is still lacking (Rudd et al. 2006, Buelow and Range 2001). A common criticism of these contracts includes their medico-legal emphasis, however, such a contract does not protect the clinician from malpractice liability if a client completes suicide (Lee and Bartlett 2005). Concern also exists that fake agreement to a contract by a frankly suicidal patient might distract a clinician from the appropriate precautions to minimize risk of harm. It is considered that such contracts can be a rough indicator of difficulties in the therapeutic alliance when not agreed to by the patient (American Psychiatric Association 2003).

**Electroconvulsive Therapy (ECT)**

ECT is a validated treatment for major depressive disorder given evidence from randomized controlled trials (Carney et al. 2003). Modest support exists for its use to treat suicidality (Kellner et al. 2005, Prudic and Sackeim 1999, Isometsä et al. 1996b) in the absence of evidence from controlled trials. Advantages of ECT in treating acute suicidality include its rapid onset of therapeutic action and good response rates, however the treatment is known to be unpopular with patients before all other alternatives have been tried (Kellner et al. 2005). The short-term therapeutic impact of ECT needs to be considered in treatment planning and the use of concurrent or subsequent pharmacological and/or psychosocial treatment might be required. While usually seen as the final treatment option, there have been recent calls for ECT to be promoted in the treatment hierarchy for suicidality given evidence of efficacy (Kellner et al. 2005, Patel et al. 2006). ECT is administered to approximately 5% of psychiatric inpatients (Munk-Olsen et al. 2006) and was found to be a rare treatment in the three months prior to completed suicide (Isometsä et al. 1996b).

**Legal and Ethical Issues**

Clinicians are required to be aware of their relevant state, professional and workplace guidelines and procedures with regards to working with suicidal patients. The limits of confidentiality need to be explained to suicidal patients as well the clinician's ethical duty to warn if an opinion is formed that a patient or others are in imminent danger as a result of the patient's behavior. Documentation of risk assessments, treatment planning and progress, secondary consultations, and supervision ought to be kept to demonstrate quality of clinical care.

**Conclusions**

Suicide risk assessment is a central competency in the management of psychiatric patients. Risk and protective factors for suicidality have been identified and inform suicide risk assessment and ultimately also treatment. Few treatments have demonstrated efficacy in reducing suicidality, limiting evidence-based practice with this population. Of the pharmacological treatments, both lithium for mood disorders and clozapine for psychosis may have efficacy in reducing risk of suicide. Evidence suggests that dialectical behavior therapy reduces suicidality in borderline populations. Treatments that show promise include Brown et al. (2005) modified CBT and ECT. In the absence of empirical evidence to guide management, treatment of the underlying psychopathology may reduce risk.

This chapter reviews the use of restraint and seclusion (R/S) in psychiatry and efforts in the mental health community at reduction and prevention. Use of seclusion and physical restraint has a long history in psychiatric facilities (Fisher 1994). Often learned “on the job” they have been an assumed part of the therapeutic armamentarium available to clinical staff. R/S are implemented typically, by nursing staff, in response to behaviors deemed aggressive, violent, disruptive, out-of-control, or dangerous to self, others, or property.

R/S definitions vary across agencies and organizations; use varies widely among hospitals, states, and in the research literature (Busch and Shore 2000). Even the United States federal regulatory agencies cannot agree on definitions, with agencies defining physical restraint in accordance with their culture and statutory authorities.

The definitions referred to in this chapter are those developed by the U.S. Centers for Medicare and Medicaid Services (CMS), Department of Health and Human Services (2001):

A physical restraint is any manual method or physical or mechanical device, material, or equipment attached to a person’s body that restricts freedom of movement or normal access to one’s body. Seclusion is the involuntary confinement of a person in a hazard-free room or area that is often locked and where the person can be directly observed.

Controversies Regarding Restraint and Seclusion

Over the years, the use of R/S has been questioned by professionals as to efficacy and usefulness (Garrison 1984, Natta et al. 1990), and promoted for their “therapeutic” value (Cotton 1989, Troutman et al., 1998). Proponents view such procedures as unfortunate last resorts in situations where patients pose a danger to themselves or others. Agitated, angry, and hostile patients have been secluded or physically restrained until they became demonstrably calmer. Although previously seen as an acceptable way to manage crises and keep patients and staff safe, R/S are no longer considered “therapeutic” and their use has been under intense scrutiny and the subject of lawsuits.

State of Research

Attempts have been made to study R/S. Most of these studies have questionable methodological rigor or problematic theoretical assumptions (Day 2002a, Child Welfare League of America, [CWLA] 2002). Most significant has been lack of support for the “therapeutic use” hypothesis, as most studies indicate that R/S are traumatizing to staff and patients (Richter and Berger 2006). Most R/S research conducted in clinical settings has focused on patient characteristics associated with their use. This literature had an a priori bias, wherein salient variables were to be found in personal pathologies. Emerging evidence supports a situational stance involving the role of the environment, including staff knowledge, behaviors, and attitudes that are equally, if not more, implicated in the willingness to use these measures (Gadon et al. 2006).

Research into R/S fails to demonstrate their therapeutic efficacy. Indeed, studies show that R/S do not lead to positive behavior change and are ineffective unit management tools (Garrison et al. 1990). They lead to superficial compliance and to staff–patient power struggles. A number of studies discovered that R/S paradoxically increased misbehavior or unwanted behaviors (Magee and Ellis 2001, Natta et al. 1990).

Several comprehensive reviews agree that research on R/S lacks cohesion and their use has no sound theoretical basis or research foundation. Day (2002a) concluded that theoretical paradigms supporting restraint use are outdated.
and there is limited research to support their therapeutic utility. These same observations have been noted by many others (CWLA 2002, National Executive Training Institute [NETI] 2005).

There is little in published standard practices to guide clinical decisions to employ R/S, no overall benchmarks for their use, and no data about the appropriate mix of R/S and medication for what kinds of patients. Although there are numerous vendors who have developed aggressive management programming and training for staff, there are no data comparing training programs to determine a best practices model. The use of R/S has been based on convention and vendor marketing efforts in lieu of empirical evidence. The literature validates that R/S procedures have often been used inappropriately, as punishment or consequence for “bad behavior,” and, sometimes, for staff convenience (NETI 2005).

What is clear is that the use of R/S is not benign. Their use can cause serious patient and staff injury and have resulted in many deaths (NETI 2005). A discussion of restraint lethality first appeared in the forensic literature when pathologists, Donald Rea and Ronald O’Halloran, documented restraint death (O’Halloran and Lewman 1993, Reay et al. 1992). Previous pathologists had labeled these deaths as “death by natural causes,” “sudden in-custody death syndrome,” or “death due to cardiac arrest,” when physically healthy psychiatric patients or prisoners were autopsied. The forensic studies focused on death by asphyxiation, and this cause subsequently emerged as the most frequent cause of restraint deaths across many settings (The Joint Commission on Accreditation of Health Care Organizations [JCAHO] 1998, Mohr et al. 2003). However, restraint death can result from many causes. Careful examination of the literature determined death by aspiration, blunt trauma to the chest, malignant cardiac arrhythmias secondary to massive catecholamine rush, thrombosis, rhabdomyolysis, excited delirium with overwhelming metabolic acidosis, and pulmonary embolism to be conditions implicated in deaths proximal to physical restraint use. Potential adverse effects of restraints increase with psychotropic medication use, with children being particularly susceptible to certain drug class effects.

In 1998, a highly publicized asphyxia death of a child who had been restrained in a psychiatric hospital led to an investigative news series in Connecticut’s “Hartford Courant” (Megan and Blint 1998). The series sparked a cascade of reactions by professionals, legislators, and consumer/advocacy groups and resulted in sustained change in, and oversight of, the way that R/S is viewed and practiced in the United States. Congressional hearings on the topic occurred in 1999, and the topic of R/S received greater scrutiny in the research literature.

Under pressure from advocacy groups, the U.S. Congress commissioned a review by the United States General Accounting Office (USGAO. 1999). This report supported the Courant’s findings and sharply criticized restraint use. JCAHO examined 21 deaths reported under their sentinel event protocol and cited lack of staff training as the single most important factor implicated in these events (JCAHO. 1998). Interestingly, lack of staff trained in the use of physical force, manual restraint, and, particularly, nonviolent intervention of agitated patients has been observed by investigators of the European Convention for the Prevention of Torture and Inhuman or Degrading Treatment or Punishment (Niveau 2004).

The U.S. reports resulted in current legislation governing restraint and seclusion use (see also the Chapter 128).

Subsequent studies indicated that patients attribute aggressive or violent behavior to problematic interactions with “controlling” staff, along with poor communication factors and dehumanizing, restrictive environments. The use of R/S was found to foster distrust between patients and staff and impede recovery (Duxbury 2002). Other studies document that patients recall these events as being confusing and report them as being traumatic to watch, as well as to experience firsthand (Mohr et al. 1998, NETI 2005). When in seclusion, patients described feeling neglected, fearful, isolated, vulnerable, and punished (Martinez et al. 1999).

The scant research on R/S has to do with methodological and ethical difficulties inherent in controlling variables leading to the use of aggression control techniques in live patients, as well as the lack of information that we have in the United States about the use of these procedures. In the United States, data on R/S are not collected except by individual hospitals, and this is done voluntarily. Efforts have been made to collect such data in other countries. In Switzerland and Germany, two independent working groups exist that deal with the prevention of violence and coercion in psychiatry. The German working group “Arbeitskreis zur Prävention von Zwang und Gewalt in der Psychiatrie” (Project of prevention of violence and coercion in psychiatry) consists of hospitals, located primarily in the South of Germany. The Swiss working group “Qualitätzzirkel Benchmarking Zwangsmaßnahmen” (Benchmarking coercion in psychiatry) consists of seven hospitals, located in the North-eastern, German-speaking part of Switzerland. Both working groups focus on reducing the frequency and duration of coercive measures, such as R/S in psychiatric settings. They focus cooperatively to coordinate data collection across the countries; efforts such as these are present in Wales as well.

Death data are collected unevenly, even when mandated by state and federal authorities (Levinson 2006). Yet, the problem of restraint death is substantial. Trying to determine the number and causes of child deaths proximal to restraint use, Nunno et al. documented the deaths of 45 children over 10 years by searching the Lexus/Nexus databases in the absence of national data (Nunno et al. 2006).

Patient R/S has provoked international interest as the European Committee for the Prevention of Torture and Inhuman or Degrading Treatment or Punishment (CPT) considers R/S matters of particular concern, given the potential for abuse and ill-treatment (Sailas and Wahlbeck 2005). In addition to publications from clinicians in the UK, Australia, and New Zealand, (Day 2002b) conferences have been organized around the topic. In 2006, an international symposium was organized by faculty at Stirling University in Scotland. Similar conferences were held in Turkey and Germany in 2007. In 2007, The Fifth European Congress on Violence in Psychiatry in Amsterdam devoted significant time to discussing restraint use and reduction.
The Legal Rights of Psychiatric Patients
A detailed discussion on case law regarding R/S in the United States and other countries, although important and fascinating, is far beyond the scope of this chapter, but several selected examples follow. Patients in the United States are not legally protected, having only civil recourse by way of malpractice lawsuits against injury or death. Even when deaths have occurred, local prosecutors have been loathe to bring criminal action against involved staff members. Logic suggests that incompetently designed behavioral programs and procedures should be subject to analysis under the U.S. Constitution, Eighth Amendment. Some lower courts have so ruled (Converse v. Nelson 1995). However, the U.S. Supreme Court has expressly upheld that the Eighth Amendment standard can be applied only in a correctional context, and that the Eighth Amendment is inapplicable in a mental institution setting (Ingraham v. Wright, 1977).

Ingraham v. Wright, 430 U.S. 651 (1977)

Sweden has passed legislation entitled the Compulsory Psychiatric Care Act and the Forensic Psychiatric Care Act to secure legal safeguards and reduce violations of patient autonomy, including the use of R/S (Wallsten and Kjellin 2004). And, although R/S are not banned in the Czech Republic, Amnesty International recently reported that the use of the “cage bed” has been banned from use in psychiatric and other institutions.

The State of Education
The need for clinician education is great and staff training and education is crucial. Presently, staff involved in R/S are the least educated or trained but often are the first responders in conflicts. There are few “best practice” guidelines despite numerous studies in the United States and Canada dating back to 1969 documenting the frequency of patient assaults on physicians. Schwartz and Park (1999) found that of 200 physicians from diverse specialties, 24% reported patient assaults.

The American Psychiatric Association’s report on clinical safety, noted that from 30–40% of residents are assaulted during a 4-year residency. It recommended that psychiatric residents should have a 10-hour course in violence management to include: antecedents of violence, evaluation of violent patients, use of verbal, mechanical, and pharmacological interventions, and the psychodynamics of aggression (Schwartz and Park 1999).

Unfortunately, there are no national curricula for professionals providing training in prevention and management of restrictive patient interventions including seclusion, physical, mechanical, or chemical restraint. Such content is poorly, if at all, addressed in clinicians’ educations. Psychology students report that their training in the management of potentially violent patients was inadequate (Gately and Stabb 2005). The situation is similar in nursing. Student nurses have less than 1 hour of instruction on this topic, and only 8% know that these procedures can be lethal (Stillwell 1991).

National and State Reduction Efforts
Since 1998, effective strategies to reduce the use of R/S have emerged (NETI 2005) and best practice models are documented by Substance Abuse and Mental Health Services Administration (SAMHSA) (2003). The public health prevention model has been postulated as an effective theoretical approach to R/S reduction (National Association of State Mental Hospital Program Directors [NAS-MHPD] 2001). This approach recommends using the public health constructs of primary, selective, and indicated prevention intervention guides to frame reduction activities. In this conceptualization, primary prevention refers to developing environments that avoid conflict through an analysis and ongoing revisions of operational policies, early individualized assessments of risk, and culture (LeBel et al. 2004). Selective prevention activities address employing early interventions to mitigate or defuse conflict when it occurs. Indicated or tertiary prevention strategies address most effective ways to minimize damage to individuals experiencing or witnessing R/S, and include problem solving activities in postevent debriefings, including mandatory involvement of patients to identify precipitating antecedents.

Another theoretical rationale supporting R/S reduction strategies use is the emerging science of trauma-informed care (Jones and Alexander 2004). The mental health literature contains numerous studies documenting the high prevalence of traumatic life experiences in histories of psychiatric patients and the general public (Saxe et al. 2003). The impact of traumatic life events, together with personal experiences of R/S events and their negative sequelae makes a strong argument for the reduction of R/S (NETI 2005).

Effective R/S reduction strategies that are empirically supported include the following:

1. Leadership that supports organizational change is believed to be the most important factor in successful reduction projects (Hardenstine 2001, NETI 2005). This strategy mandates executive leadership that provides staff direction by defining and articulating vision, values, and philosophy; developing a formal reduction plan; and holding people accountable to that plan. This strategy includes the elevation of oversight of every R/S event by an executive leader.

2. Use of data to inform practice includes using facility data to identify baseline R/S use, subsequent data collection on facility usage, and setting improvement goals and monitoring use and changes over time.

3. Workforce development strategies to create a treatment environment whose policies, procedures, and practices are based on the knowledge and principles of recovery and trauma-informed care that aims to reduce conflict and coercion (Jonikas et al. 2004).

4. Specific prevention tools to reduce the use of R/S proactively by employing assessments and interventions that are directed by policy and integrated into individual patient’s treatment plans (NETI, 2003).

5. Peer roles in inpatient settings involve the inclusion of patients, families, and external advocates to assist in R/S reduction strategies (Hardenstine 2001).

6. Rigorous debriefing techniques aimed at analyzing each R/S event and using knowledge gained to inform policies, procedures, and practices (Donat 2003). A secondary goal is to reduce adverse and potentially traumatizing effects of R/S for staff, patients, and witnesses to the event.
In sum, R/S reduction and prevention efforts require a multilevel multidisciplinary initiative and sustained methodical implementation. Successful reduction projects demonstrate that no one strategy is effective and that comprehensive interventions have the best chance of long-term reduction.

Conclusion
Viewing this subject from the perspective of reactive crisis management to violence impairs the development of multidisciplinary approaches to deal with what are often traumatic events for both patients and their health care clinicians. Since physicians are held accountable by law and society for caring for patients, it is essential for them to have a comprehensive understanding of how to prevent these crisis situations.

Frequently, restrictive intervention training is only provided to physicians and nurses by the program in which they work. These approaches vary with patient populations (adult, adolescent, child), the diagnosis (e.g., delirium, post-traumatic disorder flash back, psychotic episode), work sites (e.g., emergency unit, psychiatric hospital, residential treatment center), and philosophy regarding R/S use. This leads to piecemeal, narrowly focused, and ad hoc conceptualizations of global safety issues.

Broad-based multidisciplinary training of health professionals is needed to prevent the use of restrictive, inherently dangerous interventions. When R/S is unavoidable, they should be applied in the least coercive fashion. Additionally, patient participation in decision making is important. Such training might involve teaching by patients who had experienced R/S and could be based on current programs such as those disseminated from the SAMHSA (SAMSHA 2003) and NASMHPD’s NETI initiative (2005).

Multidisciplinary health professional education about restrictive interventions, at the time of initial exposure to patient care (i.e., medical and nursing school) would hopefully promote new techniques to enhance patients’ physical and psychological safety. For example, the use of pulse oximetry to detect low oxygen saturation during restraints, and development of Snozellen rooms to replace traditional R/S equipment (Masters, in press). Teaching should also provide an impetus to shift the focus of debate from whether R/S are “necessary,” to developing and promoting clinical strategies which will make these interventions superfluous.

Introduction
Psychosomatic medicine (PM) has had ambiguous connotations in the past, alternatively “psychogenic” or “holistic,” but it is the latter meaning that has characterized its emergence as a contemporary scientific and clinical discipline (Lipowski 1984). PM is the newest psychiatric subspecialty approved by the American Board of Medical Specialties. There have been many other names for this specialized field, including consultation–liaison (C-L) psychiatry, medical–surgical psychiatry, psychological medicine, or psychiatric care of the complex medically ill. PM psychiatrists have special expertise in the diagnosis and treatment of psychiatric conditions in complex medically ill patients (Gitlin et al. 2004). Working closely with physicians in primary care and other specialties, its practitioners treat and study four general groups of patients, sometimes referred to as the “complex medically ill”: those with comorbid psychiatric and general medical illnesses complicating each other’s management; those with psychiatric disorders that are the direct consequence of a primary medical condition or its treatment, such as delirium, dementia or other secondary mental disorders (formerly known as “organic” disorders); those with complex illness behavior such as somatoform and functional disorders; and, patients with acute psychopathology admitted to medical–surgical units, such as after attempted suicide.

PM psychiatrists are trained to deliver services in general medical settings working with the complex medically ill. They may work as hospital-based C-L psychiatrists (Kornfeld 2002), in medical-psychiatric inpatient units (Kishi and Kathol 1999), and in settings in which mental health services are integrated with primary care or medical specialties to provide collaborative care (Unutzer et al. 2002). Thus, the field’s name reflects the fact that it exists at the interface of psychiatry and medicine and focuses on the interaction between medical and psychiatric disorders. This chapter begins with the history and current status of PM, and then exemplifies the field by examining psychosomatic aspects of cardiovascular disease, cancer, and endocrine disorders. For fuller coverage of these and other diseases, see Levenson (2005, 2007).

History
The term “psychosomatic” was introduced by Johann Heinroth in 1818, and “psychosomatic medicine” by Felix Deutsch around 1922 (Lipsitt 2001). Psychoanalysts and psychophysicists pioneered the study of mind–body interactions from very different perspectives, each contributing to the growth of PM as a clinical and scholarly field. The modern history of the field in the United States (see Table 118–1) perhaps starts with the Rockefeller Foundation’s funding of PM units in several U.S. teaching hospitals in 1935. The National Institute of Mental Health (NIMH) made it a priority to foster the growth of C-L psychiatry, the name of the field at the time, through training grants (circa 1975) and a research development program (circa 1985).

The integration of C-L psychiatry into the core of psychiatric residency training began in the 1960s at individual institutions. By the 1980s, all psychiatry residency programs were required to provide substantial clinical experience in C-L psychiatry. In the United States, subspecialty fellowship training in C-L psychiatry and PM has been available for over 30 years, with well over 1000 psychiatrists educated in this subspecialty. As of December 2006, there were 35 fellowship programs in the Academy of Psychosomatic Medicine’s (APM) directory, with several more under development around the country. In the last national survey of U.S. psychiatrists’ practices, more than 2,500 psychiatrists were practicing in this field (Dorwart et al. 1992).

In 2001, The APM applied to the American Board of Psychiatry and Neurology (ABPN) for the recognition of “Psychosomatic Medicine” as a subspecialty of psychiatry, choosing to return to the name for the field imbedded in its history, its journals, and its national organizations (Lyketsos et al. 2001). Formal approval was granted by the American Psychiatric Association, the ABPN, the Residency Review Commission (RRC) of the Accreditation Committee for Graduate Medical Education (ACGME), and the American Board of Medical Specialties (ABMS). The first certifying examination was administered in June 2005 to almost 500 psychiatrists. As of November 2006, the ACGME had accredited 29 fellowship-training programs in PM, with more in the process of accreditation.

An impediment to the field’s growth has been the split between general medical and mental health care, with major adverse effects on quality of medical service delivery and patient-oriented care. This split is reflected in disparities and disintegration in the reimbursement of patient care (carve outs, lack of parity in coverage), as well as in research funding mechanisms in silos that do not promote cross-disease studies. PM can help mend the fragmentation in health care, but its growth will depend on correcting the splits in health care financing and research sponsorship.

### International Developments in Psychosomatic Medicine

International developments in PM have recently been reviewed by Smith (2006). A large collaborative study of C-L psychiatry services in Europe in the 1990s by the European Consultation Liaison Workgroup demonstrated significant variation in how C-L services were delivered among countries and played a vital role in the evolution of PM in Europe. In the United Kingdom’s national health service, there is integration between primary, specialty, and inpatient care. Many general hospitals have “liaison psychiatry services,” but only a minority actually has a dedicated psychiatric consultant. In Germany, psychiatry and neurology did not become separate specialties until 1992. C-L psychiatry services in general hospitals are provided by psychiatrists, while most psychosomatic practitioners are internists who work in outpatient private practice. In Australia, competition for limited resources with psychiatric services for psychosis jeopardized the future of C-L psychiatry, but the most recent national mental health plan does recognize its importance. While insufficient funding has inhibited the development of PM/C-L services in many countries, there nevertheless are enthusiastic growing PM/C-L movements in Japan, the Netherlands, Spain, Mexico, Brazil, Colombia, and elsewhere.

### Psychosomatic Medicine as a Scholarly Discipline

The foundation of PM is a specialized body of scientific knowledge regarding psychiatric aspects of medical illness. This has been articulated in classic (Table 118–2) and contemporary textbooks (Levenson 2005, 2007, Blumenfield and Strain 2006, Lloyd and Guthrie 2007), journals (Table 118–3), and the regular scientific meetings of national (Table 118–4) and international (Table 118–5) societies. A cadre of scholars and researchers has emerged involved in a wide spectrum of investigations looking at the medical illness–psychiatry interface. Important contributions have occurred in the interface between psychiatry and HIV-AIDS, cancer, transplantation, cardiology, neurology, endocrinology, pulmonary, renal and gastrointestinal diseases, obstetrics-gynecology, and geriatric medicine.

The frequent cooccurrence of medical and psychiatric morbidity has repeatedly been documented, especially in the complex medically ill. This comorbidity leads to increased mortality, morbidity, loss of quality of life, and excess health care utilization through several psychosocial and biological mechanisms, including promotion of risk factors,

Psychiatric morbidity in many medical disorders has been shown to be a potent risk factor for increased medical morbidity and a potent determinant of health-related quality of life. Yet potentially treatable psychiatric disorders in the complex medically ill remain often underdiagnosed and undertreated.

Early empirical efforts to treat psychiatric morbidity in the medically ill have been followed by randomized controlled trials (RCTs) focused on improving medical and psychiatric outcomes in patients with diseases like coronary artery disease and diabetes mellitus. In these studies, the psychiatric condition is treated, while its effects on medical outcomes, compliance with treatment for the medical condition, and quality of life are assessed. Other RCTs have been directed at patients with unexplained somatic symptoms and related “functional” syndromes.

### The Clinical Practice of Psychosomatic Medicine

The major goal of PM is to improve the psychiatric care of medically ill patients. It has long been recognized that nonpsychiatric clinicians provide the great majority of psychiatric care, dubbed as “the de facto mental health care system” (Regier et al. 1978). While there is a higher concentration of patients with psychiatric disorders in inpatient and outpatient medical settings, many do not receive recognition, appropriate diagnosis, initiation of adequate treatment, and/or referral for the follow-up psychiatric care they need. Failure to identify, evaluate, diagnose, treat, or achieve symptom resolution results in preventable adverse outcomes.

One major cause of the failure to identify and treat psychiatric disorders in medical settings is the absence of ready access to psychiatric expertise. Ideally, PM services for patients with psychiatric disorders and complex medical illness are integrated with the care provided by medical/surgical providers in collaborative care, which has great potential for improvement in both psychiatric and medical outcomes. However, most PM psychiatrists are on psychiatric consultation services, rarely found outside teaching hospitals, and their services are mostly acutely focused. Optimal care for patients with complex medical illnesses such as cancer or AIDS, or for those patients being considered for transplant or gastric bypass, calls for collaborative relationships with primary and specialty physicians and other allied health care professionals. Psychiatric liaison, in which psychiatrists are integrated members of a specialized care team, is a more advanced model, with greater ability to provide early detection and prevention. Such liaison services are usually limited to larger teaching and specialty hospitals, and have been difficult to financially support under managed care. Thus, there is an overall shortage of PM psychiatrists in the United States, they are mostly found in tertiary care sites, and they are not evenly distributed geographically.

Both in the United States and in other countries, there is considerable variation among the models of PM service delivery in the provision of psychiatric services in medical settings (Smith 2006). They vary in their focus on medical inpatients versus outpatients, in which disciplines are involved (psychiatry, psychology, psychiatric nursing, social work), and in how integrated they are with nonpsychiatric services and systems. They also differ in their relative devotion to consultation, liaison, education, and continued psychiatric care, and the extent to which they provide emergency psychiatric services.

### Psychiatric Diagnosis in the Medically Ill
Psychiatric disorders are frequently under- and overdiagnosed in the medically ill for a number of reasons. First, psychiatric symptoms are similar to those of medical illness. As a result, it may be problematic to determine whether such symptoms are manifestations of a physical disease or a comorbid psychiatric disorder. For example, a false
positive diagnosis of depression may occur when fatigue, anorexia, and weight loss caused by a medical illness are mistakenly attributed to depression, and a false negative diagnosis when depression’s vegetative symptoms are misattributed to the medical illness. A variety of approaches have been proposed to diminish the effect of medical symptoms confounding the diagnosis of depression. In an “exclusive” and “etiologic” approach, symptoms that are judged by the clinician to be etiologically related to a general medical condition are excluded from the diagnostic criteria for Major depressive disorder (MDD). However, how to determine which symptoms are due to a medical illness, and which are due to depression, is unclear. In a “substitutive” approach, symptoms most likely confused with medical illness, such as fatigue and weight loss are substituted with symptoms that are more likely to be affective in origin, such as irritability and social withdrawal. Such substitution eliminates the need to distinguish symptoms of medical illness from those of depression, but it also excludes some somatic symptoms that are core manifestations of depression. Furthermore, valid criteria to determine which symptoms should be substituted have not been established. An “inclusive” approach applies the unmodified diagnostic criteria, which makes it unlikely that depression will be missed, but at the price of more false positives.

A second problem in psychiatric diagnosis in the context of serious medical illness, is that it can be difficult to differentiate a normal psychological reaction from a psychiatric disorder. Normal emotional reactions occur in response to uncertainty about diagnosis or prognosis, loss of body parts or body functions, fear of death, impact of illness on identity and livelihood, dependency, reactions to strangers, and being alone in the hospital, and may include anxiety, sadness, guilt, denial, avoidance, anger, hopelessness, and obsessive control. Normal adaptive emotional and behavioral reactions to illness, maladaptive responses, and psychiatric disorder are on a spectrum, and their differentiation is one of degree, informed by clinical experience. Finally, it must be recognized that a given symptom, e.g., tachycardia or poor concentration, may simultaneously result from a normal reaction, a psychiatric disorder, and the medical disorder itself all in the same patient.

This chapter will next illustrate a PM approach to cardiovascular disease, cancer, and endocrine disorders. For more detailed coverage of these and other topics see Levenson (2005).

Psychosomatic Aspects of Cardiovascular Disease

The effects of psychological, social, and behavioral factors in cardiovascular disease have received considerable clinical attention and have been a primary focus of epidemiological and PM research for the past 30 years. Patients with severe mental disorders have about twice the prevalence of the classic risk factors for coronary artery disease (CAD) (Birkenaes et al. 2006).

Depression and Heart Disease

Major depressive disorder is the most common psychiatric disorder in patients with coronary artery disease (CAD), with a prevalence of about 15–20% in those with stable or unstable CAD (i.e., myocardial infarction and unstable angina), which is much higher than in the general population (Glassman and Shapiro 1998). Major depression has been more common after coronary artery bypass graft (CABG) surgery, approaching 30% in some studies (Blumenthal et al. 2003). Depression is also very common in congestive heart failure with a prevalence of up to 20%. Studies using depression symptom (i.e., not diagnostic) measures report even higher rates in cardiac patients. Despite such extensive studies of depression in heart disease, the diagnosis is still often missed, and only a minority of depressed patients receive treatment, and, fewer yet, adequate treatment.

Depression not only commonly occurs alongside CAD but also negatively affects outcome in CAD. Depression appears to be an independent risk factor for the development of CAD, with the magnitude of risk about 1.5–2.0. The magnitude of the effects of depression on morbidity and mortality in CAD is on a par with the effects of the recognized medical risk factors (Shapiro 2005). In a large epidemiological study, major depression tripled the relative risk of cardiac mortality in those without heart disease and quadrupled it in those who did have cardiac disease (Penninx et al. 2001). Major depression is a significant predictor of mortality after an acute myocardial infarction, with a three- to fourfold increased risk of death, which is equal to the effect of predictors like history of myocardial infarction or indices of cardiac function (Frasure-Smith et al. 1993, Carney et al. 2003b). In patients with CAD undergoing cardiac catheterization, major depression has been found to be a better predictor of cardiac morbidity and mortality than physiological measures such as left ventricular function (Carney et al. 1988). Patients hospitalized for unstable angina who also had depressive symptoms were four times more likely to have myocardial infarction or die the following year than were those without depression (after adjusting for other factors) (Lesperance et al. 2000). In patients who have CABG surgery, perioperative depression predicts an increased risk of subsequent cardiac events and also mortality.

Patients with CAD who are depressed also have poorer health-related quality of life and more functional disability in CAD, and depression has been found to be a stronger determinant of health status than objective measures of heart disease like stenosed coronary arteries, signs of ischemia, and ejection fraction (Ruo et al. 2003). Depression also adversely affects patients with congestive heart failure, worsening symptoms of heart failure, eroding health-related quality of life and functional capacity, as well as increasing the risk of death.

A number of explanations have been considered to account for the effects of depression on CAD (Glassman and Shapiro 1998, Shapiro 2005). Depression is closely associated with nicotine addiction, but depression still adversely affects CAD outcome even after controlling for smoking. Depression may interfere with compliance with recommended lifestyle changes, medication, and cardiac rehabilitation. Depressed patients may have alterations in platelet aggregation mediated by alterations in plasma serotonin. Another potential mechanism is reduced heart rate variability in depression, which may explain the increased risk of ventricular arrhythmias and sudden death in depressed cardiac patients. It is also possible that some of the adverse effects of depression are mediated through the cardiac effects of stress, as described later. Proinflammatory
mediators associated with depression may also be a contributor to CAD (Parissis et al. 2004).

Depression and cardiac disease often share some symptoms in common, which can complicate diagnosis. Insomnia and anorexia occur in both, but sadness and anhedonia occur predominantly in depression. In advanced heart failure, severe anorexia, weight loss, fatigue, poor concentration, and diminished libido all occur. In such patients, the diagnosis of depression should usually be reserved for those who also have psychological symptoms of depression.

**Anxiety, Stress, and Heart Disease**

Symptoms of anxiety are also frequent in patients with heart disease, particularly, during acute coronary events and arrhythmias. A variety of presentations are common including panic attacks, generalized anxiety, hypochondriacal anxiety, obsessive rumination, and acute and posttraumatic stress reactions. In younger patients, panic attacks and paroxysmal atrial tachycardia may present with very similar symptoms, be difficult to discriminate between, and also commonly overlap in the same patient. In the past, an association between panic disorder and mitral valve prolapse was described; however, neither is a sensitive or specific marker for the other. The mitral prolapse that has been associated with panic attacks is usually of no hemodynamic significance, and there do not appear to be any important clinical consequences of the association.

Anxiety also adversely affects outcome in CAD. Anxiety after myocardial infarction may lead to more frequent episodes of unstable angina and more recurrent myocardial infarctions, after controlling for confounding factors including depression (Frasure-Smith et al. 1995). Postmyocardial infarction anxiety is one of the strongest predictors of inhospital complications (Moser and Dracup 1996).

Anxiety’s adverse effects on outcome in CAD may be mediated via effects on heart rate variability, QT interval prolongation, or other abnormalities in autonomic nervous system responses (Januzzi et al. 2000). As with depression, some of anxiety’s effects may be related to the effects of stress on the heart. In studies of CAD patients under controlled laboratory conditions, acute experimental stress has been associated with increases in heart rate and blood pressure, and with silent (i.e., asymptomatic) myocardial ischemia.

Most patients who receive automatic implantable cardioverter-defibrillators (AICDs) receive them after experiencing life-threatening ventricular arrhythmias, an anxiogenic stressor in itself. A defibrillator discharge is extremely unpleasant physically, as well as reminding patients that they are still prone to potentially lethal arrhythmias. It is, thus, not surprising that in the early days of AICDs, there was a high rate of anxiety and other psychiatric disorders in the recipients. However, as the treatment has become more familiar and more widely used, the frequency and severity of anxious reactions have diminished. A new potential source of anxiety however has been the recent recall of selected AICDs, confronting patients with the difficult choice whether to risk the morbidity associated with replacing the device versus keeping a defibrillator that has a small chance of being defective.

**Type A Behavior**

The relation between type A behavior and CAD remains controversial. Type A is a complex construct of multiple elements, including impatience, hostility, intense achievement drive, and time urgency. The findings to date have been divided on whether type A behavior is a risk factor for the development of CAD and a predictor of worse outcome. Overall, there is more support (albeit limited) for type A behavior as a risk factor for developing CAD, than as a cause of increased morbidity or mortality in those who already have CAD. Of the type A traits, hostility has been the most consistently associated with increased coronary events and mortality (Boyle et al. 2004). Anger, which is related to but not identical to the concept of hostility, appears to be an especially potent trigger of ischemia (Ironson et al. 1992). How hostility or other elements of type A behavior might lead to CAD, or worsen its outcome, is unknown but speculated to be due to alterations in the balance between sympathetic and parasympathetic nervous system activity.

**Cognitive Disorders**

Postoperative delirium was extremely common in the early days of open-heart surgery but the incidence has declined over time in large part due to improvements in surgical technique and cardiopulmonary bypass technology. Delirium also sometimes occurs in the postoperative period following CABG surgery. More subtle cognitive dysfunction is present in about half of patients after CABG 1 week after surgery, with about a quarter of the patients still significantly cognitively impaired at 6 months (Newman et al. 2001). Persistent cognitive dysfunction in patients with CAD is most often vascular in origin since they frequently also have cerebral atherosclerosis. In severe heart failure, with ejection fraction below 15%, reduced cognitive performance is due to poorer cerebral perfusion.

**Hypertension**

Because most hypertension is essential, i.e., idiopathic, psychological factors have been intensively studied as potential contributors to its pathogenesis. The influence of psychological factors in the development of hypertension is less clear than in CAD despite many studies of the potential role of personality, coping style, and blood pressure reactivity in hypertension. In some, but not all, studies, a high level of anxiety has been a strong prospective predictor for the development of hypertension, as has job strain. One prospective study of psychosocial risk factors for hypertension found that two of the components of Type A behavior (time urgency/impatience and hostility) were each associated with double the risk of hypertension at follow-up, but symptoms of anxiety and depression were not predictive (Yan et al. 2003). However, another prospective epidemiologic study found that combined symptoms of depression and anxiety were associated with an increase for hypertension (Jonas et al. 2000). Studies of psychological treatments for hypertension, primarily relaxation techniques and biofeedback, have, sometimes, found modest but clinically significant sustained reductions in blood pressure. However, drug therapy is much more effective than such techniques.

**Psychiatric Drugs in Patients with Heart Disease**

Selective serotonin reuptake inhibitors (SSRIs) have almost no reported adverse cardiac effects, although they have rarely caused sinus bradycardia. Sertraline has been studied
in the most depth in the Sertraline AntiDepressant Heart Attack Randomized Trial (SADHART) study that found no significant adverse effects in patients who had active coronary artery disease (Glassman et al. 2002). Bupropion, mirtazapine, venlafaxine, and duloxetine have occasionally been associated with relatively small increases in blood pressure but appear to be safe for use in patients with cardiac disease. Tricyclic antidepressants (TCAs) can cause orthostatic hypotension and conduction delay (QRS or QT prolongation). An overdose of TCAs may cause fatal ventricular arrhythmias. TCAs have Type 1A antiarrhythmic effects and, therefore, are considered relatively contraindicated after myocardial infarction.

Hypotension, caused by psychiatric drugs, is usually mediated via alpha-adrenergic blockade. It is common with low-potency typical antipsychotics, very common with clozapine, and less common with other atypical antipsychotics. Clozapine is unique among antipsychotics in causing myocarditis, usually presenting as a dilated cardiomyopathy, with an estimated rate between 1/500 and 1/10000. About 85% of the cases occur during the first 2 months of treatment with clozapine.

Antipsychotics all appear capable of prolonging the QT interval but this has primarily been of clinical significance with low-potency phenothiazines, pimozide, and droperidol (droperidol and mesoridazine have been withdrawn in the United States). In patients with other causes of QT-interval prolongation, especially familial long-QT syndrome, or the concurrent use of other QT-prolonging drugs, there is some increased risk of the ventricular arrhythmia, torsade de pointes. An electrocardiogram should be obtained for patients who have a history of heart disease, hypokalemia, hypomagnesemia, or a personal or family history of sudden death or syncope.

There has been recent concern regarding an increased risk of death in elderly demented patients who have received antipsychotics, with some of the deaths being cardiovascular. Rather than this absolutely contraindicating the use of antipsychotics in such patients, it is prudent to carefully balance the risks and benefits of treating versus not treating psychiatric symptoms in demented patients.

Benzodiazepines have no recognized cardiac adverse effects (except in severe withdrawal) and have been safely used in coronary care units for several decades now. Buspirone is also free of cardiovascular effects.

Although lithium can cause sinus node dysfunction, it has been safely used even in patients with severe heart disease. Lithium levels are difficult to regulate in patients with congestive heart failure who are on salt-restricted diets and receiving varying dosage of diuretics, and it is usually best avoided in such patients. Valproic acid and lamotrigine have no significant cardiovascular effects, while carbamazepine has a similar side effect profile to the tricyclics.

Cholinesterase inhibitors may have vagotonic effects on the heart (e.g., bradycardia). While a number of clinical authorities have reported the safe use of modest doses of stimulants in patients with significant cardiac disease, including congestive heart failure, coronary artery disease, arrhythmias, and hypertension, recent concern has been raised regarding cardiac risk. Here too a careful weighing of potential risks versus benefits is warranted rather than total avoidance.

**Electroconvulsive Therapy (ECT)**

Current acute coronary artery disease (myocardial infarction, unstable angina) or recent serious ventricular arrhythmias are relatively strong contraindications to ECT, but ECT has been used safely in a variety of heart diseases including patients with CAD, congestive heart failure, pacemakers, implanted defibrillators, after aneurysm repair, and even after heart transplant. For more detailed review see Rasmussen et al. (2005).

**Psychosomatic Aspects of Cancer**

**Psychiatric Disorders in Cancer Patients**

An individual’s psychological response to cancer is influenced by specific aspects of the particular cancer. Patients’ ability to manage a cancer diagnosis and treatment commonly changes over the course of the illness and depends on medical, psychological, and social factors: the disease itself (i.e., site, stage, clinical course, cancer treatments and their complications); prior personality, coping style, and mental health; stage of life; social support; and cultural and religious background.

**Depression**

Cancer is associated with a higher rate of depression than in the general population comparable to other serious medical illnesses (Massie 2004) and may represent a normal reaction, a psychiatric disorder, or a somatic consequence of cancer or its treatment. Cancer types particularly associated with depression include oropharyngeal, pancreatic, breast, and lung. Because cancer may itself cause anorexia, weight loss, fatigue, and other vegetative symptoms, diagnosis of clinical depression relies more heavily on psychological symptoms like social withdrawal, anhedonia, dysphoric mood, feelings of worthlessness or guilt, poor self-esteem, and suicidal thoughts. Thus, there is a risk both of underdiagnosis of depression in cancer patients, misattributing depressive symptoms to the cancer and a “normal reaction,” and, over-diagnosis, misattributing cancer-caused symptoms and normal emotional upset to clinical depression. An increased risk of suicide in cancer patients is associated with advanced stage of disease, poor prognosis, delirium, inadequately controlled pain, depression, history of psychiatric illness, substance abuse, previous suicide attempts, social isolation (Massie and Greenberg 2005). Passive suicidal thoughts are far more common than true suicidality in cancer patients, yet may be expressed in some patients’ noncompliance with or refusal of treatment.

**Anxiety**

Anxiety leads some patients to deny or ignore cancer symptoms and delay seeking medical attention. Symptoms of anxiety are common after initial diagnosis of cancer, in making treatment decisions, and when worrying about recurrence or progression, but the rate of full anxiety disorders may not be higher than in the general population (Stark et al. 2002). Specific anxiety syndromes can interfere with treatment. Patients with claustrophobia have difficulty tolerating magnetic resonance imaging (MRI) scans, radiation therapy, or isolation because of neutropenia.

Needle phobia may interfere with chemotherapy, and fear of anesthesia gets in the way of surgery. Radiation
Breast Cancer

tases (very common in lung cancer), leukoencephalopathy be gained from cessation efforts. However, continued smoking is associated with decreased survival after diagnosis of lung cancer, so early antismoking efforts may help. Smokers are at higher risk for smoking, and while many smokers with cancer experience aggressive malignant tumors. In addition, the choice between active treatments is difficult because of uncertainty which treatment (surgery vs. radiation) has the best benefit-to-burden ratio. The choice is often based on the potential consequences of urinary incontinence and impotence. Androgen deprivation therapy via orchietomy or gonadotropin-releasing hormone agonists may cause hot flashes, diminished libido, fatigue, weakness, and muscle atrophy, and is associated with poorer quality of life (Wei et al. 2002).

Psychiatric Aspects of Cancer Treatments

Chemotherapy

The neuropsychiatric side effects of common chemotherapeutic agents are described in detail elsewhere (Massie and Greenberg 2005). The effects of chemotherapy on cognition have not yet been clearly elucidated (Phillips and Bernhard 2003). There are few clinically significant interactions between cancer drugs and most psychotropics, with the exception of procarbazine, which is a weak monoamine oxidase (MAO) inhibitor.
Radiation
Brain irradiation causes more profound fatigue than radiation treatment of other sites. Late sequelae of brain irradiation may include radiation necrosis in focal areas or leukoencephalopathy.

Bone Marrow Transplantation
Patients undergoing bone marrow transplantation (BMT) have been reported to experience high levels of depressive and anxiety symptoms (Massie and Greenberg 2005). The greatest emotional distress may occur after hospital admission and prior to bone marrow infusion. However, during high-dose chemotherapy and irradiation, while patients are limited in contact with their family (and frequently in isolation) and experience profound nausea, vomiting, and fatigue, psychiatric disorders remain common, especially adjustment disorder with anxiety and depression. As many as half of BMT patients experience delirium during the posttransplantation period (Fann et al. 2002) with severe graft-versus-host disease as one possible cause. While chronic anxiety and depression are the most common psychiatric sequelae, long-term survivors of BMT show no difference in psychological and social functioning than those who receive standard chemotherapy, but mild to moderate cognitive impairment is common (Massie and Greenberg 2005).

Psychiatric Treatment in Cancer

Psychotherapy
Psychotherapy can help patients cope with the diagnosis and treatment of cancer, relieving psychic suffering while supporting patients’ morale, search for meaning, and desire for dignity at the end of life (Greenstein and Breitbart 2000, Chochinov 2002). Most studies of group therapy in cancer patients have shown improvement in mood, pain, and quality of life (Goodwin et al. 2001, Spiegel et al. 1989). Relaxation training and cognitive-behavioral therapy also have reduced anxiety and depression in cancer patients. Spiegel et al. (1989) performed a small randomized controlled trial of supportive group therapy with training in self-hypnosis for pain control in women with metastatic breast cancer. The subjects in the psychotherapy treatment group had less mood disturbance, fewer phobic responses, and less pain but were also noted to have increased survival compared with the control group (34.8 vs. 18.9 months). The possibility that a psychological intervention might improve longevity in metastatic breast cancer patients was exciting, supported by some other studies (e.g., Cunningham et al. 1998), but not by the definitive replication study (Goodwin et al. 2001) as well as some others. Thus, the evidence is that psychotherapy in cancer patients results in improvement in indices of quality of life like mood, energy, and pain control. Patients can be told that group therapy contributes to living better, not necessarily longer.

Psychopharmacology
The SSRIs may cause nausea and weight loss in some cancer patients, particularly, those with cancer-related anorexia–cachexia. Mirtazapine and trazodone may be advantageous in such patients. Fluoxetine’s long half life makes it useful for patients intermittently unable to tolerate oral intake (e.g., somatitis from chemotherapy). The SSRIs and serotonin-norepinephrine reuptake inhibitors (SNRIs) reduce hot flashes in abrupt menopause caused by chemotherapy or oopherectomy, and may help with hot flashes caused by treatment in men with prostate cancer. In addition to their psychiatric indications, TCAs and SNRIs are used to treat neuropathic pain syndromes caused by malignancy or its treatment. In addition to their antianxiety effects, benzodiazepines (most often lorazepam) are frequently prescribed to augment antiemetic drugs during chemotherapy. Low doses of neuroleptics are used in the treatment of delirium in cancer patients as in other patients with delirium. Psychostimulants are used for the treatment of depression in terminally ill cancer patients because there is no delay in onset of therapeutic effects, and, more generally, may palliate fatigue and augment opioid analgesia while counteracting sedation.

Psychosomatic Aspects of Endocrine Disorders
Psychiatric symptoms and syndromes are common in patients with almost all endocrine disorders. Here, we briefly review psychiatric issues in diabetes mellitus, hypoglycemia, thyroid, parathyroid, and adrenal disorders, acromegaly, pheochromocytoma, hyperprolactinemia, polycystic ovary syndrome, and testosterone deficiency. For a more detailed review, see Goebel-Fabbri et al. (2005).

Diabetes Mellitus
Type I diabetes mellitus (insulin-dependent diabetes) is an autoimmune disorder with additional genetic and environmental influences, affecting 5–10% of U.S. diabetics. Type II diabetes is characterized by insulin resistance, etiologically related to obesity, sedentary lifestyle, and diet, and affects 90–95% of U.S. diabetics. It has been well established that intensive management of both Type I and Type II diabetes reduces diabetic complications and improves long-term health outcomes (Diabetes Control and Complications Trial Research Group 2001, UK Prospective Diabetes Study (UKPDS) Group 1998a, 1998b). Thus, the goal of achieving optimal glucose values requires complex conscientious daily behaviors, which many patients find difficult. In both types of diabetes, psychiatric disorders have been linked to treatment nonadherence, worse glycemic control, and ultimately greater prevalence of micro- and macrovascular complications.

There is conflicting evidence whether stress directly affects the onset of diabetes or its course (Goebel-Fabbri et al. 2005). Stress hormones are involved in the counterregulatory response to insulin, so it is likely that stress plays a role in increasing blood glucose. It is not clear whether stress directly influences metabolic regulation or whether people under stress change their self-care behaviors.

Depression is two to three times more common in diabetics than in the general population, and depression is associated with poorer glycemic control and increased diabetic complications. The demonstration of such associations raises the question, is depression a cause or an effect of poorer diabetic outcomes? There are a number of mechanisms by which depression can increase the risk for or aggravate diabetes. Depression is associated with an increase in the secretion of cortisol and other counterregulatory hormones. Depression is also associated with reduced physical activity, increased
smoking, poor diet, and poor ability to self-monitor. Depression results in changes in interpersonal functioning that can adversely affect the doctor-patient relationship, which is so central to diabetic management. Depression also increases the risk of a variety of other comorbidities like coronary disease. On the other hand, there are a number of mechanisms by which diabetes can result in or aggravate depression. Diabetes can lead to significant restrictions in lifestyle, demoralizing complications (e.g., renal failure, blindness, gastroparesis, amputations), and chronic pain. Diabetes is also associated with white matter lesions thought to increase risk for “vascular depression.”

There have been small randomized controlled trials demonstrating the efficacy of nortriptyline (Lustman et al. 1997) and fluoxetine (Lustman et al. 2000) in the treatment of depression in diabetes, as well as one small randomized controlled trial of cognitive behavioral therapy demonstrating that it improved both depression and glycemic control (Lustman et al. 1998). A large randomized controlled trial of collaborative care, coordinating medical and psychiatric treatment in primary care settings, demonstrated improved depression care and outcome but no improvement in glycemic control (Katon et al. 2004).

Given the high prevalence of depression and its adverse effects in diabetes, and the availability of evidence-based treatments for depression, aggressive identification and treatment of depression are warranted as early as possible in the course of diabetes. Depression should always be suspected in patients who are having difficulty adapting to diabetes and show poor glycemic control.

There is also an increased prevalence of diabetes, mainly Type II, in patients with bipolar disorder. Some of this increase is no doubt due to the increased frequency of obesity in bipolar patients, some of which is iatrogenic since most mood stabilizers may cause weight gain. The increased prevalence of diabetes may also be related to lifestyle factors (diet, sedentary), and other comorbidities. It is not clear whether bipolar disorder might physiologically aggravate diabetes, and there has also been a question of whether diabetes and bipolar disorder may share some degree of genetic risk.

Diabetes is two to four times more common in patients with schizophrenia than in the general population. While some of this increase can be attributed to the proclivity for some antipsychotics, particularly, many of the atypicals, to cause glucose intolerance and obesity, the increased risk of diabetes in schizophrenia preceded the introduction of the atypicals (Goebel-Fabbri et al. 2005). Schizophrenics also tend to have poorer diet and are more likely to be sedentary.

There is also an increased risk of eating disorders in diabetes, with anorexia nervosa and bulimia more frequent in Type I diabetes, and binge eating disorder more frequent in Type II. A downside for many patients of optimally tight control of blood glucose is weight gain. That and the increased attention to dietary intake may aggravate eating disorders. “Caloric purging” refers to the practice of using less insulin than prescribed in order to lose weight, a practice that has been found in up to 40% of Type I diabetics between the ages of 15 and 30 (Polonsky et al. 1994). Those who engage in caloric purging have elevated hemoglobin A1c, more frequent hospitalizations and emergency room visits, and more frequent diabetic complications. This practice can be very difficult to detect if it is the only means of purging used by the patient. Thus, in patients who have both diabetes and anorexia nervosa or bulimia, overly intensive diabetic management can backfire. It is important to remember that metabolic stabilization is the primary goal, and there is a need to avoid excessive zeal in pursuing ideal blood glucose levels in such patients.

While many clinicians would suspect that frequent hypoglycemic episodes from too much insulin would result in permanent cognitive dysfunction in diabetics, the evidence is equivocal. There is more evidence that frequent hyperglycemic episodes result in cognitive dysfunction, probably due to cerebral micro- and macrovascular damage (Goebel-Fabbri et al. 2005).

**Hypoglycemia**

“Reactive hypoglycemia” was a popular diagnosis in the past, often offered as an explanation for symptoms of depression, anxiety, inattention, or unexplained fatigue. A 5-hour glucose tolerance test is no longer considered necessary in evaluating such patients. However, significantly symptomatic hypoglycemia is unusual, except when it is due to insulin, usually prescribed, but rarely due to an insulin-secreting tumor (insulinoma) or factitious disorder. True hypoglycemic episodes are distinguishable from panic attacks in that the latter rarely cause acute confusion or loss of consciousness.

**Thyroid Disorders**

Hyper- and hypothyroidism are common and easily screened for with a serum thyroid-stimulating hormone (TSH) (except for pituitary or hypothalamic hypothyroidism). Somatic symptoms of hyperthyroidism include sweating, fatigue, heat intolerance, weight loss, weakness, fine tremor, and tachycardia. The psychiatric symptom pattern in hyperthyroidism most often resembles generalized anxiety, but depression, irritability, hypomania, and cognitive dysfunction are all common. In severe hyperthyroidism (thyrotoxicosis, “thyroid storm”), patients may be frankly manic.

The somatic symptoms of hypothyroidism include weakness, fatigue, cold intolerance, weight gain, constipation, and somnolence. The psychiatric presentation of hypothyroidism closely mimics depression, but cognitive dysfunction is not uncommon. Severe hypothyroidism does rarely present with psychosis (“myxedema madness”).

“Subclinical hypothyroidism” refers to the clinical condition, in which TSH is elevated but T4 is low or normal, but the patient has few or no symptoms. Subclinical hypothyroidism appears to be a risk factor for depression and is a common cause of rapid cycling in bipolar disorder. Patients with subclinical hypothyroidism often show subtle signs of cognitive dysfunction. Whether and at what point to treat with thyroid replacement in subclinical hypothyroidism remains controversial.

**Parathyroid Disorders**

Symptoms in hyperparathyroidism directly reflect serum calcium levels. In mild to moderate hypercalcemia (10–14 mg/dl), depression, apathy, irritability, lack of initiative, and lack of spontaneity are common. In severe hypercalcemia (> than 14 mg/dl), patients are usually delirious with psychosis, catatonia, or lethargy, and may progress to coma.
Symptoms in hypoparathyroidism similarly reflect calcium levels. In mild hypocalcemia, patients have anxiety, paresthesias, irritability, and emotional lability. In severe hypocalcemia, mania, psychosis, tetany, and seizures are common.

**Adrenal Disorders**

Hyperadrenalism (Cushing syndrome) most commonly results from exogenous corticosteroids but may also be the result of adenocorticotrophic hormone (ACTH) secretion by a pituitary tumor (Cushing disease), or corticosteroid secretion by an adrenal tumor. In addition to somatic consequences including diabetes, hypertension, muscle weakness, obesity, and osteopenia, psychiatric symptoms are common in hyperadrenalism and may actually appear before physical signs. Depression is most common, but anxiety, hypomania/mania, psychosis, and cognitive dysfunction are all common.

Hypoadrenalism (Addison syndrome) may be primary (a result of adrenal destruction by autoimmune disease, metastatic cancer, tuberculosis, or HIV infection) or secondary through suppression of ACTH secretion by chronic corticosteroid therapy. Common physical symptoms in hypoadrenalism include postural hypotension, anorexia, nausea and vomiting, and weakness. Psychiatric symptoms include apathy, anhedonia, fatigue, and depressed mood. Adrenal insufficiency may, sometimes, be mistakenly diagnosed as major depression. While anorexia is common in both, the presence of nausea and vomiting should suggest the former.

**Acromegaly**

Acromegaly is the result of excess growth hormone secretion by a pituitary tumor. Common physical symptoms and signs include headache, disfiguring facial and bodily features, glucose intolerance, and hypertension. Psychiatric symptoms include mood lability, personality change, and depression. Psychosis has also been reported, but this has usually appeared to be due to treatment with dopamine agonists like bromocriptine.

**Pheochromocytoma**

Pheochromocytomas are rare catecholamine-secreting tumors. They cause tachycardia, labile hypertension, headache, sweating, and palpitations. They may also cause anxiety symptoms that mimic panic attacks. Pheochromocytomas have occasionally been reported to be unmasked after the prescription of an antidepressant. Screening by testing for urinary catecholamines produces frequent false positives. The best diagnostic test is a plasma metanephrine level, which is more specific. However, these tumors are quite rare and it is not necessary to screen for pheochromocytomas in most anxious patients even if they also have hypertension.

**Hyperprolactinemia**

Excessive secretion of prolactin may be caused by pituitary adenoma, pregnancy, antipsychotics (typicals, risperidone), and antidepressants. Hyperprolactinemia in women is manifested by galactorrhea, irregular menses, and infertility. Men usually have no physical symptoms, but both genders may experience reduced libido, depression, and anxiety.

**Polycystic Ovary Syndrome**

Polycystic Ovary Syndrome is common, affecting 5–10% of women of childbearing age. Its cause is unknown, but there is increased risk in women receiving valproate. Physical signs include oligo- or amenorrhea, hirsutism, infertility, obesity, hypertension, and insulin resistance. Depression is very common, but it is not clear whether its origin is hormonal or an emotional reaction to the changes in appearance and reproductive function (Goebel-Fabbri et al. 2005).

**Testosterone Deficiency**

In men, testosterone deficiency may be the result of aging, or primary or secondary hypogonadism. Physical symptoms in men include reduced libido, sexual dysfunction, low energy, muscle weakness and atrophy, and reduced hair growth. The concept of a male climacteric is controversial. There is evidence of an increase in depression associated with reduction in testosterone levels in men (Shores et al. 2004). However, results have been mixed in randomized controlled trials using testosterone to treat depression in hypogonadal men (Goebel-Fabbri et al. 2005).

In women, testosterone deficiency results in decreased libido, low energy, and depression. However, what level should be considered to constitute deficiency has not been clearly defined, and the indications, risks, and benefits of testosterone replacement therapy in women are even less clear than in men.

**Conclusion**

PM has evolved from its beginnings in psychophysiology and psychoanalysis to become a subspecialty of psychiatry devoted to psychiatric care of the medically ill. As illustrated in this chapter for cardiovascular disease, cancer, and endocrine disorders, a PM approach entails a complex understanding of the interrelationships of medical disorders and psychiatric disorders on multiple levels. PM aims to advance the diagnosis and treatment of psychiatric disorders in the medically ill, to improve education and training of both psychiatric and nonpsychiatric medical specialists, and to develop integrated systems of care. To overcome the fragmentation in the existing service delivery system will require changes in health care insurance and financing. This will help overcome the current disintegration and disparities between mental health and general health care.

Formal recognition as a subspecialty has strengthened PM and enhanced its growth and influence. The certification of more psychiatrists with expertise in PM will help address the unmet psychiatric needs of the medically ill, improve the quality of education and training, both in psychiatry and in other areas of medicine, promote integrative research, and improve medical outcomes in complex patients with multiple disorders.

Growing interest in women’s mental health has paralleled the expanding clinical and research focus on women’s health issues over the past two decades. Research has shown that prior to puberty, both genders are equally at risk for developing mood disorders; however, with the onset of menstruation, women begin to show an increased risk for unipolar depression compared to men. Although studies have not yet revealed a consistent association between female reproductive hormones and psychiatric illness, there appears to be a subgroup of women at increased risk for psychiatric symptoms during times of hormonal fluctuation, such as premenstruation, during pregnancy, postpartum, and perimenopause. In addition to this biological vulnerability, psychosocial risk factors and intervening life events are key factors in increasing women’s risk for psychiatric illness. This chapter will focus on psychiatric conditions during important reproductive transitions in women, including pregnancy, postpartum, and perimenopause, while premenstrual syndrome and premenstrual dysphoric disorder are thoroughly discussed in a separate chapter (see Chapter 68).

Pregnancy
Pregnancy can be a stressful and high-risk time for mood instability, particularly in women with a past history of mood disorder (Cohen et al. 2006a, Viguera et al. 2000). While there has been increasing research and public health focus on postpartum depression (PPD), a significant number of women with PPD have symptoms that begin in pregnancy (Evan et al. 2001). A systematic review of perinatal depression found that the point prevalence of major and minor depression during pregnancy ranged from 6.5 to 12.9% (Gavin et al. 2005). Far fewer studies have looked at the prevalence and course of bipolar disorder, and anxiety and psychotic disorders during and after pregnancy. Clearly, many pregnant women, particularly those with a history of psychiatric illness, have worsening symptoms during pregnancy, as a result of either psychosocial risk factors’, discontinuing or decreasing medications, changes in medication blood levels or other physiologic changes during the course of pregnancy (Altshuler and Hendrick 1996, Wisner et al. 1993). Screening and treatment during pregnancy would not only help symptomatic expectant mothers but also minimize their risk of worsening mood and anxiety after delivery. This section will outline a framework for approaching patients with significant psychiatric symptoms during and after pregnancy.

Evaluation of Pregnant Women with Psychiatric Symptoms
Depression and anxiety during pregnancy frequently go undetected by providers (Kelly et al. 2001). Timely diagnosis and treatment is often hampered by confusion over whether somatic symptoms, such as fatigue and changes in sleep and appetite, are normal consequences of pregnancy or evolving mood or anxiety disorders. Routine formalized screening for major Axis I diagnoses would assist clinicians in identifying and tracking patients during pregnancy (Spitzer et al. 2000). In addition, screening for the following risk factors would help identify women at risk for depression during and after pregnancy: prior history of depression, young age, limited...
social support, marital strain, and ambivalence about pregnancy (Altshuler et al. 2000).

**Treatment of Pregnant Women with Psychiatric Symptoms**

Treatment of psychiatric illness during pregnancy requires a thorough discussion about the risks of untreated illness and the benefits of medication. Many pregnant women overestimate the risk of medication and underestimate the risk of untreated depression or anxiety. It is important for clinicians to put the risks of medication into context. For instance, pregnancy itself carries many risks, including spontaneous abortion and congenital defects. Untreated psychiatric illness can compound these risks by contributing to poor self-care, decreased prenatal compliance, increased nicotine and substance misuse (Hanna et al. 1994, Zhu and Valbo 2002), poor obstetrical outcomes (Chung et al. 2001, Kurki et al. 2000), and increased risk of PPD (Beck 2003). A first step in approaching patients involves reviewing the course of their illness, severity of past depressive episodes, and response to different treatments, including both medications and psychotherapy. Part of this risk–benefit discussion would also include review of the available data, regarding reproductive risks associated with psychotropic medications as well as review of the risks associated with discontinuing medication. For instance, in a recent study, Cohen et al. (2006b) followed 201 women with a history of recurrent major depression and found an increased risk of relapse in those who discontinued antidepressant medication compared to those who continued (68% vs. 26%).

**Major Reproductive Risks Associated with Psychotropic Medications**

**Congenital Malformations**

Teratogenesis is the malformation of fetal organs, leading to structural or functional anomalies. Drugs ingested in pregnancy are considered teratogenic if they are associated with an increased frequency of congenital malformations above the baseline risk of 3–4%. Most studies of tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors (SSRIs) have been reassuring and shown no increased risk of major congenital malformations (Hendrick et al. 2003, Malm et al. 2005). However, there is great disparity in the amount of published information on different antidepressants within these drug classes, and it remains unclear whether all drugs within a class have the same reproductive risk. Recently, GlaxoSmithKline (GSK), the manufacturer of paroxetine, issued a warning that two studies found a possible association between first trimester paroxetine exposure and increased risk for cardiac defects, particularly atrial and ventral septal defects (www.gsk.com/media/paroxetine_pregnancy.htm). In 2005, the Food and Drug Administration (FDA) issued a similar warning that first trimester paroxetine use was associated with an increased risk of major malformations (4% vs. 3%), particularly cardiac malformations (2% vs. 1%). Although the purported association between paroxetine use and cardiac defects contradicts other published studies (Einwarson and Einwarson 2005, Ericson et al. 1999, Kulin et al. 1998), the manufacturer and the FDA have changed the pregnancy labeling from category C to D, indicating that published studies in pregnant women have demonstrated a risk to the fetus. In addition, the American College of Obstetricians and Gynecologists has recommended avoiding paroxetine use in pregnant women if possible; however, it also encourages an individualized approach to treatment, since in some cases the benefits of paroxetine may outweigh the risks of discontinuing the medication (ACOG Committee on Obstetric Practice 2006).

While there have been fewer reported cases of prenatal exposures to non-SSRI antidepressants, the limited data available have not shown an increased risk of congenital malformations with venlafaxine (Einwarson et al. 2001), bupropion (Chun-Fai-Chan et al. 2005), mirtazapine (Djulus et al. 2006), nefazodone, or trazodone (Einwarson et al. 2003).

**Perinatal Effects Following Late Pregnancy Antidepressant Exposure**

Perinatal toxicity refers to transient symptoms in the neonate following in utero exposure to medication, such as antidepressants, antipsychotics, and benzodiazepines. These symptoms can include irritability, tremulousness, insomnia, poor feeding, temperature dysregulation, increased or decreased muscle tone, and/or respiratory distress. These perinatal syndromes are likely related to medication withdrawal or toxicity and have been described with many serotonin reuptake inhibitors (SSRIs) and serotonin–norepinephrine reuptake inhibitors (SNRIs) (Kallen 2004, Moses-Kolko et al. 2005, Zeskind and Stephens 2004). Using a formal screening tool, one study found that 30% of the newborns exposed to SSRIs in late pregnancy developed neonatal abstinence symptoms (Levinson–Castiel et al. 2006). In general, these neonatal syndromes have been found to be transient and not life threatening. To minimize the risk of perinatal toxicity, antidepressants can be tapered in the last weeks of pregnancy; however, this would not be prudent in patients with significant depression or highly recurrent illness.

Persistent pulmonary hypertension of the newborn (PPHN) is a serious and rare condition, affecting 1–2 out of 1000 live births and leading to death in 10–20%. In 2006, Chambers et al. (2006) published a study in which they found a possible association between PPHN and SSRI exposure after 20 weeks’ gestation. Although this study was retrospective in design and involved only a small number of affected infants, its findings are concerning and again highlight the uncertainty that patients and providers must assume in choosing to use antidepressants or any psychotropic medications during pregnancy (see Clinical Vignette 1).

**Long-Term Neurobehavioral Effects**

Neurobehavioral teratogenesis refers to the long-term neurologic or behavioral effects of in utero drug exposure. In a study by Nulman et al. (2002), preschool children exposed in utero to TCAs or fluoxetine were found to have no difference in temperament, language, and cognitive development compared to nonexposed children.

**Reproductive Risks Associated with Other Psychotropic Medications**

**Lithium** use during the first trimester has been associated with an increased risk of a serious congenital heart defect known as Ebstein’s anomaly, which occurs in approximately 1 out of 1000 live births. Lithium has also been associated with perinatal toxicity, including case reports of hypotonia,
cyanosis, neonatal goiter, and diabetes insipidus. For women with bipolar illness (i.e., recurrent mania or depression, history of psychosis, etc.), the risk of recurrence during pregnancy may overshadow the relatively small risk of Ebstein’s anomaly. For such women, maintenance lithium therapy during pregnancy may be the most appropriate course. On the other hand, for women with significant periods of euthymia and few past mood episodes, slowly tapering off lithium and reintroducing lithium after the first trimester may help reduce the risk of relapse during the postpartum.

Lamotrigine is another highly effective mood stabilizer, particularly for bipolar depression. According to the manufacturer-sponsored Lamotrigine Pregnancy Registry and other published studies (Cunnington and Tennis 2005), there appeared to be no increased risk of congenital defects above the baseline risk with lamotrigine monotherapy; however, when combined with valproic acid in pregnancy, the risk estimate was found to be elevated to above 10%. While these initial findings seemed to offer women a relatively safe alternative to other anticonvulsants in pregnancy, the North American Antiepileptic Drug Pregnancy Registry ((888) 233-2334) recently found that infants who are exposed to lamotrigine monotherapy during pregnancy have a much higher risk of oral cleft defects. In this study, 564 children exposed to lamotrigine monotherapy had a prevalence rate of major malformations of 2.7%; however, 5 infants had oral cleft lip and palate, yielding a prevalence rate of 0.5–2.0 per 1000 births compared to a baseline prevalence of 0.5–2.0 per 1000 births in unexposed infants (Holmes et al. 2006). Even if future prospective studies confirm this association between first trimester lamotrigine use and oral cleft lip and palate, the overall risk appears to be low and may be overshadowed by the high risk of recurrent illness in some women with bipolar disorder. Clinicians should encourage all pregnant patients on any anticonvulsant in pregnancy to participate in the North American Antiepileptic Drug Pregnancy Registry by calling 1-888-233-2334, as this growing database will continue to offer valuable new information.

Valproic acid and carbamazepine have well-established risks of neural tube defects of 5 and 1%, respectively. Carbamazepine is also a competitive inhibitor of prothrombin precursors and may increase the risk of neonatal hemorrhage. Newer anticonvulsants (e.g., gabapentin, oxcarbazepine, and topiramate) have limited reproductive safety data to guide their use in pregnancy. While they would not be the first choice in pregnancy, they may be indicated for particular pregnant women with refractory bipolar illness and a history of good response to these medications. Providers should encourage pregnant women who elect to continue any mood stabilizer to take high-dose folate (4 mg per day) for the theoretical benefit of reducing the risk of neural tube defects. In addition, pregnant women should undergo a second trimester Level II ultrasound to screen for major congenital anomalies.

Antipsychotics, like other psychotropic medications, are often essential during pregnancy to help minimize risks associated with psychosis, such as noncompliance with prenatal care, increased drug and alcohol use, and other high-risk behaviors. High- and midpotency neuroleptics, such as haloperidol and perphenazine, are generally considered to be the antipsychotics of choice during pregnancy since they have not consistently demonstrated teratogenic risk, while low-potency phenothiazines have shown increased risk of congenital malformations and should be avoided. There have been few studies of the reproductive safety of atypical antipsychotics, such as olanzapine, clozapine, risperidone, and quetiapine, and therefore, their risks in pregnancy are unknown.

Studies of benzodiazepines use during pregnancy have been contradictory and controversial. Benzodiazepine use during pregnancy has been associated with case reports of perinatal toxicity, including temperature dysregulation, apnea, depressed APGAR scores, hypotonia, and poor feeding. In addition, early studies revealed an elevated risk of oral cleft palate defects compared to the baseline risk in the general population. However, more recent studies have shown that the overall risk of cleft lip and palate with benzodiazepine use in pregnancy is likely quite low (Iqbal et al. 2002, Lin et al. 2004). In considering the risks and benefits of benzodiazepines, clinicians should also consider the risks of untreated insomnia and anxiety in pregnancy, which may lead to physiologic effects as well as diminished self-care, worsening mood, and impaired functioning. Given the consequences of untreated psychiatric symptoms and the limited and controversial risks associated with benzodiazepine use, some women with overwhelming anxiety symptoms or sleep disturbance may find that the benefits outweigh any theoretical risks.

Electroconvulsive Therapy
Electroconvulsive therapy (ECT) is an underutilized treatment during pregnancy despite studies supporting its safety. For high-risk situations, such as psychotic depression or mania, which require prompt relief of psychiatric symptoms to protect both mother and fetus, ECT is the treatment of choice. The safe and effective use of ECT during pregnancy requires coordination of care among the patient’s psychiatrist, obstetrician, and anesthesiologist.

Psychotherapy and Light Therapy
Although concerns about the reproductive safety of medications often prompt women to seek psychiatric consultation during pregnancy, it is important to note that psychotherapy is often a useful alternative (or adjunct) to medication. Establishing a therapeutic alliance, exploring feelings about the pregnancy, and taking inventory of strengths, supports, and stressors can help target interventions, which may include assistance with basic needs for food, shelter, or financial support. Studies have demonstrated that depressed pregnant women can also benefit greatly from interpersonal psychotherapy (IPT), a brief structured therapy focused on certain areas of particular relevance to pregnant women, such as role transitions, grief, and interpersonal disputes (Spinelli and Endicott 2003). Supportive and cognitive–behavioral psychotherapy have also been shown anecdotally to help with depression and anxiety during pregnancy. In addition, for women with a seasonal pattern to their psychiatric symptoms, light therapy can be a helpful and safe treatment during pregnancy (Epperson et al. 2004, Oren et al. 2002).

Clinical Vignette 1

Kathy is a 35-year-old attorney with a history of recurrent major depressive disorder. She is happily married and has been stable for 2 years on an antidepressant. She recently learned that she is 7 weeks pregnant and wants to know whether to discontinue her medication. Her psychiatrist reviews with her the available studies regarding her elevated risk of recurrence of depression if she stops the medication, given her past history of two major depressive episodes. In addition, her psychiatrist reviews with her the available data regarding the reproductive safety profile of different antidepressant treatment options. Kathy recalls how much her past depressive episodes cost her emotionally and professionally and is not willing to place her stability at risk by discontinuing her antidepressant. After a thorough risk–benefit discussion, she consents to continuing her selective serotonin reuptake inhibitor (SSRI) and also begins a course of interpersonal psychotherapy to address conflicts with her husband. As she enters her third trimester, she and her psychiatrist again review the risk of perinatal toxicity and pulmonary hypertension of the newborn associated with late trimester SSRI exposure. Kathy feels that the benefit she has gained from her antidepressant far outweighs the relatively slight risk of these adverse outcomes. Kathy also decides that it would be wise to withdraw medication prior to entering the postpartum period, a time of heightened risk for many women with recurrent depression. She and her psychiatrist therefore decide to maintain her current dose as she heads into the last part of pregnancy.

lead to maternal suffering, but also affect how mothers care for their infants. In a prospective study of 570 postpartum women and their 3-month-old infants, mother–infant dyads with depressed mothers had less vocal and visual communications (Righetti-Veltema et al. 2002). Other studies have shown that maternal depression was associated with impaired mother–infant attachment (Brockington et al. 2001, Moehler et al. 2006) and higher risk of child cognitive and behavioral problems (Brennan et al. 2000, Murray et al. 1996).

Studies examining the pathophysiologic basis of PPD have focused on the dramatic shifts in reproductive hormones during and after pregnancy, as well as the hypothalamic–pituitary–adrenal axis and changes in cortisol, thyroid hormone, prolactin, melatonin, oxytocin, and vasopressin (Hendrick et al. 1998, Kammerer et al. 2006, Parry et al. 2003). While there is no compelling evidence to support most hormonal changes in low-income or disadvantaged populations. The DSM-IV-TR classifies PPD as major depression that occurs within 4 weeks postpartum; however, many new mothers develop PPD more than 2 or 3 months after delivery. Clinical features include all the signs and symptoms of major depression. In addition, postpartum anxiety symptoms are extremely common and can include panic attacks, intense anxiety about not getting enough sleep, obsessive worry about the baby’s health or safety, and intrusive thoughts or mental images of hurting the baby (Brandes et al. 2004). New mothers with intrusive thoughts are often ashamed of these ego-dystonic images and may develop behaviors to diffuse some of their anxiety and fear, such as avoiding sharp objects or compulsively checking their infants’ breathing.

Postpartum psychosis (PPP) is a rare condition that occurs in 1–2 of every 1000 postpartum women. PPP can begin acutely within the first 48–72 hours postpartum and may include delirium, memory impairment, irritability, and mood lability. Psychosis can also occur in new mothers with a history of a chronic psychotic disorder or as part of a major depressive or manic episode. Psychotic symptoms in a new mother require immediate intervention in order to protect both mother and infant from harm.

Evaluation of Postpartum Women with Psychiatric Risk Factors or Symptoms

In assessing any woman with significant mood or anxiety symptoms after delivery, it is important to rule out possible organic causes of low mood, insomnia, and appetite disturbance, such as anemia and thyroid dysfunction. Clinicians should also inquire about the status of patients’ physical recovery from delivery, since prolonged pain following a complicated vaginal delivery or cesarean section can certainly contribute to sleep and mood symptoms. In screening for common Axis I diagnoses, such as major depression or anxiety disorders, clinicians should also screen for bipolar disorder, given the heightened risk of postpartum mood episodes in women with bipolar illness (Viguera et al. 2000). In addition, clinicians should ask new mothers about intrusive thoughts regarding their infants’ safety or violent images or thoughts about their infants (see Clinical Vignette 2). These intrusive thoughts are common in women with postpartum depression or anxiety, while acting them out is thankfully very rare (Brandes et al. 2004). Nonetheless, specifically asking distressed postpartum mothers about these thoughts and images is extremely important, since psychotic thinking can at times be subtle.

Systematic screening for risk factors as well as current symptoms facilitates prevention, detection, and treatment of postpartum psychiatric syndromes. The Edinburgh Postnatal Depression Scale (EPDS) is a widely recommended, cost-effective means of screening for PPD (Wisner et al. 2002). The EPDS is a 10-item self-rating scale that has been validated in Spanish and English and asks about depressive symptoms in the preceding week, including crying spells, decreased interest and pleasure, increased guilt, anxiety, sleeping problems, and thoughts of self-harm (Cox et al. 1987). To improve prevention interventions, clinicians could also screen for risk factors both during and after pregnancy. These risk factors include a personal history of mood or anxiety disorder, psychiatric symptoms during pregnancy,
limited social support, interpersonal conflicts, and negative life events during and after the pregnancy (O’Hara et al. 1991, Robertson et al. 2004, Stowe and Nemeroff 1995). In addition, a history of extreme premenstrual irritability may be a possible marker for increased vulnerability during times of hormonal fluctuation, such as the dramatic hormonal shifts after delivery (Stewart and Boydell 1993).

Treatment Considerations in Postpartum Women with Psychiatric Symptoms

Support and Psychotherapy
All women would benefit from education about the normalcy of certain psychiatric symptoms after delivery and review of the differences between the self-limited PPB and more serious conditions such as PPD. Referrals to mothers’ groups, childcare resources, or financial assistance agencies can also be extremely therapeutic. In the United Kingdom, postpartum support includes nurses with advanced training, who provide home visits to screen and assist postpartum mothers. Here in the United States, clinicians can refer women to Postpartum Support International (www.postpartum.net), an organization with many local chapters that offers support and resources for women with postpartum psychiatric illness. Other options for surrogate family assistance include the services of a doula, a professional caregiver who can assist not only with childbirth but also during the first postpartum weeks by helping with childcare or household tasks.

Studies of IPT suggest that this time-limited therapy is helpful in treating mild-to-moderate postpartum major depression (O’Hara et al. 2000, Reay et al. 2006). This form of therapy focuses on specific problem areas, such as role transitions or interpersonal disputes. Zlotnick et al. (2001) found that pregnant women receiving group IPT compared to regular care had decreased rates of PPD at 3 months postpartum. A small study comparing cognitive–behavioral therapy (CBT) and fluoxetine showed that CBT is also an effective treatment for PPD (Appleby et al. 1997).

Antidepressants
Despite the high prevalence of postpartum psychiatric illness, there are only a limited number of medication treatment studies. In small studies, fluoxetine (Appleby et al. 1997) and venlafaxine (Cohen et al. 2001) have shown efficacy in treating PPD, while sertraline has shown benefit in both preventing and treating PPD (Wisner et al. 2004, 2006). Women at increased risk for PPD should consider initiating prophylactic antidepressants either in late pregnancy or early postpartum. Alternatively, women may elect a wait-and-see approach; however, patients, their loved ones, and psychiatrists should be vigilant for early signs of recurrence in order to institute prompt treatment.

The choice of an antidepressant is largely guided by the patient’s depressive symptoms, past history of medication response, and medication side effects. If a patient plans to breastfeed, clinicians must facilitate a careful risk–benefit discussion about taking psychotropic medication during lactation (see below). To temper the tremendous changes in estrogen and progesterone following birth, some studies have looked at hormone therapy (HT). Several studies of estrogen alone or as an adjunct to antidepressants concluded that estrogen improved depressive symptoms; however, these studies were small and have limited generalizability.

Breastfeeding
All psychotropic medications are secreted into breast milk. Mothers on psychotropic medications therefore require a thorough risk–benefit discussion of breastfeeding and taking medication to treat psychiatric symptoms.

1. Antidepressants. A recent analysis of the available studies of antidepressants during lactation revealed that sertraline, paroxetine, and nortriptyline are the least likely to lead to accumulation in the infant (Weissman et al. 2004). Other studies of TCAs and SSRIs have been reassuring and shown no consistent association between any particular antidepressant and problems in nursing newborns. There have been isolated case reports of elevated infant levels and toxicity with breastfeeding mothers taking doxepin or fluoxetine. Little is known about the safety of other antidepressants during lactation, such as venlafaxine, bupropion, or mirtazapine.

2. Mood stabilizers. For women with bipolar illness, the choice to nurse while on a mood stabilizer is even less clear-cut than with antidepressants. Lithium can quickly accumulate in the nursing infant and lead to levels exceeding 50% of the maternal level. Given this risk of lithium toxicity in the nursing infant, breastfeeding while on lithium is generally not recommended. Although not absolutely contraindicated in nursing mothers, valproate has been associated with infant anemia and thrombocytopenia, and carbamazepine has been associated with transient hepatic dysfunction.

In general, clinicians should advise nursing women on psychotropic medications to monitor infants for behavioral changes, such as excessive sedation, jitteriness, or inconsolable crying. Infants who develop any of these symptoms should be evaluated by their pediatrician for possible drug toxicity. In the meantime, mothers can consider temporarily pumping and storing/discarding their breast milk and using formula to see if their infants’ symptoms resolve. In infants who are preterm or have any medical problems, mothers on psychotropic medication could also consider pumping and storing/discarding breast milk and introducing nursing later when the infant is healthy and can presumably metabolize medication more efficiently.

Menopause
Perimenopause refers to the 5–10-year transition from regular menstrual functioning to menopause. Hormonal changes during this period include significant fluctuations in estrogen and progesterone levels until menstrual cycles cease and reproductive hormones remain stably low. Most women naturally transition to menopause, while other women experience a more abrupt “chemical” or “surgical” menopause as a result of exogenous hormone treatment or following bilateral oophorectomy.

Some women experience significant mood symptoms during the menopausal transition. As with premenstrual syndrome and postpartum psychiatric symptoms,
Clinical Vignette 2

Mary is a 32-year-old married nurse with a history of panic attacks that have been well controlled for years. She presents 3 months postpartum, following a difficult pregnancy complicated by severe hyperemesis gravidarum and dysphoria and resulting in a traumatic delivery with a third-degree perineal tear. Mary now complains of crying spells, decreased appetite, insomnia, and obsessive worry over the baby’s health. She feels isolated from her husband, who is overwhelmed by her emotional needs and tends to retreat to work. Her psychiatrist completes a thorough diagnostic assessment and determines that Mary suffers from major depression and generalized anxiety disorder. When she is feeling particularly overwhelmed, she also has violent and intrusive thoughts of throwing her infant against a wall. These thoughts are ego dystonic and very distressing for Mary, who has no evidence of psychosis and no history of violence. She begins a course of cognitive-behavioral therapy to address her anxiety symptoms and negative thinking. She also enlists the support of a babysitter several mornings per week to allow her additional rest, which improves her perineal pain and gives her some much-needed time for herself. In addition, she begins a selective serotonin reuptake inhibitor, and within a few weeks, she starts to feel much more composed and connected to her baby.

Perimenopausal hormonal fluctuations may increase mood symptoms in a subset of at-risk women. Several studies have found that perimenopausal depressive symptoms are likely associated with reproductive hormonal changes rather than abnormally low levels of estrogen or androgens (Schmidt et al. 2002). Furthermore, several trials have shown that estradiol reduced depressive symptoms in perimenopausal women and that baseline or posttreatment estradiol levels did not predict therapeutic response (Schmidt et al. 2000, Soares et al. 2001). Other theories of perimenopausal depression have highlighted the “domino” effect of somatic symptoms associated with estrogen withdrawal, such as hot flashes, which in turn lead to sleep and mood disturbance. In addition, psychosocial factors have also been shown to increase risk for midlife depression in women, including negative life events, health complaints, and relationship difficulties (Schmidt et al. 2004). The confluence of other developmental midlife transitions, such as having adult children leave home or aging and dying parents, may also play a role in increasing risk for psychological distress; however, studies of this so-called empty nest phenomenon have been contradictory (Dennerstein et al. 2002, Greene and Cooke 1980, Schmidt et al. 2004). Although interpreting the available data regarding the link between perimenopause and depression is hampered by the lack of a standard definition for menopausal status in different studies, biological and psychosocial factors seem to play a role. This multifactorial etiology of perimenopausal depression was supported by two recent prospective studies, in which premenopausal women with no history of major depression were found to have increased risk of depression during the menopausal transition (Cohen et al. 2006b, Freeman et al. 2006). A previous depression history, vasomotor symptoms (e.g., hot flashes), negative life events, and variability in estradiol levels were also associated with increased risk for depression. These findings are consistent with the notion that biological as well as psychosocial factors increase risk for depression during the menopausal transition.

Approach to the Patient with Perimenopausal Mood Symptoms

Perimenopausal depression requires a biopsychosocial assessment and treatment approach (see Clinical Vignette 3). Psychiatric evaluation should include screening for major Axis I diagnoses and a history of psychiatric symptoms during other reproductive events. In addition, clinicians should take inventory of recent stressors, personal coping strengths and liabilities, and the extent of social supports. Screening for alcohol and substance abuse can also help identify possible reasons for worsening psychiatric symptoms. Medical evaluation should include assessment of reproductive endocrine status by taking a menstrual history and screening for perimenopausal vasomotor symptoms, such as hot flashes and vaginal dryness. Hormonal changes in menopause include a decrease in estrogen with subsequent elevations of luteinizing hormone and follicle-stimulating hormone. Clinicians should also rule out possible medical causes of mood symptoms that are common in midlife women, including thyroid and cardiac disease.

Treatment Considerations in Women with Perimenopausal Mood Symptoms

Studies have clearly shown that HT alleviates vasomotor symptoms, such as hot flashes (Warren 2004). Some studies have also found that estrogen may have antidepressant properties, possibly as a direct neuromodulatory effect as well as a result of the psychological relief depressed women experience as their vasomotor symptoms diminish (Schmidt et al. 2000, Soares et al. 2001). For perimenopausal women with significant vasomotor symptoms, short-term HT may alleviate mild mood symptoms along with insomnia, vaginal dryness, and hot flashes. Prior to recommending HT, however, clinicians should consider the Women’s Health Initiative study results, in which HT was associated with an increased risk of breast cancer, coronary heart disease, and thromboembolic events in postmenopausal women (Manson et al. 2003, Rossouw et al. 2002). It remains to be seen whether these risks are generalizable to younger perimenopausal women on HT and whether or not the benefits of short-term HT for depressed perimenopausal women outweigh the risks.

For perimenopausal women who present with major depression, clinicians should consider standard treatment including antidepressant medication and psychotherapy. There is some evidence that menopausal status may affect the efficacy of different classes of antidepressants (Kornstein et al. 2000, Pinto-Meza et al. 2006, Thase et al. 2005). For instance, in one study, premenopausal women with major depression were found to respond better to sertraline than imipramine, while postmenopausal women responded similarly (Kornstein et al. 2000). Some psychotropic medications such as the SSRIs (Gordon et al. 2006, Soares et al. 2006, Stearns et al. 2003), venlafaxine (Evans et al. 2005, Ladd et al. 2005), and gabapentin (Reddy et al. 2006) have also been shown to alleviate hot flashes, although none has an FDA indication for this use. Among the botanical and dietary supplements, St. John’s wort and black cohosh appear to be the most beneficial for mood and anxiety changes during...
menopause (Geller and Studee 2005). In addition, psychotherapy, both alone and in combination with medication, is also highly beneficial for women coping with the challenges associated with midlife.

Conclusion

Women have higher rates of major depression compared to men in every age group, with peak rates during the reproductive years. This observation has inspired a field of research examining psychiatric conditions associated with reproductive events, such as menses, pregnancy, and menopause. The transition to motherhood and, later, to menopause can be fraught with challenges as women adapt to shifting roles and other life changes. In addition, the hormonal changes after delivery and during the perimenopausal transition contribute to mood and anxiety problems in a subset of women who are prone to psychiatric symptoms during hormonal shifts. Recent studies questioning the reproductive safety of certain psychotropic medications as well as the thromboembolic and cancer risks associated with postmenopausal HT underscore the fact that reproductive psychiatry is a dynamic and evolving area of research. Whether treating perinatal or perimenopausal patients, clinicians therefore must adopt an individualized treatment approach that addresses biopsychosocial factors as well as incorporates an up-to-date discussion of the risks and benefits of medication and psychotherapy options.

Introduction
Death, including dying and bereavement are among life’s most difficult experiences. Yet mortality is clearly a natural part of life. Those who understand this are better able to cope with the pain of facing their own death as well as loss of loved ones. CS Lewis provides an eloquent description of death as a natural sequence in a relationship,

“For all pairs of lovers without exception, bereavement is a universal and integral part of our experience of love. It follows marriage as normally as marriage follows courtship or as autumn follows summer. It is not a truncation of the process but one of its phases; not the interruption of the dance, but the next figure. We are ‘taken out of ourselves’ by the loved one while she is here. Then comes the tragic figure of the dance in which we must learn to be still taken out of ourselves though the bodily presence is withdrawn, to love the very Her, and not fall back to loving our past, or our memory, or our sorrow, or our relief from sorrow, or our own love.” (Lewis 1961, p. 63.)

While Lewis is writing about loss of a spouse, his ideas are applicable to the loss of other loved ones. Yet not everyone arrives at this kind of philosophical acceptance, and those who do, including Lewis, are not spared a prior period of great disruption. As a result, dying patients and their bereaved loved ones often develop mental and/or physical symptoms. Psychiatrists may be called upon to assist in providing support, solace, and clinical interventions to dying patients and their caregivers, and to bereaved people following the death of a loved one. This chapter will provide a discussion of death, including its rates and causes, current thinking about management of terminally ill patients, an overview of the identification and management of suicide risk, and information about bereavement and grief that can inform psychiatric practice.

Death and Dying
“World Death Rate Holding Steady At 100 Percent” heads a satirical article in the internet journal The Onion that draws attention to the American cultural attitude of defiance of death, and the expectation that it is the job of the medical profession to avert death at all costs:

“World Health Organization officials expressed disappointment Monday at the group’s finding that, despite the enormous efforts of doctors, rescue workers and other medical professionals worldwide, the global death rate remains constant at 100 percent. Death, a metabolic affliction causing total shutdown of all life functions, has long been considered humanity’s number one health concern. Responsible for 100 percent of all recorded fatalities worldwide, the condition has no cure… Many are suggesting that the high mortality rate represents a massive failure on the part of the planet’s health care workers. The inability of doctors and scientists to adequately address this issue of death is nothing less than a scandal,” concerned parent Marcia Grello said.” Do you have any idea what a full-blown case of death looks like?…” (Jan. 22, 1997, Issue 13, no.2).

The Onion’s 100% lifetime death rate translated into 2,398,343 deaths in the United States during 2004, according to CDC statistics (Minino et al. 2006). This number represents an average age-adjusted rate of 801 per 100,000. Age-adjusted, death rates in 2004 for men were 955/100,000 and for women 680. The leading causes of death in the US were as follows: (1) Diseases of heart; (2) malignant neoplasms; (3) cerebrovascular diseases; (4) chronic lower respiratory diseases; (5) accidents (unintentional injuries); (6) diabetes mellitus; (7) Alzheimer’s disease; (8) influenza and pneumonia; (9) nephritis, nephrotic syndrome, and nephrosis; (10) septicemia; (11) intentional self-harm (suicide); (12) chronic liver disease and cirrhosis; (13) essential (primary) hypertension and hypertensive renal disease; (14) Parkinson’s disease; and (15) pneumonitis due to solids and liquids. Death rates for men and women, as well as infant death rates, are considerably higher for blacks than whites.

The attitude satirized in the Onion article is still extant among a substantial proportion of the population, and
especially physicians. Thankfully, there have been important efforts to change this. In spite of medical efforts, death remains an everyday occurrence, and many deaths occur under the care of a physician. For much of the 20th century, medicine was oriented primarily to preventing death whenever possible. To a great degree this effort was successful as the average life span has lengthened considerably. Now, there is now a focus on quality as well as quantity of life, and assistance with dying, provided by hospice and/or palliative care, is a valued activity. The hospice and palliative care movement have a strong foothold and are growing in the United States and elsewhere. Still, a recent survey of hospices in Australia indicates that few function in an optimal manner (Carlson et al. 2007). Moreover, a humane approach to death remains primarily the province of specialty care and has not yet been well infused into the everyday practice of medicine.

Bedell, Cadenhead, and Graboy (Bedell et al. 2001) called attention to the need for physicians to support family members of their deceased patients as their final responsibility to the patient. The authors suggested writing a personal letter of condolence, acknowledging barriers to doing so. They recognize that physicians are very busy and sometimes haven’t seen the patient for a while. The physician may hesitate because of not knowing the patient very well, because of feeling a sense of personal failure regarding the death, or simply not knowing what to say. Nevertheless, these authors emphasize the importance of reaching out to the family. They outline a possible approach to such a letter and emphasize how helpful such an approach can be for bereaved family members. It is unclear how widespread this practice has become. Moreover, before death, many physicians are uneasy about maintaining a relationship with a dying patient for whom they have no further healing treatments.

Continuing to provide care to a terminally ill patient is clearly important, even when there are no further curative possibilities. Yet for many physicians, interest in the patient dwindles in parallel with dwindling treatment options. At best, such physicians may refer their patient to a palliative care service. This medical subspecialty is strong and growing. Psychiatrists may be involved in the terminal care of patients, either through their own practice or through work in palliative care. Investigators have begun to document the clinical issues involved in treating terminally ill patients. Reports in the psychiatric literature pertain primarily to the elderly. In fact, due to the tremendous advances in medicine over the last century, 80% of deaths now occur among the elderly. A recent paper outlines the issues relevant to end-of-life care in the elderly (Lyness 2004). The issues raised by this author also have relevance to those relevant for younger people (Table 120–1).

**Work with Terminally Ill Patients**

A major goal in effective end-of-life care is to bring treatment as closely as possible into alignment with the wishes of patients and their families. Studies to date show that this goal is often not achieved (Butow et al. 2004). Lyness suggests that sensitive discussions about end-of-life care should begin early in the course of a chronic illness, when the clinician can explore lifelong values, including those related to culture and religion, the patient’s relationship with her/his family, and her views about life-threatening illness and medical treatment. The physician communicates a commitment to assisting the patient to die with dignity, an attitude of respect for the patient’s wishes, and assurance that she will not abandon the patient if and when treatment is no longer effective.

The clinician’s tasks change as a terminal disease progresses. At times, there may be bad news to deliver. This should be done with sensitivity to the patient’s readiness to hear the news and openness to engage in a discussion about the information. During this and other times, the clinician needs to monitor the patient’s symptoms, including pain, anxiety, and depression, as well as changing functional capacities and the status of important relationships. Many dying patients experience cognitive impairments and these must be accurately assessed. Over time, the patient and family will be confronted with choices regarding care options, and they will need to make decisions about these. Clinicians need to provide accurate information about prognosis and treatment options, handle unrealistic hopes and wishes in a sensitive, empathic, and supportive manner and assist in guiding the decision-making process.

The goal of pain management for a dying patient is to eliminate pain, unless the patient states that she/he does not want this. Studies have documented that it is usually possible to achieve this goal without intolerable analgesic side effects. Pain management uses a stepped approach, changing the potency of medication as the pain intensifies. It is important to assess pain, like emotional symptoms, in an ongoing manner and by direct questioning of the patient. Lyness summarizes an approach to pain management in palliative care, beginning with acetaminophen, nonsteroidal anti-inflammatory drugs for mild pain, and progressing to opioids as the treatment of choice for severe pain. Adjunctive doses can be successfully used for breakthrough pain in patients on opioid analgesia. A range of further management strategies have been developed and reviewed in an ongoing series of publications in the Cochrane Library and summarized in the Journal of Pain & Palliative Care Pharmacotherapy. For example, sub-anesthetic doses of...
Ketamine (Wiffen 2006a, 2006b, 2006c) can reduce analgesia requirements and decrease nausea and vomiting. New approaches target different types of pain such as corticosteroids, biphosphonate, or calcitonin (Chang et al. 2006) to augment opioids for bone pain, or antidepressants or anticonvulsants to augment opioids for neuropathic pain. A number of nonpharmacological approaches to pain management have also been developed and tested. Among these are acupuncture, herbal remedies, and music, all of which have been found to have some beneficial effects as adjunctive treatments in pain management.

Psychiatric symptoms common among dying patients include depression, anxiety, and cognitive impairment. Suicidal ideation is also seen and needs to be carefully evaluated. Although research is scanty in this population, information that exists suggests that major depression occurs, that it responds to standard antidepressant medication and that, untreated depression worsens medical prognosis. Diagnosing depression can be tricky as many symptoms of depression overlap with those of the underlying medical condition. Many researchers use an inclusive approach to diagnosis. However, this can lead to over-diagnosis and is not universally accepted. An alternative approach is symptom management. For example, psychostimulants can be helpful in increasing well-being and reducing anergia, even in the absence of full-blown major depression (Lyness 2004).

A range of anxiety disorders may be seen in dying patients, including generalized anxiety disorder, focused on worries about the future, about the well-being of family members, about disability or loss of resources or a myriad of other daily life difficulties for ill patients. Anxiety may be focused on aspects of the terminal illness including illness progression, pain management, and/or death. PTSD may occur as a reaction to a life-threatening diagnosis and/or painful or frightening medical procedures. Panic attacks may occur and may be more common among patients with respiratory distress. Treatment of anxiety may be achieved with benzodiazepines, though these should be used cautiously in terminal patients as vulnerability to cognitive impairment is increased. Low-dose antipsychotic medication, especially an atypical antipsychotic, can be very helpful in controlling anxiety, including rumination and agitation. Opioid treatment of respiratory distress and pain can be helpful in reducing anxiety related to these problems. Supportive and/or cognitive-behavioral psychotherapy can be useful for patients who are alert and able to participate in such a treatment.

Delirium is very common among dying patients. This occurs most commonly as a consequence of progression of the underlying illness, or as a side effect of medication treatment of pain. While reducing medication that is causing a delirium may be useful, this must be balanced against potential loss of pain control. Management of delirium can usually be accomplished with the use of antipsychotic medication, and this may be preferable to treating the underlying problem in a terminally ill patient with anxiety, agitation, and delirium. Stimulus control may also be of some use. Work with family members is often necessary in the management of delirium, as this can be an especially difficult problem for caregivers.

Psychotherapy has a role in the management of terminally ill patients. A supportive therapist can be especially helpful if there is time to develop a strong alliance, and if the therapist has known the patients prior to the onset of the later stages of terminal illness. In such a situation, the therapist can assist the patient in problem solving, goal setting, and interpersonal interactions. Therapists working with terminally ill patients need to include work with the family in order to optimize the supportive resources of the family, assist the family in coping with the illness and impending death of a loved one, and to address interpersonal toxicity, if it occurs. Intervention with distressed family members can be helpful in reducing caregiver burden and may play a role in decreasing the likelihood of bereavement-related problems such as depression or complicated grief. Work with parents of terminally ill children may be especially important as loss of a child is clearly the most difficult stressor a parent can endure. Recent studies by Meert and colleagues have documented the importance of availability and attentiveness of hospital staff to parental needs for information and honest, complete communication (Meert et al. 2005, 2007, Sharman et al. 2005). Physicians may need help in learning to communicate with parents of terminally ill children in a sensitive, respectful, caring, and empathic manner, while not withholding information. Another study documents that parents often want the opportunity to have a conference with the physician after a child dies, and that this occurred in only 13% of deaths in a pediatric ICU. A French group (Lautrette et al. 2007) provided a brochure and a conference to family members of patients dying in ICUs and found evidence that this lowered bereavement-related PTSD and depression.

In summary, physician communication is very important for dying patients and their family members. Psychiatric involvement may facilitate this process. Psychiatrists have a role in providing assessment, pharmacotherapy, and psychotherapy. Effective intervention, including acceptance of death as a normal part of life, honest, empathic, and sensitive communication about terminal illness and its prognosis, is an important part of effective palliative care. However, not everyone dies in a palliative care setting. Among those who do not are people who have taken their own lives.

Suicide

The American Foundation for Suicide Prevention provides useful information for suicidal individuals, their family members, physicians, and the media. Suicide is frightening and stigmatized, and only recently have we begun to learn about its underlying causes. Treatment studies of suicidal patients are still sparse. Suicide is a surprisingly common cause of death. Among the overall population in the United States, it ranks 11th while among people between the ages of 18 and 65, suicide is the 4th leading cause of death. Rates are estimated as 10–20 per 100,000. An estimated 32,439 people die by suicide each year in the US and 1,000,000 worldwide. Elderly white males have the highest rate of suicide. Suicide is one of the top three worldwide causes of death among 15-44-year-olds. Women are twice as likely as men to attempt suicide, while men are four times more likely to die from suicide. In 2004, suicide was the 3rd leading cause of death among 15–24-year-olds in the US. While suicide rates among this age group doubled from the 1950s to 1970s, there was a steady decrease since 1990. On the other hand, suicide in younger children increased over this time period. Unfortunately, in recent years, the adolescent suicide rate has again begun to climb.
Psychiatric illness is a critical risk factor for suicide. It is estimated that 90% or more of patients who die by suicide have a diagnosable psychiatric condition. Two-thirds of those who complete suicide have a major depression. Looked at from the other side, an estimated 20–30% of people diagnosed with bipolar disorder die by suicide and up to 50% may make a suicide attempt at some point in the illness. Substance abuse is common among people with bipolar disorder and increases the risk of suicide. Substance abuse alone is also a risk factor. Schizophrenia is a risk factor for suicide with an estimated 40% of people with this diagnosis making a suicide attempt. Approximately 10% of people with schizophrenia die by suicide. Other psychiatric disorders associated with increased risk of suicide include PTSD, panic disorder, social anxiety disorder, generalized anxiety disorder, eating disorders, and personality disorders. In the context of an ongoing psychiatric disorder, often untreated, a suicide attempt is triggered by a specific event such as an important interpersonal loss and/or a marked increase in dysphoric affect. Risk factors for suicide include family history and past history of suicide attempts and impulsivity. Dramatic reporting of high-profile suicides by the media has been found to be associated with increased rates of suicidal behavior among viewers or readers of such reports. Among psychiatric patients, a clear relationship has now been demonstrated between suicide attempts and low CSF serotonin levels. However, it is not clear that serotonin active medication is differentially effective in treating suicidality.

There have been relatively few studies of prevention of suicide or treatment of suicide attempts. It makes sense that treatment of individuals with psychiatric problems comprising high risk for suicidal behavior would be an approach to prevention. However, studies targeting suicide as an outcome have been difficult to undertake, in part because of the very low base rate of completed suicides even among ill populations. Additionally, there has been no uniform, reliable manner of assessing different kinds of suicidal behaviors. Researchers and research ethics committees have faced dilemmas in how to recruit and randomize to experimental treatments of individuals at risk for suicide. Nevertheless, studies are beginning to appear. The most impressive one to date is a study of a 10-session cognitive therapy targeting repeat suicide attempts among a group of people who presented to an emergency room following an attempt (Brown et al. 2005). This group of individuals is estimated to have a 30–40 fold increase in likelihood of future attempts compared to individuals who have never attempted suicide. The approach used targeted thoughts, images, and beliefs that occurred just prior to the suicide attempt as well as assistance in coping with stressors. Additionally, the treatment addressed hopelessness, problems solving difficulties, impulse control, social isolation, and adherence. A relapse prevention task conducted in one of the later treatment sessions activated the specific thoughts, images, and feelings associated with prior suicide attempts in order to test the patient’s ability to respond to these effectively. Completion of treatment was based on successful completion of this task and additional sessions were provided until this was accomplished. The result of this intervention was a statistically significant 50% reduction in suicide attempts over the ensuing 18 months. This is clearly a very promising approach for suicidal individuals.

There has been considerable recent controversy regarding the relationship between the use of antidepressant medication and suicide attempts. An FDA meta-analysis of pharmaceutical company studies of serotonin active medications in children suggested that there may be an increased rate of suicide among individuals treated with these drugs. These results led the FDA in 2004 to institute it’s most severe “black box” warning related to suicide risk for the use of these medications in children. In 2007 this warning was extended to young adults. However, this ruling has been challenged by experienced investigators. Several major problems with the data sets include the fact that suicidal patients were excluded from studies of the medications in question, so information relates only to people without evidence of serious suicidality at baseline (Posner et al. 2007). Additionally, erratic reporting of suicidal behavior, led in some cases to overestimation of risk. Two large naturalistic studies are in press, one evaluating claims data (Simon and Savarino 2007) and another targeting veterans (Gibbons et al. 2007), each showed more suicide attempts prior to instituting SSRI antidepressants. In an editorial discussing this work, Brent (2007) draws attention to the fact that adolescent suicide rates, on the decline during the past decade, began an alarming rise coincident with publicity related to a possible relationship between antidepressant medication and suicide. Taken together, the emerging information suggests that suicide is more likely when serotonin active medications are withheld than when these medications are provided. Additionally, it is very clear that careful clinical monitoring of suicidal individuals is essential to appropriate clinical management. The use of proven efficacious psychotherapy techniques is highly desirable and clinicians treating suicidal patients should learn to provide this intervention.

Among the problems faced by clinicians working with suicidal patients is the management of bereavement among loved ones if the patient completes suicide. Bereavement is widely recognized as one of the most severe of life stresses, and the ensuing period of grief, variable in intensity and duration, comprises a state of distress and impairment that is equal to some of the most debilitating states of anxiety and/or depression. As pointed out by multiple authors, it is only because of the known cause and the universality of the response that we do not consider grief a pathological condition. We now know that a subgroup of people do develop a pathological form of grief, currently labeled complicated grief. This condition arises when grief is complicated by thoughts, images, beliefs, and behaviors, difficulty with emotion regulation, and/or toxic or deficient social supports that impede integration of the experience of the loss. Circumstances of the death can sometimes trigger these complications. Suicide bereavement is widely believed to be one of the most difficult to cope with because of the stigma surrounding suicide and the tendency for caregivers to blame themselves for not preventing the death. A sensitive, available clinician can be helpful in mitigating these painful aspects of suicide bereavement.

**Bereavement and Grief**

“Loss of a loved person is one of the most intensely painful experiences any human being can suffer. And not only is it painful to experience but
it is also painful to witness, if only because we are so impotent to help. To the bereaved nothing but the return of the lost person can bring true comfort; should we provide fall short of that it is felt almost as an insult.” Bowlby (1980, pp. 7–8)

Bowlby’s comments draw attention to the intensely stressful nature of bereavement, as well as the difficulty in trying to help bereaved people. Because it is a confrontation with death, and because loss of an attachment figure dramatically affects one’s sense of safety, it is appropriate to consider bereavement as a trauma (Shear and Shair 2005, Shear et al. 2007). However, unlike other traumatic life events, death of a loved one is an expected and universal occurrence. Among the population bereavement is frequent. Given the yearly US death rate of about 2.4 million people, and using an estimated average of four bereaved people for each death, almost 10 million people lose a close friend or relative in the United States each year. As with other traumatic events, the great majority of people weather the storm of such a death. Some even find themselves stronger, having a greater sense of purpose, renewed faith, or a sense of new meaning of life. While bereavement is considered a risk for a myriad of health problems, in fact only a minority develop such problems. For this clinically important sub-group, bereavement leads to long-lasting negative outcomes. Clinicians may see bereaved individuals who continue to suffer for many years following the death of a loved one. In order to treat such people, it is important to understand the mechanisms by which problematic consequences follow bereavement, and to know as much as possible about what is happening when things go well.

A natural biobehavioral grief process, influenced by cultural input, mediates adjustment to loss of an attachment figure. Rather than an effortful, deliberate psychological process (“grief work”) with a goal of detachment from the deceased, it now appears that grief is a more automatic process that is enduring yet fluid, and works to facilitate adjustment. The psychiatric literature pertaining to bereavement and grief sometimes uses terms interchangeably. However, to improve communication and precision of thinking, bereavement researchers have suggested that we define bereavement as “the objective condition of having lost someone significant” and mourning as “the actions and manner of expressing grief, which often reflect the mourning practices of one’s culture” (Stroebe et al. 2001, p. 5). Grief is the reaction to bereavement. Different designations have also been used to refer to the clinical syndrome that occurs when the progress of grief is blocked. Currently, the most commonly used designation is complicated grief. From descriptions in the literature, it is clear that this is the same condition as pathological, unresolved, delayed, chronic, or traumatic grief. Since the loss of an attachment figure is the most devastating type of bereavement, we include a brief summary of current thinking about the nature of these relationships.

John Bowlby (1980) introduced the idea that attachment has a biological basis and is important throughout the life span. Subsequently, investigators have demonstrated that an attachment relationship can be identified as a person (1) who is a target of proximity seeking, (2) from whom separation is resisted, (3) to whom a partner turns to for “safe haven” when under stress, and (4) serves as a secure base from which the partner freely interacts in the world, seeking novelty, taking risks, and exploring the unknown (Hazan et al. 1999, Feeney 2004).

Mental representations of attachment relationships enable older children and adults maintain a sense of attachment in the absence of physical proximity to a loved one. Also called “working models,” such mental representations derive from repeated salient experiences with the attachment figure. Information provided by a working model is continuously matched with information derived from experiences pertaining to the relationship it represents. However, once established, the working model does not easily change its configuration (Bretherton 1999). Only in the context of a consistent mismatch, is the working model revised. Given this view of working models, it is clear that these mental representations need to undergo profound change when an attachment figure dies, and also that this change will not occur quickly. This means that bereavement is associated with a temporary impairment in functioning of the attachment system.

Numerous studies have shown that internalized cognitive representations of attachment relationships are activated upon exposure to stress (e.g., Mikulincer et al. 2002, 2003, Pereg and Mikulincer 2004) and that the security of such relationships influence the perception of available social support (Collins and Feeney 2000). Attachment security influences cognition, emotion, and behavior, especially with respect to interpersonal functioning, and may affect other psychological and physiological functions. Individuals with stable secure attachments have been repeatedly shown to be psychologically healthy and resilient. Those with anxious and fearful attachment often have difficulty with affect regulation (Mikulincer et al. 2003) and so experience heightened levels of negative emotions, including sadness, anger, shame, and anxiety as well as lower positive emotions. These people tend to experience low self-esteem and low confidence in the esteem of others, often enter into dependent relationships, and are especially vulnerable to stress.

Attachment security also contributes to motivation for interactions in the world. Thus, the attachment system modulates the activity of the exploratory system (Elliott 2003). The latter, in turn motivates active interest in the environment, needed for learning and overall effective functioning in the world. A physically accessible and emotionally responsive caregiver who provides a sense of security facilitates exploration and learning and minimizes fear. In other words, the biobehavioral systems for attachment, fear, and exploration are linked. Considering that the death of a loved one disrupts attachment functioning, there is associated inhibition of the exploratory system as well as impaired regulation of fear and other emotions.

An important aspect of adult attachment relationships is that caregiving is as important as receiving care (Feeney and Collins 2001, 2003). Among those who lose a loved one, and a child in particular, effects on the caregiving system are likely to be dominant. A very typical though often neglected aspect of grief is the occurrence of self-blame, related to the caregiving function. In summary, the experience of acute grief is characterized by aspects of a trauma relationship, impairment in attachment functioning, inhibition of exploratory functioning, impaired emotion regulation, and a tendency for caregiver self-blame. It is useful to
think of acute grief as having these components. Over time, as the loss integrated, the grief response is also integrated. The trauma is resolved, attachment functioning is re-established, interactions with the world resume, along with effective emotion regulation and resolution of self-blame.

Ideas about grief were outlined by Freud and/or Bowlby. According to Freud and his followers effective adjustment to bereavement requires a period of “grief work” While not explicitly defined, and sometimes misconstrued to mean intense emotional pain, the grief work idea has some merit. The idea is that through a process of “reality testing” in which there is repeated confrontation with unpleasant reminders of the loss, the bereaved person eventually accepts the reality of the loss, and feelings of intense sadness and yearning subside. Unless this is accomplished, the bereaved person remains shackled through an ongoing, unrevised attachment to the deceased. Continued longing and searching for the deceased restricts the freedom of a bereaved person, especially the ability to deeply engage with the living. These people remain preoccupied with thoughts of the deceased loved one, and continually laden with pain and suffering caused by their loss.

Most of these ideas hold true, although often a strong sense of connection to the deceased person remains, even after the loss has been integrated and acute grief subsides. Additionally, there is a new model, supported by some empirical data, that posits coping with bereavement entails coping with a number of different kinds of stressors that can be broadly grouped as restoration-related or loss-related (Stroebe and Schut 1999). Another difference is that the traditional model considers pathological grief to be the consequence of an ambivalent relationship. However, complicated grief appears to occur instead when someone has lost a very special and very positive relationship. Table 120–2 lists some common ideas about grief, and the empirical findings related to these.

Bereavement is widely understood to be a severe stressor. In fact, as Stroebe and Schut (1999) point out, loss of a loved one is not one stressor, but rather a number of simultaneous stressors. Our close friends and family members touch many areas of our lives. When we lose them, our lives are profoundly changed and we must adjust to the changes. Some aspects of bereavement are related to the loss. Loved ones provide us with a sense of purpose. We do things to make them feel proud, to bring them happiness, to keep them close and to help them feel safe. A close relationship is an important source of pleasure and solace. We may attain social status, financial security, and/or self esteem from our relationships with people we love. These are the people who bolster our confidence, help us feel important and proud of ourselves. Our loved ones provide a sense of balance and completeness. They comfort us and humør us when we are feeling vulnerable or hurt. Bereavement entails loss-related stressors such as these. In addition to psychological support, people we live with may regulate our neuroendocrine system, influence our sleep and social rhythms, and provide myriad of small cues that can trigger conditioned emotional responses. Places and things may have special meaning because of associations with a loved one. Activities may be satisfying because they are shared.

Other aspects of adjustment to an important loss are related to how we organize our lives without the person who died. These restoration-related stressors entail taking care of things related to the death, such as disposition of the body and arranging the funeral or memorial service, as well as disposing of personal possessions, managing financial matters and taking on household tasks that were previously done by the deceased person. Social life is reorganized; it may be necessary for someone who was staying at home to become employed. There may be children or other dependents that need to be looked after. Different kinds of plans may need to be changed. Thus, bereavement is not one, but sometimes a virtual encyclopedia of severe stressors.

The stress of bereavement clearly requires active coping. Some information is available about which coping methods are adaptive which are not. Folkman outlines models of coping that she and her colleagues have developed. First, they define coping as “the changing thoughts and acts that an individual uses to manage the external or internal demands of stressful situations.” They remind readers that coping and mastery are not the same things. Additionally, coping occurs in an environmental context, that it is a continually unfolding process that may change over time following the stressor. Coping with a specific stressor is usually multidimensional with some problem-focused and some emotion-focused strategies, some approach and some avoidance, and some interpersonal and some intrapersonal.

Bonanno (in Stroebe et al. 2001) employs a social-functional model in considering the emotional response to bereavement. This empirically based model posits an association between negative affect, disrupted social relationships, and later physical and mental health problems across a range of situations. Thus, in contradistinction to traditional ideas about “grief work,” a social-functional perspective predicts that internal psychological functioning and adaptive social functioning are impeded by painful negative emotions and enhanced by positive emotions. Studies of bereavement of AIDS caregivers also support the importance of positive mood states in adjustment to

bereavement (Moskowitz et al. 2003). With the exception of a few weeks immediately after the death, positive mood states were as prevalent among AIDS caregivers as negative ones during both caregiving and bereavement. Active problem solving and positive reappraisal were important in maintaining positive mood states, and these, in turn helped foster more adaptive coping. This work supports the idea that good grief outcome is as strongly related to the presence of positive mood as to the absence of negative feelings.

Wortman and Silver (1989) wrote a seminal paper challenging traditional concepts of grief, which they described as myths. They concluded that it was not proven that grief work was essential to enable the bereaved to come to terms with their loss. They identified two patterns of normal grieving, one in which a bereaved person moves from high to low emotional distress over time and the other in which people never experience high distress. A third grief trajectory is that of persistent high distress, continuing for years. This is the pattern of complicated grief.

Follow-up studies have continued to find little evidence that low levels of negative emotions and/or absence of a period of preoccupation with the deceased leads to poor adjustment. There is no evidence that early grief intensity is inversely correlated with later pain. Instead, the opposite seems to be true. Stroebe et al. (2002) examined the relationship between self-reported disclosure and emotional distress at 4, 11, 18, and 25 months after the death of a spouse and found that greater distress predicted more disclosure, rather than disclosure predicting lower subsequent grief. In a second study (Stroebe et al. 2005), they compared grief outcome in bereaved widows randomized to keeping a diary about emotions and/or bereavement-related problems to a control group who kept no diary. Intrusion and avoidance symptoms, as well as depression, anxiety, and somatic symptoms, present at baseline decreased over time (1 week and 6 months) in all groups. Frequency of disclosure of emotions, or reported need for disclosure did not moderate these results. These authors conclude that intervention is not needed for bereaved people who do not seek help.

Researchers have also reconsidered the idea of detachment from the deceased. Freud rethought his ideas about bereavement following the death of his daughter, expressing a newer view in a letter to a friend, “Although we know that after such a loss the acute stage of mourning will subside, we also know we shall remain inconsolable and will never find a substitute. No matter what may fill the gap, even if it be filled completely, it nevertheless remains something else. Actually, this is how it should be. It is the only way of perpetuating that love which we do not wish to relinquish (1961a, p. 239) (pp. 207–208). In line with this idea, investigators (Richards et al. 1999) studied bereaved male partners of men dying from AIDS more than 3 years after the death and found 70% reported a continuing relationship with the deceased. This sense of inner relationship with the deceased partner did not correlate with distress.

Field and colleagues reported a series of studies of continuing bonds (Field et al. 2003, 2005, Field and Friedrichs 2004, Field 2006a, 2006b). Results suggested that some types of continued connection with the deceased were associated with more prolonged grief. However, grief was not more intense when the connection was related to thoughts about how a deceased spouse made a difference in the life of the bereaved person, or gaining enjoyment from reminiscences about the deceased. These researchers highlight the distinction between behavioral manifestations of continuing bonds, as compared to an internal state of felt-connectedness. The internalized representation seems to allow the deceased to play a sustaining role in the emotional life of the bereaved person that is not inconsistent with the reality of their death. Once integrated in this way, thoughts and memories of the deceased continue to grow and change (Neimeyer et al. 2002).

Sociocultural factors often play a role in grief and mourning. Perhaps more than most stressors, bereavement is a public event that occurs in a larger social context. Most cultures provide rules for the disposition of a deceased body, and some supply procedures for disposing of the belongings of the deceased. Cultures frequently contain beliefs about the proper public expression of emotions and private thoughts, and about the need to confront or avoid emotionally provocative situations. Religion has an obvious place in the process of coping. Death rituals and customs are universal components of religious rites. One way cultural/religious practices exert their influence is through directives regarding the expression of emotion after a loss. Formal ceremonies often encourage the bereaved to confront and release emotions. However, the value placed on emotional expression varies in different cultures. For example, in some cultures, emotional expression is thought to be a threat, interfering with good judgment, and affecting others, as well as oneself. In others, open display of emotions is thought to be needed in order to cleanse the soul. In some cultures ancestors, who have the power to do harm to the bereaved, are thought to be offended by excessive show of emotion. In some cultures there is a focus on working through grief in order to distance oneself from a deceased loved one, while in others the emphasis is on maintaining a relationship with the dead ancestor who is treated as a living person, being offered food and other things, and seen as remaining present in the life of the bereaved (Yamamoto 1969).

Religious beliefs help mourners envision a transition of their loved one to a final resting place. This provides an important form of continuity with the person who died. Being able to imaginably locate a deceased person seems to be helpful in the process of coping with the death, especially if this contains an idea that the spirit is at peace. Religious rituals also focus on marking a separation of the dead. In some cultures, a change in residence is prescribed, along with removing all physical reminders of the dead and avoiding mention of the name of the deceased. Some native American tribes have a 4-day accepted length of mourning after which person is expected to return to normal life and neither speak of the deceased nor discuss personal feelings about the loss. These practices are associated with a belief that too much emotion is offensive to the deceased. Interestingly, and in line with findings from naturalistic studies summarized above, it has been reported that members of cultures with such final ceremonies appeared less likely to experience chronic grief. Many religious practices dictate a prescribed period of mourning. For Jews, after a year of mourning there is an unveiling ceremony at the grave site. Clothes that were rent at the time of the death are mended and worn as a sign that life, though scarred, must go on.
In summary, the usual trajectory of grief following loss of someone very close (see Figure 120–1) is for the bereaved person to experience acute grief lasting weeks to months and characterized by symptoms related to (1) trauma (e.g., disbelief, intrusive thoughts and memories, a tendency to avoidance); (2) an activated malfunctioning attachment system (e.g., longing, yearning, searching for the deceased, sense of insecurity or self-doubt, intense sadness); (3) emotional and physiological dysregulation; (4) thoughts and feelings of self-blame; and (5) inhibition of interest and engagement with ongoing life. In the context of cultural rituals and social support, acute grief usually subsides, transitioning to a state of integrated grief. When loss and grief have been integrated, memories and thoughts are no longer preoccupying. Longing, yearning, and searching lessen. Emotional and physiological regulation is reestablished. Feelings of security and self-confidence are restored, and there is renewed interest and engagement in ongoing life. Metaphorically speaking the deceased loved one has moved from preoccupying the mind of the bereaved person to residing comfortably in her heart. Sometimes, this progression does not occur smoothly and bereavement triggers the onset of a psychiatric disorder, most commonly major depression or PTSD. In addition, for an estimated 10–20% of bereaved people (roughly 1 million people per year) the loss is not integrated and the debilitating chronic condition of complicated grief supervenes.

Bereavement-Related Depression and Anxiety

Grief resembles depression in the prominence of sadness, loss of interest in ongoing life, and the frequent occurrence of sleep and appetite disturbance and a sense of remorse or guilt. However, grief can also be distinguished from depression. A careful longitudinal survey of spousally bereaved individuals documented an occurrence of major depression of 10–15% over the year following bereavement (Zisook et al. 1994). Rates are higher transiently in the early bereavement period but even then, only 30% met criteria for MDD. A recent study shows that depression in the first 2 months of bereavement can be treated with antidepressant medication (Zisook et al. 2001). Although the DSM currently includes an exclusion for major depression in the first 2 months of bereavement, there is good evidence that bereavement-related depression is not different from depression following any other kind of life stressor and should be diagnosed and treated (Zisook and Kendler 2007, Zisook et al. 2007).

PTSD criteria in DSM-IV-TR include the death of a loved one only if this occurs suddenly and unexpectedly. However, again, studies have documented that PTSD does occur in the wake of bereavement from other causes (Zisook et al. 1998). In fact, in at least one community sample, bereavement was the most common trigger of PTSD (Bre-slau et al. 1998). As discussed above, loss of an attachment figure is a trauma and typically triggers a response similar to other traumas, that includes a sense of disbelief and a mixture of intrusions, alternating with avoidance. However, grief also differs from other trauma responses in that the prominent emotion is sadness and there is intense yearning and longing not usually seen following a trauma. Individuals with bereavement-related PTSD are sometimes included in treatment studies, and, similar to MDD, do not seem to comprise a clinically meaningful subtype. On the other hand, the trauma-like reaction of complicated grief does differ from PTSD.

Complicated Grief

Clinicians have long recognized the problem of prolonged intense grief reactions. These have been labeled in various ways, including pathological, unresolved, chronic, delayed, traumatic, or complicated grief. In recent years, researchers have devised reliable ways to assess a syndrome, currently designated as complicated grief, that is believed to be the same condition as these variously named syndromes. The hallmark of complicated grief is persistence of the symptoms of acute grief well beyond the time they would be expected to subside. Grief is prolonged by complicating biological, psychological, and/or social-environmental problems. People with this condition continue to have difficulty comprehending the death, and experience acute grief as though their loved one had died very recently. Additionally, they exhibit negative cognitions related to grief intensity (e.g., fear, embarrassment, or shame regarding their own emotions) and/or catastrophic misinterpretation of the consequences of separation (e.g., ideas that they cannot survive or function without the person who died; thoughts of betrayal or guilt regarding the death) and disruptive behaviors (e.g., impairing avoidance and/or compulsive proximity seeking), ineffective emotion regulation and/or social-environmental toxicity or resource depletion (see Figure 120–2).

Complicated grief is a chronic debilitating syndrome that has been found to be associated with suicidal ideation, serious work and social impairment, long-term health problems (e.g., cardiovascular and neoplastic illness) (Prigerson et al. 1997) and substance abuse. The condition is not currently identified in the DSM-IV-TR but it has been recognized by the psychiatric editor of JAMA as having the features of an illness (Glass 2005). Work is underway to present this condition for inclusion in the DSM V. Complicated grief does not respond to standard treatments for depression (Reynolds et al. 1999). A recently completed study of a targeted treatment resulted in better response than a standard grief-focused psychotherapy (Reynolds et al. 1999). Open trials show some response to antidepressant medication; however, randomized controlled trials have not been done.
In summary, psychiatrists encounter death and bereavement in many aspects of their work. Psychiatrists can be helpful in the assessment and treatment of dying patients and their caregivers. Psychiatrists play a central role in the management of suicidality. There are an estimated 10 million bereaved people every year in the United States, and approximately 10–20% of these people will suffer from bereavement-related psychiatric illness. It is important that psychiatrists understand how to diagnose and treat people suffering from mood and anxiety disorders and complicated grief that occur in the wake of bereavement.

A broad shift in the American economy away from a manufacturing base, combined with related housing shortfalls, ushered into the 1980s a social epidemic of homelessness that continues today (Koegel et al. 1988, U.S. Conference of Mayors 2006). It swept mentally ill persons into particular vulnerability and public attention. This chapter reviews the historical evolution of services for people with mental illness and homelessness and describes a resultant model of care, accentuating psychiatry’s role.

**Background: The Evolution of Services**

The plight of people with mental illness and homelessness prompted an evolution of specialized services that is understandable in terms of four phases that are demarcated by gradual developments at federal, state, and local levels.

**Phase One: Ad Hoc Service Delivery and Early Epidemiology (1978–1986)**

In November 1978, the advocacy group Community for Creative Nonviolence occupied the National Visitor’s Center in Washington, DC, USA. This protest was a touchstone moment, bringing into focus a “new” national crisis of homelessness and creating a context for events that quickly unfolded across the country. Although there were already scattered reports of a new generation of mentally ill “street people,” by 1981 scholars and social activists around the country were describing an overwhelmed constellation of shelters and soup kitchens that were lodging more and more people with psychiatric disorders (Baxter and Hopper 1981).

The appearance of homelessness, juxtaposed with a transition to a service economy that reduced unskilled employment; an emerging low-income housing shortage; and the decline of census in hospitals, led some observers to cite this epidemic among the mentally ill as an unforeseen byproduct of deinstitutionalization (Lamb 1984a, 1984b). For example, in 1970, there were 413,066 beds in state and country mental hospitals in the United States. By 1988, these had diminished to 119,033 and by 1998, the decline had continued to 63,526 (Manderscheid et al. 2000).

Population data and funding for needed mental health services were scant or nonexistent and effective methods of service delivery had yet to be developed. Until 1986 there were virtually no federal funds allocated for service delivery. Without adequate information on how to construct a rational service system or federal funding to support services, localities funded programs in an ad hoc manner. While some communities used limited local funds to develop programs, others sought legal remedies to force the homeless off the streets—or out of town. Almost all municipalities had huge service gaps and most had no services at all (Table 121–1).

The patchwork of mental health services that were implemented included a few street outreach programs and mental health services grafted onto preexisting shelters, mission houses, and soup kitchens (Axleroad and Toff 1987). These early programs run by community-based
The introduction of new funding streams reinforced the development of programs for the mentally ill homeless that had by then begun in many urban areas. The greatest innovation came from staffs of nonprofit CBOs which had both the administrative flexibility and a history of working in nontraditional settings to enable them to transition to service delivery for mentally ill homeless people (Dincin et al. 1995, American Psychiatric Association 1997). Conversely, traditional settings, like hospitals and clinics continued to show limited inclination to meet the service needs of mentally ill homeless people. However, there were exceptions, and a few hospitals experimented with shelter-based services (Cat on et al. 1990). New York's Bellevue Hospital created a specialized admission and inpatient service in conjunction with a state hospital and an innovative street outreach team empowered to involuntarily transport people to its emergency room (Katz et al. 1993). So, as Phase Two developed beyond a few well-funded model programs that included psychiatry, only a small number of motivated psychiatrists explored care, largely through their own initiative (Arce et al. 1983, Cohen et al. 1984, Lipton et al. 1983, Susser et al. 1990) and often on a volunteer basis (American Psychiatric Association 1986, American Psychiatric Association 1991a).

Research did continue to develop through this phase. Under McKinney funding, research dollars grew through NIMH and other federal sources and a crucial series of clinical trials were undertaken to test strategies for relief of the homeless among mentally ill individuals. The publication of the findings would appear in the next phase of care.

Through the 1990s, the epidemic of homelessness developed to an endemic status. Although on a local level the picture has widely varied, some communities tacitly acknowledged the endemic nature of homelessness by creating bureaucracies for services to homeless people. In 1993, for example, New York City created its Department of Homeless Services to oversee and manage programming in a large municipal shelter system.

During Phase Three, much of the research represented an extension of the epidemiological base already developed. However, five new developments that further underscore the social permanence of homelessness merit noting.

First, research emerged indicating that homelessness is more prevalent than had been understood even by some advocates. Two milestone studies independently estimated that approximately 3% of Americans experienced homelessness in a previous 5-year period (Culhane et al. 1994, Link et al. 1994). Second, the frequency with which families are afflicted by homelessness was brought to greater attention and as of 2001, families represented about one-third of the homeless population, and in many regions were its fastest growing segment (U.S. Conference of Mayors 2001). Third, the emergence of high rates of HIV and tuberculosis (TB) among homeless populations in general, but also specifically among the mentally ill homeless, has been documented, accentuating issues of medical disability. These epidemics have contributed to mortality as well as to the complexity of clinical care.
Fourth, the field began a quest for evidence-based interventions. Assertive community treatment (ACT) (Leisman et al. 1997), supported employment (Bond et al. 2001), and critical time intervention (CTI) (Sussner et al. 1997) are examples of services under exploration. The CTI approach focuses on the power of the rehabilitative relationship of case management to assist people as they adapt to new housing and service providers during “critical” transitions. CTI case managers provide extended follow-up, advocate for, and assist their clients as they begin to form new helping relationships through housing programs. Sheltered mentally ill homeless men in CTI have been shown to spend significantly fewer nights than non-CTI cohorts over an 18-month period (30 versus 91 nights).

Without effective rehabilitative intervention, mentally ill homeless people lose housing and often occupy a closed circuit between shelters, hospitals, and incarceration (Hopper et al. 1997). As part of this initiative, and encouraged by epidemiological research, federal and local agencies pursued more systematic approaches to care. In 1994, the US Department of Housing and Urban Development began requiring its housing grantees to provide a “continuum of care” (Barnard Columbia Center for Urban Policy 1996). Cost reductions in shelter, health, and mental health services have been pursued more systematically in the U.S. Department of Housing and Urban Development. In 1994, the US Department of Housing and Urban Development began requiring its housing grantees to provide a “continuum of care” (Barnard Columbia Center for Urban Policy 1996). McKinney funding made possible the multilocation Access to Community Care and Effective Services (ACCESS) program, a major initiative evaluating local models of integrated service (Calloway and Morrissey 1998).

Finally, an influential study by Culhane et al. (2002) explored housing’s effect on the costs associated with a person’s use of services. Analyzing New York City utilization data concerning 4,679 homeless people placed in supportive housing, and using matched control groups, this investigation documented that 95% of the annual cost of supportive housing in the first two years after placement was offset by cost reductions in shelter, health, and mental health services.

**Phase Four: Outcomes for a Heterogeneous Population (Since 2003)**

The Culhane et al. (2002) study heralded deeper understanding by government policymakers that data analysis is practical in service planning. This has influenced a coalescence of policy vision in the first decade of the new century. Research has also tracked epidemiological shifts. Although there have yet to be a new generation of epidemiological studies of homelessness similar to those carried out in Phase One, there is evidence of an increase in psychopathology. North et al. (2004) analyzed comparable data from 1980, 1990, and 2000 among the adult homeless population of St. Louis, Missouri, USA and discovered that Axis I disorders have increased over the past two decades, notably mood disorders and, dramatically, chemical misuse. In 2000, among 396 homeless single individuals, 84% of men and 58% of women had an alcohol or other chemical misuse disorder, accounting for a majority of overall psychopathology. In a sample of homeless single adults in Grand Rapids, Michigan, USA, Forney et al. (2007) uncovered similar chemical misuse findings (77% of men and 55% of women) and a diagnosis of mental illness in 35%.

Another finding is population heterogeneity among homeless people with psychiatric disorders, leading to programming interventions. For example, during 2006, family units with children were estimated to still comprise between 30% of the American homeless population and therefore represent the single largest bloc of homeless individuals (U.S. Conference of Mayors 2006). Single women usually head homeless families (Smith et al. 2005). Household conflict, violence and sexual trauma, substance use, and individual mental problems fit prominently into the experience of homeless mothers (Banyard and Graham-Bermann 1998, Bassuk et al. 1998, Bogard et al. 1995, Zima et al. 1996, Shinn and Weitzman 1998, Burt et al. 1999). Studies have shown that children and adolescents in shelters with their families appear to have worse health, mental health, behavioral, and educational outcomes than middle class children—and often worse than other poor children (Molnar et al. 1990, Rafferty 1995, Rafferty and Shinn 1991, Shinn and Weitzman 1996). There has been substantial growth in the development of supportive housing and other programs to assist homeless families as they reestablish residences in the community. Unfortunately, the bulk of research on these programs is evaluative or descriptive in nature with little research on effectiveness (Rog 2004, Nolan et al. 2005). An exception is adaptation of the CTI model to this population which attempts to quickly move families from shelters using intensive short-term case management, focusing on any of the above noted vulnerabilities (Felix and Samuels 2006). The program has shown significant benefits to children engaged in CTI concerning a range of maladaptive behaviors and other psychiatric symptoms, as well as attitudes toward school (Samuels J and Shinn M, unpublished report).

An outgrowth of family distress is the phenomenon of unaccompanied homeless youth. Estimates of the size of this population ranges from 575,000 to 1.6 million per year (Hammer et al. 2002, Thompson et al. 2002). Homeless youth are typically described by the circumstance of their homelessness: runaways, throwaways, and street youth (Green et al. 1995) and adolescents who become homeless upon release from the juvenile justice system and/or age out of the foster care system.

There are over a half a million children in foster care in the U.S. (U.S. Department of Health and Human Services 2005) and approximately 20,000 per year age out of that system (U.S. Department of Health and Human Services 1999). One large follow-up study of aging youth, the Midwest Evaluation (Courtney et al. 2006), found that at age 19, many leaving foster care are neither employed nor in school and many young women have children who they are unable to care for. Studies of residential instability among youth aging out of foster care consistently show rates of at least one night of homelessness that range from 10-35% (Cook 1991, Casey Family Programs 2003, Mason et al. 2003, Reilly 2003, Courtney et al. 2006). Regardless of their trajectory to homelessness, homeless youth also have a history of academic difficulties and social and behavioral problems (Clark and Robertson 1996). Many have had traumatic experiences such as extreme family conflict, separation from parents and siblings, and a history of residential instability. It is no wonder that they have been found to be at high risk for mood disorders, suicide attempts and post-traumatic stress disorder (PTSD) (Powers et al. 1990, Greenblatt and Robertson 1993, Rotheram-Borus 1993, Clark and Robertson 1996, McCaskill et al. 1998, Fronczak and Toro 2003) and chemical misuse (MacLean et al. 1999, Baer et al. 2003, Thompson et al. 2003, Van Leeuwen et al. 2005). Typically,
services for homeless youth are either outreach services or shelter-based with case management (Toro et al. 2006). Since the most consistent reason for youth homelessness is family conflict (Sanabria 2006), services often include family conflict resolution and reunification. Poignantly, intervention studies for this population have failed to keep pace with comparable initiatives for adult mentally ill homeless populations.

During Phase Four, people released from incarceration have gained increasing prominence among mentally ill homeless populations. First, there is evidence that an arrest history increases the duration of even first-time homelessness (Caton et al. 2005). Second, there is a backdrop of data showing that 24% and 21%, respectively, of individuals in state prison and jail are diagnosed with a psychiatric disorder and that mentally ill inmates are twice as likely to have been homeless in the year before incarceration (James and Glaze 2006). This offers scope to knowledge that homeless ex-offenders face a variety of unmet medical, chemical dependency, and mental health needs (Kushel et al. 2005). Projects have appeared that focus on inmate community re-entry and on diversion from incarceration for people with mental illness, yet there are few programs that specialize in the mentally ill homeless subpopulation. Examples of innovative programs combine housing with teams that resemble an ACT model (Project Renewal 2006).

And if homelessness is endemic and fully eradicated only with broad economic and social policy change, a new national effort to at least end chronic homelessness has now emerged. Chronic homelessness arguably presents especially dire consequences, with both personal demoralization and high societal cost. For example, data from New York City’s municipal shelter system show that 50% of shelter bed-nights are occupied by the 16% of homeless adults who have spent at least two of the past four years in shelter (City of New York 2005).

Consistent with the findings of Culhane et al. (2002), resources for shelter could be better used for housing and related supports. This was the basis of two 2003 federal reports (U.S. Department of Health and Human Services 2003, Substance Abuse and Mental Health Services Administration 2003) citing chronic homelessness as particularly pernicious, especially among those with mental illness and chemical misuse. In 2003, the federal government outlined its “blueprint” for ending chronic homelessness among people with mental illness, identifying a need to integrate services, to provide adequate financing, and to use evidence-based and promising practices. It also articulated two relatively novel concepts for the field: adopting the recovery paradigm and measuring programmatic results.

These developments coincide with emerging understanding that people with mental illness experience a process of recovery. Recovery, as such, does not signify “cure,” but denotes the personal odyssey of reaching self-defined goals, marked by hope and the development of relationships, work, and for some, spirituality. Recovery’s application to mentally ill homeless people lies at the core of reintegration to the mainstream. Services aimed at this population must therefore show concrete outcomes consistent with these values, perhaps the foremost of which is successful housing.

Toward measuring outcome, in 2004, the Federal government resurrected the Federal Interagency Council on Homelessness, first created by McKinney funding in the late 1980’s, pooling policy initiatives towards ending chronic homelessness, challenging states and localities to create ten-year plans to do so. By 2006, this call to action yielded over two hundred states and localities to create such plans. In New York City, for example, efforts to reduce chronic homelessness by this proportion within five years has led to new initiatives in reorganizing street outreach services, with targets for providers to rapidly house street people (City of New York Departments of Homeless Services and Health and Mental Hygiene 2006).

The need for outreach to rapidly house people continues to be challenged, however, by relentless pressures on low-cost housing and real estate (New York Times 2006). Simultaneously, well-serviced shelter care is viewed as costly. Some localities see economical opportunities in funding “housing-first” models that directly place people into available housing that serve in a transitional or permanent manner, also providing different measures psychosocial support (Chicago Continuum of Care 2003, City and County of San Francisco 2004). These approaches challenge a traditional wisdom developed during Phases Two and Three of a “continuum” model of building services to gradually move a person from street to shelter to transitional, then permanent housing (Federal Task Force on Homelessness and Severe Mental Illness 1992) and have initiated debate concerning the differential application of these models. As discussed below, research has yet to offer clear guidance on housing approaches amply adapted to the heterogeneity of persons with mental illness and homelessness (Table 121–2).

Finally, though full discussion is beyond our chapter’s scope, the social and economic underpinnings of homelessness in other developed countries are similar to those in the US, though with national and regional texture. For example, in the European community, immigration has been cited as a particular stress on housing, as well as having a role in creating social exclusion (Edgar 2005). It is generally believed that the magnitude of post-industrial homelessness, especially street homelessness, is not usually as great as in the

United States, but prevalence rates are difficult to evaluate because of differing definitional and methodological approaches (Edgar 2005), thus limiting focused public health intervention. European national policies on solving homelessness have varied from robust, as in the UK’s Rough Sleepers Strategy, to nearly invisible (European Federation of National Organizations Working with the Homeless (FEANTSA) 2004, Edgar 2005).

The Stages of Care
Through these phases of evolving services, a method of engagement and reintegration of mentally ill homeless people has effervesced. It is useful to consider this methodology as an overlapping, stage-wise process from the street (Susser et al. 1992), leading to housing, work, and reestablishing lost social ties. Depicted schematically in Figure 121–1, the current conceptualization of these stages is described in terms of (1) engagement, (2) intensive care, and (3) ongoing rehabilitation. Although these rehabilitative stages might apply to people who are not homeless, they take on a primary application with homeless people, especially considering an often-prolonged engagement and usually very complex treatment process.

Within the stages, there exists a range of services and technologies that are themselves on different levels of development. Furthermore, as we describe below, in most cases care actually begins prior to any contact with mental health professionals, especially psychiatrists (Figure 121–1).

Engagement
Classically, the first point in the continuum of services is street outreach. Street outreach programs were among the earliest novel interventions in the development of homelessness services, responding to the need to engage a very disaffiliated population of potential clients. Teams of human services workers, many of whom themselves have histories of

![Figure 121–1](source: Adapted From Gillig PM and McQuistion HL (eds), American Association of Community Psychiatrists’ Clinical Guide to the Treatment of Mentally Ill Homeless People. Reproduced by permission of American Psychiatric Publishing, Inc.)
homelessness, gently but persistently approach and engage homeless people in public spaces, offering incentives like food, clothing, and an open mind for listening (McQuistion et al. 1991). Gradually, they establish sufficient trust such that a homeless individual agrees to take a risk to move into his or her own dwelling with appropriate support or otherwise stay indoors at a shelter or drop-in center where he or she may find meals, showers, and daytime services. This process can take a matter of weeks, but has been known to last much longer, sometimes years. The street population is generally regarded as particularly disabled and alienated and the outreach process is very labor-intensive, requiring many short, usually apparently casual, helping interactions to achieve engagement and to provide service.

Alternatively, some mentally ill homeless people are first encountered in shelter or drop-in settings. Some find their way to shelter after a precipitating personal crisis, while others have been referred to or are accompanied by street outreach teams that are connected with the facility. At the point of arrival at an indoor setting, there is potential opportunity for multidisciplinary intensive care described later, but early interactions indoors also often require outreach while workers concentrate on establishing trust. Relationships are hard-won, and they require patience and flexibility, even tolerating a person’s self-destructive behavior that may, for example, include drug or alcohol dependence. At this stage, a harm-reduction approach to chemical misuse, or risky lifestyle (e.g., sex work) is practical (Marlatt 1996). Appropriate techniques include respectfully educating a person about risks, about the “side effects” of using street drugs—like never having money or suffering psychological and other health effects, including trauma from a rough lifestyle. In this manner, a goal during engagement is to move a person from a position of “precontemplation” of drug and alcohol use to contemplating change (Prochaska et al. 1992), illuminating alternatives and beginning to help lift him or her from a condition of demoralization (Frank and Frank 1991).

Simultaneously, a challenge exists of balancing these approaches with being able to respond decisively to a crisis or risk to community safety (Diamond 1996). Mental health professionals, usually psychiatrists who are working in street or shelter settings, must recognize and respond to emergencies that require involuntary transport to an emergency room, and they must have the means for emergency rescue at the service center and in the community. When judiciously employed, this work is humanitarian, potentially lifesaving, and may offer new opportunities for engagement. There is ongoing debate about whether ultimate community reintegration can actually be achieved through such coercive means, yet psychiatry, especially, has a unique responsibility in clinical decisions concerning involuntary treatments.

The combination of homelessness and serious mental illness adds to the complexity of a right to refuse treatment. In the US jurisdictions, the standard for involuntary admission is dangerousness to self or others in the foreseeable future, usually marked by acute suicidality, making threatening statements, or aggressive behavior. However, there are subtler situations where assessment of dangerousness is challenging. Examples include a person who continues to sleep outdoors despite freezing temperatures, who crosses streets without paying attention to traffic, who yells random comments at passersby, or a person who eats out of trash cans without regard for personal health. None of these situations necessarily warrant involuntary intervention. Many people cross streets while engrossed in iPod tunes, free speech is a right, and some choose to camp out in frozen arctic tundra. Yet, in the context of psychosis and impaired judgment, any one of the aforementioned behaviors might indicate dangerousness. The clinician must carefully balance the legal, ethical, and relational risks with exercising unilateral power.

In our view, there is a continuum of clinical negotiation or leverage. It ranges from involuntary hospitalization to subtler forms, for example, when a service provider assumes the role of representative payee of a person’s entitlements, or when delays are imposed in making housing referrals for people not addressing chemical misuse. In these cases, the fulcrum of successful leverage is usually the clinical alliance, with the person understanding that there is something advantageous in a continuing relationship. This highlights the critical nature of initial engagement.

Mark’s situation, as we now describe, illustrates how involuntary hospitalization, and other uses of leverage, can be carefully constructed to help a chronically homeless person move toward rehabilitation:

Fifty years old and homeless for almost two decades, Mark had not always been destitute. He had excelled in school before entering a prestigious college. In college, though starting to be socially isolated and obsessed with ideas of starting his own religious cult, he did well enough to enter graduate school in engineering, demonstrating exceptional mathematical abilities. During graduate school, he had his first psychotic episode, requiring hospitalization and leave of absence from school. While on leave, he declined continued psychiatric treatment. After several hospitalizations and desperate efforts by his family to stay connected with him, Mark’s illness ultimately led him to the streets. After a single day in a municipal shelter, Mark left, fearing he would be killed. He finally found an isolated room in a subway tunnel that became “home” for almost two decades.

During these years, Mark had intermittent contact with an outreach team while he panhandled above ground. Occasionally, he would come to a drop-in center operated by the same outreach team. Though Mark established relationships with a number of case managers and psychiatrists at the center, he never accepted psychiatric medication. But he did become increasingly trusting of program staff, accepting food, clothing, and showers.

Mark’s usual problematic behavior included screaming in the street, washing his face in a toilet, eating out of garbage cans, rarely bathing or changing clothes, and pointing at people and saying “The Lord is vengeful.” Occasionally, he would push or hit a passerby, necessitating police intervention and transport to an emergency room, where he would always present to clinicians as calm and nonthreatening, culminating in release. During a subsequent period during which Mark was frequently pointing at people and threatening them with divine vengeance, the drop-in center psychiatrist exercised authority under local law to petition an involuntary transport to a hospital.

This was a more studied intervention than a call for less expert (and legally constrained) police to assess a person’s acute dangerousness. It was done in close collaboration with the
Regardless of whether a person is methodically transitioned to a shelter or vigorously supported in housing immediately from the street, treatment of psychiatric disorders, co-occurring chemical dependency problems, and general medical needs also begin to take on an important role during intensive care. Even as intensive care proceeds, approaching these needs requires special skills, primarily using nontraditional techniques (Table 121–4). These techniques are born out of a necessity to treat people who usually do not consider themselves “patients,” but rather out of circumstantial necessity, happen to interact with health providers. Psychiatrists in shelters and similar nontraditional settings have to “unlearn” habits while they integrate standard practice and nontraditional techniques (Felix et al. 1996). For example, it is at times acceptable to joke around and laugh with patients, to give gifts, to self-reveal, to play cards or ping-pong, and to be a visible advocate and deliverer of concrete services. Implicit in this is continuing attention to an alliance with the patient, including maintaining unwavering reliability.

Perhaps in no single area of the relationship between the psychiatrist and the homeless person can alliance be more critical as in the instance of introducing medication. The clinician persistently works with the patient, searching for a shared rationale for prescribing; simultaneously signaling to him or her that the clinician’s purpose is in helping him or her meet his or her personal goals. Being a real object communicates this nonverbally.

Choice of medication is tempered by realism. For example, medications that require frequent laboratory monitoring may not be realistic in many nontraditional settings especially if the person cannot predictably appear for phlebotomy. When a medication regimen is established, too, attention to adherence is important. Psychiatrists must be flexible and realistic with dosing schedules, prescribing once a day whenever possible. Many programs have devised ways to track medication adherence through supervision or pill counts. If there is nonadherence, further negotiation is indicated, carefully listening to the person’s concerns. Harm-reduction techniques are also appropriate, as in continuing antipsychotic medications when a person is actively using street drugs.

Because intensive care is a time of active psychiatric stabilization, clinicians may continue to be confronted with questions of personal risk to self and others. All basic “intensive care settings” are by necessity least restrictive and particularly in drop-in centers and shelters, staff must be skilled in diffusing potentially explosive interpersonal situations among clients, thereby focusing on preventative environmental techniques to enhance safety, including attending to medication adherence and substance use. People are also at varying stages of recovery and often exit these settings for periods ad libitum. This reality requires staff that tolerates
ambiguously risk. Just as they need to be comfortable with intervening acutely, they must also be ready to take leave of a homeless client, and revise a treatment plan when he or she returns.

During intensive care and especially while exploring housing options, chemical dependency becomes a serious focus. Though it is unlikely that chemical misuse is a primary cause of homelessness (VanGeest and Johnson 2002), the corrosive nature of drug addiction lends support to substance abuse as a cause of chronic homelessness. Mounting data buttress this (Breakey et al. 2001), and there is emerging consensus on effective techniques addressing co-occurring substance use and psychiatric disorders (Drake et al. 2001). However, gaps remain in understanding differences between homeless and non-homeless dually diagnosed populations. Filling them will offer effective solutions to homelessness. Possible programmatic solutions include housing geared to treating active chemical dependency and integrating substance abuse programming with the psychologically and socially restorative effects of vocational training. The latter offers a pathway out of the demoralization induced by severe poverty, which itself may foster chemical abuse.

Finally, homeless people encounter the same chronic physical illnesses that everyone else does, with the important exception that they have dramatically more difficulty in obtaining care. Compounding this is a higher than usual prevalence of epidemic illness, like HIV and hepatitis C (Susser et al. 1993b, Rosenblum et al. 2001). With the exception of a few innovative mobile programs that visit shelters and drop-in centers or travel on the streets in specially outfitted vehicles (Nuttbrock et al. 2003), homeless people usually get medical care on an emergency basis at a high cost and mortality rate. When they do obtain quality shelter or housing, it may be the first time that they receive ongoing medical services. In these settings, staff is aggressive in addressing often multiple medical problems of clientele. Psychiatrists especially, have a role in leading the effort to access a mentally ill homeless person to medical care, advocating with human service workers to facilitate Medicaid enrollment and with off-site health care providers to treat homeless patients.

### Ongoing Rehabilitation

The transition from intensive care to an open-ended stage of ongoing rehabilitation is an especially gradual one. Achieving full community integration necessarily involves a new sense of self-identity and recovery, and is composed of several ingredients.

Albeit crucial, housing is merely the first step. Becoming stably domiciled is a formal benchmark and successful transition to housing demands careful clinical attention. A useful approach in determining fit between an individual’s needs and housing type involves conceptualizing a spectrum of structure, or treatment intensity, among available housing types. These range from relatively restrictive, usually congregate care “community residence” settings that require on site program attendance and psychiatric care, to less costly “supportive housing.” The latter is characterized by more independent apartment living. This may be either a single room occupancy building, often with optional program participation, or in scattered sites, also closely identified with housing-first models. The more structured and intensive the housing environment is, including available mobile services delivery, the more the clinical work continues to resemble intensive care. Furthermore, among the more structured housing environments, accommodations may also be transitional—up to two years. Typically, multidisciplinary outreach teams armed only with experience and clinical skills determine the fit between homeless individuals and housing programs, using program structure as a guidepost.

Services researchers are only beginning to explore reliable approaches to successfully match housing with potential residents based on clusters of personal needs. This includes analyses of housing models and the effects of addressing clinical issues like medication adherence, concurrent treatment of chemical misuse (Susser et al. 1991, Grunebaum et al. 1999), medical comorbidity, and family involvement. As recent reviews have highlighted (Fakhoury et al. 2002, Rog 2004), the challenges have hovered on the realities of performing research in naturalistic settings. This includes problems such as the existence of few controlled studies, relatively low statistical power, inconsistent terminology and methodology, and investigations of housing programs that are themselves incompletely described.

However, formative information does exist. Because of its relatively wide array of housing programs and an overseeing administrative system, New York City has been a frequent study locale. In a retrospective study of 2,937 housing placements in New York, correlation with longer housing tenure in high service intensity settings included the availability of medication management and non-congregate living that contained mixed populations of disabled and nondisabled tenants (Lipton et al. 2000). In low intensity settings, longer tenure was associated with mood disorders. In all settings, it was associated with older age. Not surprisingly, and consistent with other studies, there was an association between co-occurring active substance abuse and short housing stays (Table 121–5). A subsequent quasi-experimental study by Siegel et al. (2006) examined eighteen-month outcomes of 157 New Yorkers placed in either supportive settings (usually low intensity) or community residences (uniformly high-intensity). These authors found that housing tenure was statistically indistinguishable between these settings, though housing satisfaction was rated higher in supportive environments. As other research has noted, for many living in supportive settings—including “housing-first”—there was an associated greater sense of personal isolation. Across both housing paradigms, indices of depression and anxiety yielded poorer community integration and quality of life, indicating that people who experience these issues should be targeted for vigorous mental health intervention. Individuals most likely to lose

housing status were younger; less educated; had a diagnosis of bipolar disorder or poly substance abuse; and had relatively more frequent psychiatric hospitalization.

Rigorous explorations of housing program structure itself include Goldfinger and colleagues’ (1999) in Boston comparing 18 month housing stability among 118 people randomized to an independent apartment program (with case management support) or group homes with on-site psychosocial services. This study found somewhat fewer homeless days among participants in staffed housing. In addition to minority ethnicity and lifetime chemical misuse, participants who had the very highest degree of preference for minimally structured independent living also correlated with housing instability. While respecting consumer preference has also been associated with favorable outcomes (Srebnik et al. 1995), this study highlighted a complex interrelationship of consumer choice and professional judgment, indicating a need to employ active collaboration to find the desired “fit.”

As noted above, there is policy interest in understanding who best adapts to housing-first models. Housing-first is often identified with consumers’ wish to be domiciled quickly and independently, in contradistinction to the continuum model’s stepwise method of evaluating housing readiness while accentuating clinical stability and psychosocial support. Partially addressing this from a housing-first stance, Tsemberis et al. (2003) examined the role of psychosocial support in housing stability in independent apartment living. These authors functionally combined ACT services with housing-first opportunities using ACT to aggressively obtain housing placement and flexibly maintain mentally ill clients through recovery. In a six-month follow-up of 99 people randomly assigned to this program, 79% retained housing versus 24% of 156 controls assigned to continuum-model housing. In a 24-month follow-up, the variance in housing stability was maintained (Tsemberis et al. 2004). Housing-first advocates, in fact, argue that the issue of matching program structure and individual characteristics is obviated through the use of flexible ACT-like services.

Once a person has found a satisfying housing environment, the rehabilitative focus transitions from symptomatic stability to emphasis on the development of a set of new roles that render as obsolete the individual’s identity as homeless (Table 121–6). Vocational and relational identities are integral at this stage and psychiatrists who work within this phase focus much less on crisis and immediate psychiatric and medical needs, but more on identifying and achieving with their patients long term goals, while also helping them identify stressors: a focus increasingly on illness self-management. This is done by listening carefully to a patient’s hopes, translating them into a collaborative reality-based plan, being flexible to tolerate setbacks, and coordinating closely with vocational and social skills programs and other counselors.

Goal setting around work can often start during the stage of intensive care, with many entering active vocational training at that point. As a person struggles less with day-to-day survival, he or she begins looking for a sense of financial independence and sources of personal pride. Supported employment has enjoyed the highest preference, but many professionals value transitional employment models, like those in clubhouses. These models need further focused research among homeless and formerly homeless populations.

The other important development during ongoing rehabilitation is the formation of more meaningful human relationships, marking dissolution of the alienation engendered by chronic homelessness, especially. This includes the reestablishment of family ties for many who have been separated through the vicissitudes of mental illness and chemical misuse. Psychiatrists and other workers have a role in acting as a conduit to families, providing family psychoeducation and support to their patients. For those people whose families are not accessible, even more incentive exists for professionals to link them to other support systems through clubhouses, redeveloped personal interests, religious and other spiritual affiliations, and work environments. The recovery and reentry of mentally ill homeless people, while often painstaking, is accentuated by their heretofore-severe indigence and disaffiliation. It is therefore ultimately profound.

### Administration, Academics, and Advocacy

Psychiatrists are important in providing both leadership and collaborating in service within all the stages of rehabilitative care of people with homelessness and mental illness. As the evolution of services to this population had progressed over the past two decades, they have found additional roles in administration, academics, and advocacy.

Owing to their location within CBOs, nonmedical professionals lead most programs serving homeless people. Nevertheless, the role of medical director has developed in CBOs (Ranz et al. 2000). The role of the CBO medical director represents both shifts in CBOs toward accepting a meaningful medical contribution and an adaptation of psychiatric administration to include nontraditional models. Medical directors work in partnership with, or under the aegis of, nonmedical program or agency directors, and how they manage this relationship requires flexibility and collaborative skills. For example, in the area of clinical accountability of nonmedical staff, the medical director needs to provide clinical consultation and supervision to nonmedical colleagues, and assert a commitment to quality care, often without direct line authority.

Over the last twenty-five years, there has also been a gradual acceptance of the need to educate psychiatric house staff in meeting the needs of mentally ill homeless people (McQuistion et al. 2004). Academic faculty who came of age during the phases of the homelessness problem lead today’s teaching experiences. These teachers understand that working with mentally ill homeless populations affords the trainees opportunity to learn omnibus skills in diagnosis

an management of very complex and distressed patients, including work at the frontiers of epidemics like TB, HIV illness, and hepatitis C.

Training medical students and physicians to work with mentally ill homeless people necessarily involves describing a theoretical framework. In addition to outlining a clinical methodology such as that presented in this chapter, this includes education concerning the social and economic roots of homelessness and how community psychiatry fits within applied public mental health. Trainees are placed in clinical programs that are known to be successful and student-friendly. Supervisors must offer vision, theory, and role modeling, as they also teach cultural competence, work with countertransference, and imbue special techniques.

Finally, advocacy is required to advance recovery and help homeless people with psychiatric disorders to enter the social mainstream. Homelessness is tied to structural economic, social, and political conditions and it will not disappear until poverty is adequately addressed. In our view, the realities of housing shortages, the continual labor shifts within a market economy, and their interplay with race, social class, and a societal value of individual sufficiency are at the center of the problem. While constructing a solution for this quintessentially American issue is beyond the purview of the behavioral health sciences, psychiatrists and other mental health professionals nevertheless are uniquely positioned to influence social policymakers and politicians. On a basic level, the very existence of psychiatrists working with homeless people constitutes advocacy by drawing professional attention. Psychiatrists working with homeless people must also influence the organizations for which they work to identify a corporate function in advocacy, moving beyond service.

Through research, psychiatry can elucidate and then transmit information concerning the public health costs of mental illness and homelessness and inform community intervention strategies that point to technology, such as vocational rehabilitation models, that provide opportunities for impoverished mentally ill people to gain personal and social productivity. Prevention interventions, including models to divert people with psychiatric disorders away from incarceration, are also areas appropriate to psychiatric contribution, as are efforts to inform policymakers about how poor families, and their communities, might be supported to reinforce protective factors against beginning or perpetuating a family cycle of homelessness.

On an activist level, in some localities, litigation has been a critical tool in driving public policy on homelessness. Psychiatry offers special expertise to legal advocacy and exercising this role has a potent effect on facilitating social change. In this manner, psychiatrists have given expert testimony in important class action suits and professional organizations have issued formal statements of support. Organized psychiatry has also combated the stigma of mental illness extending itself to homelessness, too (American Psychiatric Association 1991b, Lamb et al. 1992). These documents provide a recognizable reference point of leadership for psychiatrists to engage in public advocacy as they form alliances with others, including consumers and families, educating policy makers about the needs of this population.

In 1973, the American Psychiatric Association’s (APA) Board of Trustees, after extensive scientific review and debate, removed homosexuality per se as a mental illness from the Diagnostic and Statistical Manual of Mental Disorders, Second Edition (DSM-II). If sexual orientation is not a mental illness, why is there a chapter on this aspect of human sexuality in a psychiatric textbook? Understanding the variations of sexual orientation and the range of adjustments individuals and society in general make to sexual orientation is as important as understanding the influence and importance of culture, ethnicity, race, and gender on the psychological development of a person and the way mental health issues may be shaped or express themselves.

Homosexuality is a normal variation of human sexual and affectional (loving) expression. Sexual orientation is a complex phenomenon with many variations along a spectrum of heterosexuality to homosexuality. A nonpathological view of homosexuality as well as homosexual and bisexual men and women removed the stigma of mental illness and opened up vast areas of study, research, hypothesis, and knowledge about sexual orientation itself; the expression of sexual desire, the psychological and social forces that influence the lives of people with homosexual and bisexual sexual orientations, and the life cycles of such men and women, including the nature of bias and prejudice based on intolerance to differences.

**Definitions and Concepts**

The term “gay” has a long history of association with homosexual males, but became more of a standard and accepted term replacing “homosexual” since the latter is seen to have a pathological association and is seen as too focused on sex alone, and not on the total complexity of a sexual orientation. In this chapter, males with homosexual sexual orientations will be referred to as “gay men,” females with homosexual sexual orientations will be referred to as “lesbians,” and men and women with bisexual sexual orientations will be referred to as “bisexuals” or “bisexual men and women.”

Sexual orientation may be simply defined as the erotic and affectional attraction to another person, including erotic fantasy, erotic activity or behavior, and the need for love and affection. Homosexuality can be seen as part of a continuum of human sexual and affectional expression, ranging from same-sex attraction to opposite sex attraction.

Some people with homosexual or bisexual orientations, as indicated by fantasies, may not engage in homosexual behavior as a result of internalized homophobia (the fear of accepting homosexuality or homosexual impulses, discussed below), societal pressures, or personal choice. For some, the fear may lead to denial or repression even at the fantasy level. Many gay men, lesbians, and bisexuals recall feeling different from others—even as early as age 4—and have linked that feeling to a differing sexual orientation (though they may not have acted on their differing sexual feelings until well into adulthood).

Sexual behavior, or sexual activity, alone does not define orientation. Sexual identity usually refers to one’s sense of self as male or female but is also used at times to connote sexual orientation.

Sex is the biological distinction between men and women. Gender is the concept of maleness and masculinity or femaleness and femininity. Gender identity is the sense of self as male or female, with no reference to sexual orientation, gender role, or even biological sex. Gender role refers to behaviors and expectations that are viewed as masculine or feminine by a particular culture.

It is common in most Anglo-European/Western cultures to call behavior, styles, or interests shown by a male that are associated with women “effeminate” (boys are often labeled “sissies”) and the equivalent by a woman “masculine” or “butch” (girls are often labeled “tomboys”). As will be discussed, much of the confused and prejudicial thinking about homosexuality in the past was due to confounding sexual orientation, sexual behavior, gender identity, and gender roles, overlaid with a generalized sexism that dismissed women and men who were thought to be like women, supporting the mistaken notion that gay men—since they are attracted to men—are in some way like women, and, in turn, lesbians are in some way like men.

**Heterosexism** is defined as an ideological system that denies, ignores, denigrates, or stigmatizes any nonheterosexual form of emotional and affectional expression, sexual
activity, behavior, relationship, or socially identified community. Homophobia, though a popular term, lacks precise meaning; it is used to describe fear and loathing of gay men and lesbians, and also used to describe self-loathing, fear, or resistance to accepting and expressing sexual orientation by gay men, lesbians, and bisexuals. Antigay bias and antihomosexual bias are better phrases to describe the first concept, and internalized homophobia is better for the latter. Internalized homophobia is a key concept in understanding many of the developmental and clinical issues facing gay men, lesbians, and bisexuals.

History of Homosexuality and Psychiatry

Early Thinking

Though homosexuality as a specific category was not described in the medical or psychiatric literature until the early 1870s, psychiatry and the fledgling psychoanalytic movement made homosexuality a topic of special interest and focus. Most psychoanalytic approaches tended to seek one cause or explanation for homosexuality, and most of this writing confuses sexual orientation and gender identity, working often from the premise that gay men identify with femininity and lesbians identify with masculinity.

Sexual orientation in and of itself, Freud believed, no way impaired judgment or caused problems in delivering medical or psychiatric care. Freud's (1960) famous “Letter to an American Mother” stated: “Homosexuality is assuredly no advantage, but it is nothing to be ashamed of, no vice, no degradation; it cannot be classified as an illness.” He goes on, however, to state: “We consider it to be a variation of the sexual function, produced by a certain arrest of sexual development.” Though his thinking on homosexuality itself was not entirely consistent, having described at least four theories of male homosexuality—nor free of pathological associations—he did believe in innate bisexuality and in a biological contribution to sexual orientation (Lewes 1988).

In Europe, Rado (1969) proposed that homosexuality was caused by cultural and familial influences, based on a fear of the opposite sex, and, accordingly, treatable with psychotherapy. Fenichel (1945) further elaborated a fear of castration and developmental arrests and fixations, but described cultural influences on the expression of homosexuality and believed that there was an element of choice in sexual orientation, not just in its expression.

Many American psychiatrists promoted the notion that homosexuality was a mental disorder. Bieber et al. (1962) extended the Freud and Rado theories to propose that family upbringing and childhood influences were entirely responsible for producing homosexuality in male children. He described the “classic” combination of a distant, uninvolved father and an overinvolved mother seeking to meet her needs through her child. (He did not comment on the finding that even more of his heterosexual males had that parental pattern than the matched homosexual males.)

Socarides (1968) described male homosexuality as a preoedipal problem and, therefore, severely psychopathological and developmentally somewhere between borderline and psychotic conditions, seeing family upbringing as the cause of homosexuality. He contended that homosexuality could indeed be “treated” with psychotherapy, especially psychoanalysis, because it resulted from conflictual issues, an attempt to resolve the separation and individuation from mother in the face of a weak or cruel father.

Female homosexuality was not focused on as much as male homosexuality. Freud (1920) was not consistent in his thought about female homosexuality either, seeing it either as severe penis envy with a turning away from heterosexual objects and a regression to earlier fixations on mother, or a narcissistic identification with father, thus seeking other women, and therefore, homosexual objects.

Other psychoanalytic writing also refuted a biological component to female homosexuality, seeing it as caused primarily by early developmental disturbances. Expressing a view that clearly reflected the culture of the times, Deutsch (1932) saw homosexuality as regressive and transitional, with male homosexuals acting out passive or feminine wishes and female homosexuals, failing to learn to sublimate their aggressive energy into acceptable submissive behavior, acting out masculine or active wishes. She believed that the normal progression to adolescent heterosexuality was interrupted in lesbians by a probable masochistic disturbance in the early mother/daughter relationship.

Socarides (1968) also espouses this theory, but further emphasizes the failed separation and individuation at the preoedipal stage. Newer theories suggested that the disturbance between the daughter and mother was due to maternal narcissism, or due to an awareness of societal devaluing of women, and another notes a possible fixation at the genital level and an overidealization or overinvestment in the genitals in a sexual relationship with another woman to make up for poor or limited mothering (reviewed in Magee and Miller 1997).

Newer Thinking

Kinsey opened the possibility of new perspectives on homosexuality with his surveys of the sexual practices of men and woman (Kinsey et al. 1948, 1954). He proposed a continuum to describe sexual behavior, with a scale from 0 for exclusive heterosexual behavior to 6 for exclusive homosexual behavior. His studies have been criticized for a variety of reasons, including poor sampling, but they certainly made Americans aware of sexuality and sexual behavior previously rarely discussed. Kinsey’s data, counting sexual contact resulting in orgasm, found that 37% of the male population had some homosexual experience between the beginning of adolescence and old age. Of unmarried males who are 35 years of age or over, almost 50% had had a homosexual experience since the beginning of adolescence. Kinsey found that 4% of the white male population is exclusively homosexual throughout their lives. Study of the sexual behavior of women showed percentages of women with homosexual encounters to be roughly one-half of the parallel categories for men. Most people fell in a bisexual range from 1 to 5.

The Kinsey Institute did further reviews and surveys including a path analysis of all the data known about homosexuality available to them at the time. It concluded that homosexuality must be biologically based—something one is born with—and not determined by family upbringing (Bell et al. 1981).

Evelyn Hooker can be credited with initiating the acceptance of changes in thinking about homosexuality within the
mental health field. She demonstrated that there were no discernible differences between the psychological profiles of gay men and heterosexuals, effectively beginning the dismantling of the theory that gay men were psychopathological with preoedipal fixations (Hooker 1957).

An era of new thinking from psychoanalysts began in the 1980s. For example, Isay (1989) made the assumption that sexual orientation is probably biologically based and looked at how the oedipal complex may be different for gay men and how some subtle or not so subtle aspects of the gay son may be recognized and responded to by the father, leading the father to withdraw or treat that son differently than a heterosexual son.

Lesbians and female homosexuality have also been studied and reviewed from the nonpathological perspective. The literature on gender and gender roles offers additional ways to look at both male and female homosexuality, and is particularly useful in understanding the issues facing same-sex couples. For example, Gilligan (1982) points out the divergent paths for male and female development: boys are brought up to be not like their mothers, that is different from an important nurturing figure, whereas girls are brought up to be like their mothers, that is closely identifying with the nurturing figure. Such an observation may help to explain the problem of comfort with intimacy within many male couples or the “fusion” or intense intimacy within many lesbian couples as described by many clinicians working with same-sex couples (see below).

Magee and Miller (1997), as noted, completed an extensive review of psychoanalytic thinking on female homosexuality, emphasizing the heterosexist and phallocentric assumptions. They conclude that there are no psychodynamic etiologies to female homosexuality.

**Biology, Genetics, and Cultural Perspectives on Homosexuality and Bisexuality**

Data on the true prevalence of homosexuality in America are difficult to obtain, partly because of the difficulty in obtaining honest and complete responses or information in surveys, and partly because of a lack of agreement on terms and definitions of the population to be studied. The popular estimates that 10% of the male population and 5–6% of the female population are exclusively or predominately homosexual are based on an interpretation of the Kinsey data, which only described sexual behavior and did not attempt to describe sexual orientation or a self-identified sense of self as gay, lesbian, or bisexual. Michaels (1996) undertook a thorough analysis of the limited data available, differentiating the concepts of sexual behavior, sexual desire (i.e., who the person would prefer to be with sexually), and self-reported identities as gay men, lesbians, or bisexuals. He notes that there is no possibility of giving an overall meaningful prevalence, since the data indicate a wide variety depending on gender, age, marital status, education, religion of upbringing, current religious affiliation, race, and place of residence (ranging from urban to rural). His summary estimates that in America, 9.8% of men and 5.0% of women report same-gender sexual behavior since puberty, 7.7% of men and 7.5% of women report same-gender desire, and 2.8% of men and 1.4% of women report a homosexual or bisexual identity.

**Culture and Cross-Cultural Issues**

People who relate to people of the same sex for love, relationships, and sex have been noted throughout history and in almost all countries and cultures. Boswell (1980) documented both the acceptance of and intolerance to homosexuality in Christian Europe, linking the tolerance to economic and political variables: if all was well economically and politically, homosexuality was well tolerated; in periods of political turmoil and economic unrest, gay men and women were scapegoated.

Many studies of the animal kingdom have shown homosexual behavior to occur in other species. There are examples of some animals within a socially organized species, such as some monkeys, who exhibit nearly exclusive homosexual behavior (Denniston 1980).

Cross-cultural studies not only help to put homosexuality into global perspective, but also contribute significantly to the understanding of clinical issues facing gay men, lesbians, and bisexuals in the United States who are from an ethnic or cultural minority group (Herdt 1996). Most significantly, the understanding of bisexuality benefits from cross-cultural and historical perspectives, since many cultures outside of that in the United States condone homosexual and bisexual behavior, in certain prescribed circumstances.

**Biology**

The biological studies, for the most part, seem to grow out of the confusion noted above between sexual orientation and gender identity: most studies have tried to show some physical trait in gay men that must be like that of women, and vice versa for lesbians. Though there have been a multitude of studies and reviews, and critiques of the studies, they have not been consistent in their findings, they have not been replicated, or conclusive, and most have had major flaws in their design (reviewed in Pillard 1998). Animal studies in particular are difficult to correlate with human findings: in some, stereotypic sexual behavior of rats is used to describe a sexual orientation (a male rat who assumes the female lortotic position and allows other male rats to sexually mount him is seen as the “gay” or homosexual rat, where there are no conclusions drawn on the mounting rat).

Some studies of differences in brains between gay men and heterosexual males are based on a hypothesis that the brains of gay men are different and would be similar to those of heterosexual women. LeVay’s (1991) study showed a twofold difference in size of the third interstitial nucleus of the anterior hypothalamus (thought to be associated with sexual behavior)—the gay men’s being half the size of the straight men’s—consistent with the finding that the women’s are about half the size of men’s. There were several problems with the study—including tissue samples from men who died of AIDS, caused by the neurotropic HIV—and no certainty of the sexual orientation verses the sexual behavior of the deceased; the study has not been replicated.

Hypotheses that gay men must lack testosterone or have high estrogen levels and lesbians have the opposite are based on the same type of thinking noted above, but hormonal differences in gay men and lesbians from heterosexuals have never been demonstrated consistently. There have been some studies looking at hormonal influences on sexual orientation in utero, with the hypothesis that maternal stress may somehow affect the hormonal levels that in turn affect the
development of the fetus, possibly influencing brain development and sexual orientation (Ellis et al. 1988). Other possible correlations between physical traits or developmental events and sexual orientation include the birth order where gay men seemingly are born later in sibling order (Bogaert 2006), left-handedness and homosexuality (Rosenstein and Bigler 1987), and leftward pattern asymmetrical fingerprint patterns and sexual orientation (Hall and Kimura 1994). Other than the birth order review, no studies have been replicated.

Studies of intersexual people, that is, people with sexually ambiguous genitalia or true hermaphrodites, are often conducted, but such studies ultimately illustrate more about gender role expectations; that is, what happens when one is brought up as a male or as a female regardless of biological or genetic sex, than add any additional understanding to homosexuality (Rosario 2006).

Genetics
The most promising areas of study involve genetics and familial patterns. The genetic and familial patterns studied by Bailey, Pillard, and their colleagues have demonstrated the most consistent and replicated data (Bailey and Pillard 1991, Bailey et al. 1993). Pillard (1996) notes that gay men are much more likely to have other gay or bisexual male siblings than a heterosexual male—based on expectations of the incidence of homosexuality in America—but no more likely to have a lesbian sister; lesbians, in turn, are more likely to have other lesbian siblings, but no more likely to have a gay brother.

Combined with other studies on twins and heritability (Whitam et al. 1993), this body of research helps underline the probable genetic substrate of sexual orientation in all people, with different genetic influences for male homosexuality, male heterosexuality, female homosexuality, female heterosexuality, and, possibly, even for bisexuality. Heritability does not imply a direct gene but does indicate the fraction of the trait studied seen in a given population that is attributable to genetic differences among individuals; certain genes may influence factors that then shape responses that may influence sexual orientation, and thus not be genes for homosexuality itself. Though a complex set of behaviors and feelings such as seen with homosexuality could not be explained by any single factor, the genetic basis may be the foundation on which other biological and familial and societal influences work to shape the development and expression of sexual orientation in adult men and women.

Bisexuality
Bisexuality has also been known to exist throughout all recorded history. Freud, as noted, believed in innate bisexuality, and that any one individual evolves into having a heterosexual, homosexual, or even bisexual sexual orientation. Though Kinsey demonstrated the frequency of bisexual behavior in America, estimating the prevalence of bisexuality as a sexual orientation is as difficult to determine as is the prevalence of homosexuality. The differences between behavior and self-identification are especially important here. A survey in New York City of the sexual behavior and identity of men reported that 10% of the men who reported to have sex with men called themselves “straight” or heterosexual even if they did not have sex with women (Pathela et al. 2006). Weinberg et al. (1994) have described the theoretical approaches to bisexuality and critically reviewed the research on bisexuality.

Developmental Issues Facing Most Gay, Lesbian, and Bisexual People
Understanding the developmental issues for most gay men, lesbians, and bisexuals will help in the clinical work with such people, and will further enhance the awareness that many of the clinical issues that are unique for gay and bisexual people are a result of the adjustment to a minority sexual orientation and not due to any psychopathology associated with the orientation itself. There are three major tasks that gay, lesbian, and bisexual people have to undertake that heterosexual people do not need to do: (1) recognize that there is indeed something “different” about them, and that this sense of difference usually precedes an awareness of sexual and affectionate feelings different from the majority; (2) “come out,” that is, acknowledge first to themselves and then eventually to others that they have a different sexual orientation from the majority; and (3) process the internalized homophobia and possibly confront both heterosexism and antigay bias in coming out to others and living in the world as openly gay, lesbian, or bisexual.

Learning to live in a society that does not accept difference readily shapes the sexual identity development of many children who will grow up to be gay, lesbian, or bisexual, as they transition from childhood into latency period. De Monteflores (1986) in particular describes how difficult it is growing up different. Whereas a person of color cannot hide skin color, and the difference is obvious to all, a person with a homosexual or bisexual orientation, while aware of being different, may not be recognized as different by anyone else. The sense of difference in these children may be confusing and alienating, leading to social isolation and denial of natural feeling. For those children who are gender discordant in behavior, that is, children who exhibit behaviors or mannerisms associated with the opposite of their biological sex, profound deficits in self-esteem and in other aspects of the personality may result from being shunned, humiliated, and derided by their peers (Hanson and Hartmann 1996).

Most parents are heterosexual and raise their children either assuming that they will be heterosexual, or not thinking about sexual orientation at all. For the pregay or prelesbian child (i.e., the child who will grow up to be gay or lesbian), exposure to such nonconfirming behavior and parental expectations enhances the feelings of being different. As a coping mechanism, pregay or prelesbian children may learn to disconnect and dissociate from their true selves and sexual orientation and adapt to parental expectations by creating and presenting a false self or behaviors that are not genuine reflections of the true self.

Many parents who cannot respond to or give support for what is unfamiliar or uncomfortable for them will either ignore those attributes of the child that suggest difference or try to change them. The process of ignoring may be quite subtle, a process of neglect similar to that described by Swiss psychoanalyst Alice Miller (Miller 1981). Parental reactions help to shape and validate the expression of the needs and longings of their children; since parents more frequently reward what is familiar and acceptable to them and tend to discourage or de-emphasize behavior and needs they do not value or understand.
Dissociation and denial may become major defenses in the personality structures of such children, since they learn early that their feelings and needs are not acceptable and must be hidden or suppressed. In adolescence, their sexual feelings emerge with greater urgency, but there is rarely any context or permission for their expression. Adolescents in particular often reject and isolate those who are different and encourage conformity, which further supports denial and suppression of the emerging homosexual feelings. As a result, the adolescent who is gay or lesbian may even further split off any awareness of affect and behavior related to his or her homosexuality (Martin 1982).

When adolescents begin to recognize the source of their sense of difference—their sexual and affectional attraction to people of the same sex—they may work even harder to suppress these feelings by isolating themselves and avoiding situations that may stir up their longings. Some of these youths may devote extraordinary energy to academic or career success to cover up their underlying shame and sense of being defective; others may become depressed, isolated, guarded, and lonely, expecting to be rejected and ignored if their true feelings are revealed. Often these young people become ashamed not only of their sexual feelings, but also of their bodies, their social interactions, and other aspects of themselves. Because of personal resilience, not all gay men and lesbians have the same degree of difficulty traversing childhood and integrating a sexual identity that is generally stigmatized into a healthy personality structure.

Internalized homophobia and antigay bias combined with heterosexism are the major negative forces that gay men, lesbians, and bisexuals must deal with in our society. Almost all gay people have internalized homophobia, having been brought up in a heterosexist society that tends either to promote prejudicial myths about gay people or to ignore gay and bisexual people in general. The coming out process may be delayed or involve great difficulties depending on the intensity of internalized homophobia (e.g., by holding onto the belief that homosexuality is a sin, an illness, unnatural, evil, or will only lead to sadness, loneliness, and isolation) and may well require the help of psychotherapy.

The process of coming out to family and/or friends may be quite rewarding, but also carries the danger of outright rejection. For many gay and lesbian adolescents, the attempt to get their family to fully accept them by coming out to them has led to physical and verbal abuse, or to being thrown out of the home and running away to live on the streets (Savin-Williams 1994).

Many gay people will create their own “family,” that is, a close network of friends that serves the needs often met by traditional families. Becoming part of a couple is also an important step. Even though there are limited legal sanctions for such relationships (varying state by state and country by country), the majority of gay people are in relationships (McWhirter and Mattison 1996). Having or adopting children is yet another step many individual or coupled gay men and lesbians undertake, and there is an ever growing literature on gay or lesbian parents and the children of lesbian or gay parents (discussed below).

**Psychotherapy: Special Considerations**

Gay men, lesbians, and bisexuals will seek mental health services for the same reasons anyone might—help with emotional and social problems, treatment for mental illness, treatment for substance abuse, couples therapy, family therapy, and so on—but there are some special considerations in working with this population. Jones and Gabriel (1999) reported that gay men, lesbians, and bisexual utilize psychotherapy more than the general population, though not always satisfied with the therapist.

The higher use may have several explanations. Data suggest that gay, lesbian, and bisexual people are subject to higher rates of affective disorders and anxiety disorders (Gilman et al. 2001, Mills et al. 2004). There are psychosocial stresses related to discrimination (perceived and directly experienced) toward a sexual orientation that differs from that of the majority (Mays and Cochran 2001). And, as discussed below, substance use and abuse seems greater among gay men and lesbians than the general population (Cabaj 1996).

While sexual orientation is usually not the primary issue in most mental health situations, a mental health provider with a clear understanding of the issues facing most gay and bisexual people will be able to provide better and more sensitive care, and will not have to depend on the patient to teach the provider about gay, lesbian, and bisexual issues. A complete and thorough assessment is, of course, necessary to determine the best treatment plan, and all relevant treatment modalities—such as individual short- or long-term therapy, group therapy, psychopharmacology, substance abuse services, medical evaluations, and couples or family work—should be considered in devising the therapeutic intervention.

Most gay and bisexual patients will be quite open about their sexual orientation if asked directly, especially if the therapist sets a nonjudgmental and accepting tone. Ideally, mental health providers will not assume that all patients are heterosexual and will be careful not to use words or phrases that are heterosexist or that imply an assumption of heterosexuality. Clinics and treatment centers should review their forms and documents to eliminate statements or categories that will exclude or alienate gay and bisexual people (e.g., categories limited to “married” or “single” may not allow a gay person in a committed relationship to comfortably provide information).

Even if concerns about being gay are not part of the presenting problem, the therapist’s acknowledgment and simple acceptance of the patient’s homosexuality can be incredibly powerful and helpful, given the years of hiding and fearing rejection some gay and bisexual people experienced. Asking such people if the adjustment to their sexual orientation was difficult will not imply that the therapist sees homosexuality as pathological or problematic; rather, such inquiry can create an empathetic frame that lets patients know that they are free to talk about their sexual orientation if it is a concern, and implies that the psychotherapist can, if necessary, help provide a corrective experience to past parental avoidance or rejection by parents and others. Being comfortable taking a sexual history is essential for an initial evaluation.

The therapist will need to let patients discuss their own feelings about being gay or bisexual, and not provide quick or immediate assurances that having a different sexual orientation is not a problem; this stance may replicate the rejection of such patients’ own feelings and fears, by not allowing a discussion of self-doubts and uncertainties. Allowing an
open presentation and exploration of patients’ feelings about their sexual orientation, and how they came to recognize those feelings, will set the stage for an understanding and an acceptance based on the patients’ actual experiences.

**Issues Related to Sexual Orientation**

The problems that the patient presents may be directly related to sexual orientation, such as in seeking help in coming out, questioning whether one can change one’s sexual orientation, attempting to recognize and overcome internalized homophobia, or needing treatment for stress from a verbal or physical attack for being gay. How to accept and be comfortable with a differing sexual orientation will be the focus.

Cohen and Stein (1986) outlined seven major themes that occur frequently in therapy with most gay men and lesbians, including the impact of being different and how coming out as a unique process for each individual gay person has both positive and negative consequences on personal identity development. Successfully negotiating coming out will provide psychological tools useful in other situations. Stein (1988) further elaborated some general issues in therapy with gay men and lesbians, emphasizing how important it is for the therapist to have a solid knowledge base about homosexuality and gay men and lesbians and, in general, to be open minded and nonjudgmental.

Lesbians may have some specific issues that need to be highlighted. Compared to gay men, they are more likely to have lower incomes (as do women in general, compared with men); lesbians are more likely to be parents (about one-third of lesbians are biological parents); lesbians face the prejudices aimed at women as well as those against lesbian; lesbians are more likely to come out later in life (about 28 years of age vs. 18 years of age in men); and lesbians are more likely to have bisexual feelings or experiences (Bell and Weinberg 1978, Bell et al. 1981). According to several surveys, lesbians are somewhat more likely to be in a long-term relationship than gay man and to be parents (Jones and Gabriel 1999), so the psychotherapy with lesbians may require a focus on relationships and parenting and family concerns.

Bisexual people may also have specific concerns—often focused on feeling alienated or not accepted by either gay or straight people. How to express sexual feelings and behaviors may be a focus—single partners, multiple partners, shared complex relationships, for example, may cause the bisexual person confusion or even guilt or acting on wide-ranging sexual feelings. The married or committed bisexual person (as can also be true for a person who thought him- or herself to be heterosexual but then discovered either homosexual or bisexual feeling emerging later in life) may also need help in working with the spouse or partner and acting on sexual feelings for someone of the opposite sex.

**Additional Psychotherapeutic Issues**

**Sexual Orientation of the Therapist**

Many gay, lesbian, and bisexual patients may wish to see a therapist who is also gay, lesbian, or bisexual, believing that they can avoid the overt effects of antigay bias and more easily develop a sense of trust, safety, openness, and personal comfort with a matched therapist. Many gay, lesbian, or bisexual therapists, in turn, may hold similar beliefs that homophobia can be avoided, that a special rapport can be established quickly, and that a shared base of knowledge and experience exists when gay, lesbian, and bisexual patients and therapists work together. However, not all gay and lesbian therapists will themselves have fully dealt with their own internalized homophobia and care must be taken not to assume that the therapist’s and the patient’s coming out processes were similar.

In general, conscious awareness of internalized homophobia and parallel heterosexism is an asset for the psychotherapist treating gay, lesbian, and bisexual patients. Gay-sensitive therapy—treatment provided from a perspective that understands and accepts gay, lesbian, and bisexual concerns—and gay-affirmative therapy—treatment provided from the perspective that being gay, lesbian, or bisexual should be affirmed and that openness about sexual orientation should be encouraged—can be provided by heterosexual as well as gay, lesbian, or bisexual clinicians.

**Couples and Family Issues Including Child Rearing**

There is extensive literature on what constitutes a gay or lesbian couple and an extended family as well as on couples and family therapy with gay men, lesbians, and bisexuals (Cabaj 1988, Cabaj and Klinger 1996, McWhirter and Mattison 1984). The therapist must understand the impact of internalized homophobia, antigay bias, and the issues involved when two people of the same sex—and similar culturally determined gender role expectations—attempt to meet, bond, and establish relationships.

McWhirter and Mattison (1996) developed a stage model for gay male relationships (the stages may also apply, with some alterations, to lesbian couples, as well as to heterosexual and bisexual relationships). Briefly, the stages can be summarized and characterized as follows. Stage I: blending—marked by merging, romantic love, equalization, and high sexual intensity and activity. Stage II: nesting—marked by homemaking, compatibility, as well as ambivalence and decreased romantic love and sexual activity. Stage III: maintaining—marked by reemergence of the individual, with risk taking, increased conflicts, but establishing traditions. Stage IV: building—marked by collaborating, increasing productivity, independence, but ability to count on partner. Stage V: releasing—marked by trusting, merging of finances and possessions, as well as taking the partner for granted. Stage VI: renewing—marked by security, inward dwelling and remembering, and restoring the partnership.

This author (Cabaj 1988) proposes a four-dimensional assessment to evaluate couples and determine the best treatment intervention: assessment of each individual for those factors that determine stage in the life cycle, maturity, mental health problems, cultural factors; assessment of the gay or lesbian sexual orientation development including openness, coming out, effects of internalized homophobia; staging of the relationship, noting stage discrepancies between the partners; and assessment of other factors such as health, financial issues, children, and influences of families of origin on daily life.

In working with lesbian couples, the concept of merging is often discussed—the intense connection or even fusion of the two individuals in the relationship. Though this
phenomenon is not unique to lesbian couples, the couple’s treatment technique known as “intimacy through distancing” was developed to work with such couples (Kaufman et al. 1984). Since many gay, lesbian, and bisexual people have children, children may also have a role in therapy or may be the concern of the parents in therapy. The children in these families may be adopted or come from previous marriages or through alternative insemination or other biological arrangements. In looking at the sexual orientation of the children of such relationships and families, the children seem to develop sexual orientations that are distributed just like the general population, that is, predominately heterosexual, and they appear to have the same or even better psychological adjustment as other children (reviewed in Patterson 1995). A study (Golombok et al. 2003) indicates that children raised by same-sex couples may actually be better adjusted—more accepting of differences and more tolerant of varying forms or sexual expression—and not experience as much childhood ridicule as was speculated. Further studies are in progress, including looking prospectively and for a long term at the children of lesbian couples (Gartrell et al. 2005).

The issue of same-sex marriage has entered the arena in the last decade. While seen by many people as a religious or civil rights issue, the mental health aspects of marriage and recognized and sanctioned relationships are increasingly being recognized (Pawelski et al. 2006). Evidence shows that people in relationships, especially marriage, have increased mental health and better coping skills with issues that they will face, such as health problems and so on.

Changing Sexual Orientation
This chapter makes clear that sexual orientation is a very complex phenomenon, with probable genetic, biological, social, familial, and cultural forces in its origins and expression, and psychological and psychodynamic forces that may result from having a particular sexual orientation and the adjustment to and acceptance of it. Sexual orientation, therefore, is not a result of how someone is raised, but sexual behavior, on the other hand, and the adjustment to one’s sexual orientation is very much dependent on how and in what setting one is raised. A limited number of therapists and clergy promote treatments that attempt to change sexual orientation, often from conservative religious sectors as well as a small group of conservative psychoanalysts. These approaches are sometimes called “conversion” or “reparative therapies.” Nicolosi (1991) is a strong advocate of such approaches, describing reparative approaches and techniques.

These approaches assume that homosexuality is pathological and the result of deficient parental upbringing. Instead of exploring and understanding internalized homophobia and the consequences of antigay bias in gay and lesbian people who are troubled by their sexual orientation, advocates of such treatments take a “shame-based” approach and usually tell the patient that his or her sexual orientation is, indeed, a major problem and can be changed. Confounding gender role expectation with sexual orientation, these interventions assume that the gay man did not have enough masculine support or modeling with his father and the lesbian did not have enough feminine support or modeling from her mother.

There is very little objective data or clinical material to support such types of treatments (reviewed in Drescher and Zucker 2006). What appears to happen, as a result of such interventions, is that someone temporarily changes sexual behavior but does not change basic sexual orientation (maintaining same-sex sexual fantasies and desires) and usually returning to homosexual behavior over time. Spitzer (2003) reported results of a phone survey of people who wanted to change sexual orientation and a handful who said that they did; Drescher and Zucker (2006) focused on the extremely flawed nature of the survey and Spitzer himself has condemned the use of the study to indicate that true change in sexual orientation is possible.

Gay-, lesbian-, and bisexual-supportive therapists, in fact, report significant emotional and psychological harm from such attempts to change sexual orientation, with resulting depression, shame, anxiety, guilt, and suicidality (Haldeman 1994). Interventions that attempt to treat something that is not an illness, to try and change something that most likely cannot change, and to cause emotional harm in the process seem at best without merit and at worse unethical. All major national organizations related to mental health, including the APA and the American Psychological Association have condemned “reparative” or “conversion” therapy.

If a patient truly is troubled by his or her sexual orientation, exploration of the source of the distress and attempts to relieve the conflicts would be much more beneficial than suggesting the possibility of change. The internalized homophobia or external antigay pressure can usually be addressed in therapy and would help a patient far more than creating a deepened sense of shame and fear of acting on sexual and loving feelings.

Societal and Domestic Violence
Antigay bias at times takes the form of violent attacks on sexual minorities, or people perceived to be such. The violence may range from verbal abuse to physical assaults violent enough to result in death (Huebner et al. 2004). The attacks are reported as hate crimes in many police surveys: one review reported that up to 28% of urban gay men, lesbians, and bisexuals reported physical assault or abuse, and 50% reported some form of harassment (Otis and Skinner 1996). Survivors of such abuse will need physical and psychological care, often developing posttraumatic stress syndromes with exaggerated internalized homophobia and fears of further antigay bias (Herek et al. 1999).

In addition, people in gay or lesbian relationships are also subject to domestic violence, just as are heterosexuals. Though the topic is not well studied, one survey reported that 25% of lesbians in committed relationships have been abused (Brand and Kidd 1986), and it is estimated that 10–20% of gay men in committed relations have been abused (Island and Letellier 1991); by comparison, battering occurs in 25–33% of heterosexual couples. Domestic abuse may be further fueled by substance abuse, and is often ignored or discounted by medical and mental health providers.

Substance Abuse
Alcohol and other drugs have a major impact on the lives of many gay men, lesbians, and bisexuals. Most studies or reviews of surveys, and the experiences of clinicians
working with gay men and lesbians, estimate an incidence of substance abuse of all types at approximately 30%, with ranges of 28–35% (in contrast to a generally accepted incidence of 10–12% for the general population) (Guss and Drescher 2000). While many of the studies are methodologically flawed, it is clear from these studies that gay men and women, on average, drink more than the general population, are likely to abuse certain drugs at different points in their lives (often associated with going to particular social settings), but may not have greater drug or alcohol dependency than the general population.

The increase in substance abuse may have many explanations. Limited types of sanctioned social outlets available to gay men and lesbians make bars, private homes, or clubs where (alcohol and other drugs and prominent) play very important parts of the social fabric for many gay and lesbian people. Often, the role models for many young gay men and lesbians just coming out are gay people using alcohol and other drugs, often met at bars or parties.

For many men and women, this linking of substance use and sexuality persists and may become part of the coming out and social and personal identity developmental processes, many having had their first same-sex sexual experiences while drinking or being drunk to overcome their societally influenced internal fear, denial, anxiety, or even revulsion about gay sex. Many gay people continue to feel self-hated; the use of mood-altering substances temporarily relieves, but then reinforces this self-loathing in the drug withdrawal period.

For some gay people with high degrees of internalized homophobia, substance use may make “living in the closet,” with its built-in need for denial and dissociation possible, or serve as easy relief from guilt or other negative feelings. Alcohol and other drugs can cause dissociation of feelings, anxiety, and behavior, thereby mimicking the emotional state many gay people had to develop in childhood to survive (as described above). Thus, the symptom-relieving aspects of substance use can serve to disinhibit what are experienced as forbidden behaviors, foster social comfort in bars, and, most importantly, provide comfort through the familiar experiences of numbing, dissociation, and isolation of feelings.

Self-acceptance of one’s sexual orientation thus appears to be crucial to recovery from substance abuse. Recovery for gay and bisexual people will often depend on participation in 12-step or other self-help programs such as Alcoholic Anonymous (AA) and Narcotics Anonymous (NA), and many AA and NA groups are specifically aimed at gay, lesbian, and bisexual people.

In the last decade or more, the use and abuse of methamphetamine (also known as “speed,” “crystal,” “tina,” “crank,” and other names) has emerged as a particular problem for gay men. Though use is not exclusive to gay men (adolescents across the country and urban younger Asian and Latina women are also noted to be high users), the problem has multiple psychological and medical concerns for gay men in particular.

The use of the drug is highly associated with sexual activity and is popular at “circuit parties” where large numbers of gay men gather for partying, dancing, and sexual activity (often accompanied by drugs use) (Mansergh et al. 2001) and with men seeking sexual partners over the internet (“party and play”). Methamphetamine is experienced as heightening sexual feelings and duration of sexual activity, allowing some men to have sex for 12 hours or more. There are risks for increased exposure to HIV with multiple sexual partners and unprotected anal intercourse (sex without condoms) and injecting drug use (IV)—all of which are associated with methamphetamine use (Wainberg et al. 2006).

Many urban areas have started to address the concerns specific to gay men and some specific treatment programs are emerging for methamphetamine abusers. Contingency-management types of behavioral modifications are showing promise as successful interventions, and traditional 12-step programs are increasing with a focus specific to methamphetamine (Rawson et al. 2004).

**Chronic Mental Illness**

As noted above, depression of all types and anxiety disorders present more often for gay, lesbian, and bisexual people, but gay, lesbian, and bisexual people are most likely subject to the same rates of serious mental illness as the general population. Many programs that are specialized for the chronically mentally ill minimize a focus on sexuality and sexual activity and may only rarely address sexual orientation itself. There may be particular benefits to the seriously mentally ill gay, lesbian, or bisexual person in addressing sexual orientation—especially when it comes to issues of housing, roommate matching, vocational rehabilitation, and health interventions and education around HIV prevention—and programs that focus on the seriously mentally ill should include a focus on sexual orientation routinely (Hellman and Drescher 2005).

**Aging**

As gay, lesbian, and bisexual people age, they will face issues similar to all people moving through the life cycle. There are more studies looking at older gay and lesbian people, some pointing out that the resilience from dealing with antigay bias over the years may make it easier to cope with some of the challenges about getting older. Since many older gay, lesbian and bisexual people have faced losses of close friends in large numbers to AIDS, many such people have developed skill to cope with death and dying and grief as they get older and lose family, friends, and partners (Grossman et al. 2000).

**Suicide**

Suicidal thinking, attempts and completed suicides are major concerns for lesbian, gay, bisexual, and transgender (LGBT) people—especially for youths and young adults. All ages have been looked at for LGBT people, but most studies have focused on youth, some noting the incidents of successful suicides as high as three times the national average for that age group, and as many as 30% of gay and bisexual people may have attempted suicide (Cochran and Mays 2000, Paul et al. 2002). The increased rates of suicidality seem tied to the struggles for acceptance in the face of antigay bias and self-esteem damaged by internalized homophobia, but an additional risk factor may be the higher rates of affective disorders among LGBT people noted in studies such as Mills et al. (2004). Studies now look at both the increased incidence as well as the contributing risk factors, and interventions that may help prevent or at least lower the rate of actual suicide if not suicidal ideation itself (Eisenberg and Resnick 2006, Friedman et al. 2006).
HIV and AIDS
HIV and AIDS affect many gay men, lesbians, and bisexual men and women, either by being infected themselves or by being close to a person with HIV/AIDS. Gay men, who are depressed or suffer from damaged self-esteem and shame due to internalized homophobia, may put themselves at risk for HIV infection, consciously or unconsciously, via risky sexual practices especially under the influence of drugs or alcohol, or sharing needles (Cabaj 1998). Lesbians are also at risk for HIV infection, not only from drug use and shared needles, but from the fact that many lesbians also have sex with men. HIV-prevention efforts are mental health issues for many gay and bisexual people. Therapy with people living with HIV infection and AIDS is beyond the scope of this chapter.

Minority, Ethnic, and Cultural Issues
There are both cultural and ethnic issues involved for people of color that may make it difficult to come out or adjust comfortably to a gay, lesbian, or bisexual identity (Grov et al. 2006). Many people, especially people of color or people from a culture other than the Anglo/European-Western, who have sex almost exclusively with people of the same sex, may not self-identify as gay or even bisexual (Pathela et al. 2006). The provider may not need to worry about such labels if the patient is allowed to have open and frank discussions with the therapist or provider. Openly gay, lesbian, and bisexual people of color must often deal with bias and prejudice and stigma for racial, cultural, and sexual orientation factors, and thus present with complex social, emotional, and mental health concerns. For example, Cochran and Mays (1994) focused on the specific factors and issues for depression in African-American gay men and lesbians.

Youth
Awareness of a differing sexual orientation may occur at any point in life, but most often in childhood or adolescence. Recognizing the tremendous social pressures to conform in adolescence, and the extraordinary efforts it takes for a gay male or lesbian to be out with peers and family, will help therapists understand the pressure openly gay, lesbian, or bisexual youth may face. Gay and lesbian youth are also subject to sexual abuse or exploitation by others, often related to insecurity and reduced self-esteem. As noted, some gay, lesbian, and bisexual youth may run away and face the many stresses and risks of living on the streets (Savin-Williams 1994). The youth who stay in school and at home may also face great difficulty from the attitudes of peers, teachers, and parents (D’Augelli 1996).

Gender Identity and Transgender Issues
Gender identity, as noted above, is an independent variable from sexual orientation. The subject is often included in discussions of sexual orientation since the biases and prejudices against people who have gender identity disorder (GID) or who ultimately identify as transgender (i.e., a person of one biological sex who is contemplating becoming, living like, or undergoing sexual reassignment surgery to the opposite sex) may be similar.

GID is still included in the DSM-IV-TR, though there have been extensive reviews of the justification of such a diagnosis. The diagnosis has been helpful to some people who are undergoing biological treatments (hormone replacement or sexual reassignment surgery) since these treatments may be covered by insurance. Some transgender people and advocates of the study and treatment of gender identity concerns believe that a mental health diagnosis is prejudicial since it is not a mental illness per se but likely a biological or genetic issue. There are insufficient studies to illuminate the origins of gender discordance and identity conflict, but future DSM research agendas may address the issue.

Childhood GID is often a concern both for the youth as well as the family—often a source of confusion, embarrassment, shame when not understood by the family. Gender discordant behavior—that is, behaviors usually associated with the opposite gender of the identified youth—may be a manifestation of childhood GID, but is also demonstrated in youth who grow up to have no conflict between biological and perceived gender. In the past, some therapists urged parents to try and change the behaviors of such children with the belief that if the child could “fit in better” with peers, he or she would be better accepted (and perhaps even change the course of development of either GID and a nonheterosexual orientation similar to the hopes of the reparative therapy literature) (Green 1985). As is true with attempts to change sexual orientation, such interventions with gender discordant children result in psychological harm, shame, frustration, and possible depression and suicidality (Haldeman 1994).

Transgender can be considered a broader concept, including people who live like or become a member of the opposite sex, as well as people who wish to cross-dress or live as a member of the opposite sex, even if there is no perceived difference between biological sex and personal sense of gender. Though often described in terms of gender discordant behavior, a transgender person may look and act just as is societally expected of their biological sex, even if they are quite aware of the difference internally. Many transgender people do begin to dress and live like a member of the other sex, and some eventually seek sexual reassignment surgery. The concept of sexual orientation as independent of sexual identity is demonstrated by this example: a biological male may see himself as a woman or even had sexual reassignment surgery to become a female, and if attracted to women, would be considered to have a female homosexual orientation, and if attracted to men, be considered to have a female heterosexual orientation.

A person with a gender identity discordance may go through several stages of acceptance similar to a person who recognizes a differing sexual orientation. Recognition of the difference, acceptance of it, a decision about how to act on or live with those differences, and deciding who should know are steps all transgender people face.

There is an increasing body of literature on gender identity issues and specific studies of transgender people. Health issues have been a focus—including mental health and substance abuse. These studies indicate that transgender people may experience higher rates of depression, substance abuse, suicidality, may be greater victims of violence, and may have limited access to health care, place themselves at higher risk in sexual situations and therefore have higher rates of HIV infection and AIDS, when compared to the general population (Clements-Nolle et al. 2001, Fitzpatrick et al. 2005).
Future Efforts and Research

Many issues related to sexual orientation and the understanding of gay men, lesbians, and bisexual men and women require further study and research. A major effort is needed to provide clear, unbiased, and sensitive information about this topic to mental health and medical professionals at all levels of educational efforts. The APA has developed a series of minority curricula for psychiatric residents, and the gay, lesbian, and bisexual curriculum was the first to be published (Stein 1994).

Legal and political forces will continue to shape both the societal attitudes that influence acceptance of gay and bisexual people—and the funding available to study issues related to sexual orientation. Combating antigay bias and its resultant internalized homophobia will be enhanced more by legal protections than by education and attempts at changing social attitudes alone.

Further study and research is clearly needed on topics such as the following: the genetic and biological factors leading to the development of a gay, lesbian, or bisexual identity; bisexuality; transgender issues; substance abuse in the gay, lesbian, and bisexual community; gay, lesbian, bisexual, and transgender youth risk for suicide; people of color with sexual orientations that differ from the majority; attempts to change sexual orientation; what effects legalizing or sanctioning gay and lesbian couples may have; and, the emotional and psychological development of children of gay male and lesbian couples.

Introduction
The management of the elderly psychiatric patient involves the intersection of a number of important elements. The effects of the aging process itself must be considered, which may include reduced vigor, lessened efficiency of vital organ systems, impairments in vision, hearing, and other senses, loss of mobility, slowed cognition and other changes. Many elders suffer from significant medical morbidity, often involving multiple disease states that may have overlapping or cumulative effects. These medical issues impact mental functioning, while psychiatric illness can also have a significant effect on physical health. Problems such as weight loss, cognitive decline, sleep disturbances, and falling are important in medical geriatrics as well as geriatric psychiatry. The aging process also involves changes in pharmacokinetic and pharmacodynamic processes. Elders frequently take a large number of medications. The effects and interactions of these drugs comprise an important element of geriatric management. Both medical and psychiatric illnesses may present in altered or even atypical fashion in elders, complicating the diagnosis. Older patients and their families must adapt to new roles in the family and community, often involving increased dependence on others. Referral of geriatric patients for psychiatric care is typically made by family, other physicians, or agencies rather than self-referral. Obviously, these sources of referral have a stake in the patient's care often involving an expectation of ongoing involvement. The aging process is markedly heterogeneous, influenced by genetic influences, disease, and other factors. The increasing numbers of elders in many societies will burden health-care systems. Since the number of geriatric specialists is limited, general psychiatrists (and nonpsychiatric physicians) will be called upon to address much of this need. Sophisticated knowledge of geriatric management is particularly important for frail or very elderly patients. This chapter deals with management issues commonly encountered in geriatric psychiatry. Certain syndromes such as dementia and mood disorders are especially important in geriatric psychiatry and will be used to illustrate key elements of geriatric management.

Approach to the Patient
Social Setting
Evaluation of an elderly patient involves an understanding of his or her social setting. The patient's role in the family and community is crucial in understanding their behavior. Elders may reside at home alone or with family or other caregivers. They may also live in a variety of other settings. Those who reside in nursing or assisted living homes often face special challenges. Among these challenges are maintaining as much independence as possible while also preserving dignity and privacy. The enormous financial burden of long-term care must often be met by patients and their loved ones. Families are often intimately involved in geriatric care at every level. Families provide much of the caregiving for disabled elders, often at a tremendous physical, emotional, and financial toll. Elderly patients and their families must deal with difficult questions balancing independence with safety, often with limited personal and financial resources. Unfortunately, lack of financial resources often severely limits options for elders. Psychiatrists caring for frail or cognitively impaired elderly patients must forge an alliance with caregivers. Caregivers provide much needed data to the clinician and often carry out the treatment plan. While respecting the patient's autonomy, the psychiatrist must be sensitive to the caregiver's need for support and information.

Certain social situations are common aspects of aging. Retirement involves adjustment to a new schedule and often a change of status, especially for persons whose identity is associated with a profession. Retirement can also lead to social isolation when friendships have been work based. Marital relationships may have to find a new equilibrium. For many, retirement can bring financial hardship as well. Elders must adapt to the “empty nest” as adult children...
move out of the family dwelling and establish their own homes and families, often in a different city. For many elders the role of grandparent can bring great emotional fulfillment. However, an increasing number of elders find themselves having to assume parenting responsibilities for grandchildren or great-grandchildren.

As parents age, their adult children must also learn new roles. They must often assume decision making, caregiving, or financial responsibilities while maintaining their own families and careers. These duties can strain marriages and sometimes provoke conflict among the elder and the adult children or among the children themselves. This problem is compounded when family members reside in different locales, adding distance to the stresses involved. Increasing dependency in an elderly relative evokes powerful emotional reactions in loved ones and can be an especially difficult if the patient or family is in denial. This situation often leads to conflict among relatives over treatment planning decisions, especially when these decisions can reduce the elder’s independence.

Many elders are dependent on a web of social programs. In the United States programs such as Social Security, Medicare, or Medicaid can provide income, health insurance, and prescription drug coverage (Hoffman et al. 2005). A basic understanding of these programs and their role in the patient’s life is necessary in providing comprehensive care. Although these programs are crucial to the well-being of elders, they do not provide for a seamless system of care. For example, Medicare nursing home coverage provides only for a limited number of skilled care days. Medicaid has much more extensive nursing home coverage, but many elders (even those of limited financial means) do not qualify for Medicaid until their existing financial resources have been exhausted or “spent down.” Although Medicare is a federal program and is therefore more or less standardized throughout the United States, Medicaid is a joint federal-state program. Overall Medicaid standards are set by the federal government, but individual states determine eligibility requirements, covered services and provider types, and levels of reimbursement. Medicaid coverage can be quite variable from state to state. Other programs can contribute the well-being of elders, such as Meals on Wheels or adult day programs. Elders residing in rural areas may not have these services available. Government also has a responsibility to investigate, prosecute, and address elder abuse and neglect though adult protective services programs. The cost and accessibility of social services for elders differs dramatically in different countries.

**Functional Assessment**

Functional capacity may be affected by aging or illness. An assessment of ability to perform activities of daily living (ADL) is a crucial element of a geriatric evaluation (Resnick 1998). This functional assessment may be informal or may represent a formalized part of the evaluation requiring specialized testing. Such testing can involve referral to other physicians or specialists such as psychologists, physical therapists, audiologists, or occupational therapists. Often, the patient’s ability to care for themselves in their own environment becomes as significant as the medical or psychiatric diagnosis. When functional deficits are present, treatment planning must take them into account. Determining the appropriate level of care is largely based on functional level. Basic activities of living such as feeding or dressing one’s self are a necessary part of living alone. More advanced activities often involve using tools of some type (such as a telephone). Patients who have impairments of these more advanced functional activities may continue to struggle to maintain independence despite faltering abilities. For instance, a patient who no longer drives may not be able to continue a fully independent life. Inability to negotiate stairs may necessitate a move to a one-story home. On occasion, adaptational methods or devices can be suggested in an effort to maintain as much independence as possible. Function is also greatly influenced by the patient’s ability to see and hear. Evaluation and management of deficits in these areas can greatly improve an elder’s function and quality of life and sometimes reduce psychiatric morbidity. Impairments of gait and mobility as well as falling are common problems in geropsychiatric patients. These impairments can result from neurological or orthopedic disorders, visual impairments, cognitive loss, or some combination of these factors. A serious fall, especially if injury occurs, often leads to significant psychological effects including loss confidence or even depression. Therefore, treatment planning should involve diagnosis and management of these problems of gait and mobility.

**Cognitive Evaluation and Management**

Since cognitive decline is a common problem in geriatric care, the mental status examination should include a thorough cognitive evaluation. Minimally, this evaluation should include an assessment of immediate recall as well as short- and long-term memory. Additionally, orientation, attention, calculation, and visuospatial abilities should be examined. Speech and language functioning should be tested as should reading and writing. Also, executive abilities such as planning and problem solving should be assessed. Cognitive testing will be further discussed later in this chapter.

**Guardianship and Power of Attorney**

Cognitively impaired elders who need supervision may require a legally empowered surrogate decision maker (Kane 2001). In the United States and many other countries, this may be accomplished by action of courts through assigning a guardian to oversee and protect the interests of the elder. Such actions typically require a formal, independent evaluation followed by a hearing in which the elder is entitled to legal representation and due process. Usually, substantial cognitive impairment must be demonstrated in order for the court to assign a guardian who will continue to serve unless relieved by the court. Such court-ordered guardianships are therefore involuntary. They are a legal finding that the patient, who is otherwise entitled to a presumption of competency, is now incompetent. A guardianship cannot be established in advance, but only after this determination has been made. The judge delineates the exact limits of the guardian’s authority. The power of attorney (POA) is another pathway which can accomplish some of the same goals by a very different mechanism. A POA is a private, voluntary contractual agreement between two or more individuals in which a person is empowered to act on another’s behalf.
It is not a court order, but a form of “advance directive.” The POA must be created when the patient is sufficiently competent to understand its provisions. Therefore, after a dementia has progressed it may be too late to initiate a POA. A POA designed for health care and dementia is known as a “durable” POA. The POA document typically delineates the precise authority granted, but usually includes health care as well as financial decisions. A durable POA only becomes operative when the patient has become cognitively disabled. Although often useful, POA have limitations. For example, a patient with mild-to-moderate dementia who remains verbal and interactive may not accept a determination that they are disabled, creating doubt about the document’s applicability (Table 123–1).

**Physical Evaluation**

Management of geriatric psychiatry patients also involves a careful physical assessment (Finkel and Woodson 1997). While the psychiatrist should participate in this element of care, most patients will also require a medical evaluation by the family physician or other specialists. Ideally, the psychiatrist should communicate with these other physicians in formulating the overall plan of care. Obviously, medical illnesses common in elders such as cancer, heart disease, stroke, diabetes mellitus, COPD, and arthritis have an impact on psychiatric status. Likewise, dementia, depression, or psychosis will have a significant effect on the care of the patient’s physical disorders. The choice of medications to treat medical as well as psychiatric disorders should be a matter of discussion among specialists. For example, the anticholinergic drugs commonly used to treat bladder incontinence can have a negative impact on cognition. The drug chosen to treat psychotic symptoms may complicate care of diabetes. Increasingly, psychiatrists are expected to be aware of the intersection between psychiatric and medical management and the medical consequences of psychopharmacologic treatments. Polypharmacy is a common problem among the elderly and can only be dealt with by discussion among the various physicians prescribing for the patient. The entire medication list, including over-the-counter medications must be scrutinized. The psychiatrist should consider the possible psychiatric ramifications of each medication as well as potential drug interactions. In performing this analysis of the medication regimen, the psychiatrist should remember that patients may not take medications as prescribed for a variety of reasons. Patients may forget to take medicines, not be able to afford or obtain their drugs, or stop them because of side effects. Friends or family members may occasionally advise patients not to take prescribed medication. Patients may also save medications from previous episodes of illness, or receive medications from friends or family members. Communication among specialists is also necessary in the evaluation and management of several syndromes that are especially common in elderly patients. For instance, unexplained weight loss can be an indicator of carcinoma, depression, or dementia. Insomnia is also very common in elders and can be related to a host of problems. Psychiatric problems such as depression, dementia, or substance abuse, sleep disorders such as sleep apnea, pain syndromes, or medical problems such as nocturia can all contribute to insomnia.

**Multifactorial Approach to Geriatric Assessment and Management**

Psychiatrists caring for the elderly must take a multifactorial approach, developing an appreciation for the psychosocial and developmental as well as medical issues in caring for their elderly patients. This approach must be respectful of the special needs of elderly patients yet not be patronizing. The evaluation process involves collecting information not only from the patient but also from other physicians, the medical record, and family members. Frequently, consultation with psychologists, occupational therapists, social workers, physical therapists, and other medical specialists may be required. The psychiatrist plays the role of coordinator of the mental health team. Many geriatric illnesses are chronic and require a strategy of coping and improved quality of life rather than cure. This type of approach requires patience as results unfold over the long run. Some older patients are uncomfortable with psychiatric labels and psychiatrists. These negative attitudes may be a reflection of the societal beliefs of the patient’s formative years. Psychiatrists should be sensitive to this self-stigmatization and be prepared to educate the patient and family.

In the United States, elders comprise more than 10% of the population. This percentage is expected to grow in the US and many other societies as the “baby boom” generation ages and life expectancy increases. Those over the age of 85 years are the fastest growing segment of the elderly population as well as the group with the greatest medical and psychiatric morbidity. It is unlikely that there will be sufficient geriatric psychiatry specialists to provide care to all these patients. General psychiatrists will need to fill much of this need.

**Management of Dementia**

**Evaluation of Dementia**

Dementia may be defined as a syndrome of persistent, acquired cognitive deficits sufficient to affect function. Dementia is an increasingly important and prevalent problem as the number of the elderly increases, especially those over the age of 85 years who are at highest risk. Although advancing age is a risk factor, dementia is never
considered to be merely a part of normal aging. Dementia requires thorough assessment as a prelude to management (Table 123–2). Although fully reversible cases are rare, dementia evaluation requires a careful assessment designed to identify potentially treatable medical problems which may contribute to cognitive impairment. The initial workup includes a complete blood count (CBC), chemistry profile (such as a comprehensive metabolic profile), thyroid profile, and vitamin B12. Most clinicians consider neuroimaging with head CT or MRI advisable as part of the initial evaluation. A variety of other tests may be ordered depending on the history and clinical findings such as electroencephalography, A variety of other tests may be ordered depending on the history and clinical findings such as electroencephalography, electrocardiogram (ECG), urinalysis, sedimentation rate, or folate level (Table 123–3). Occasionally, screening for heavy metals or inflammatory conditions such as systemic lupus erythematosus may be required. Lumbar puncture may rarely be indicated if meningitis or encephalitis are suspected [American Psychiatric Association (APA) 1997, Spar and La Rue 2006a, 2006b]. PET scanning is not routinely performed today, but may be useful in distinguishing Alzheimer’s disease (AD) from frontotemporal dementias such as Pick’s disease in certain cases. In the future, PET or MRI may play a greater role in dementia assessment as promising new technologies make it possible to visualize amyloid deposits, which cannot be done with currently available neuroimaging (Petrella et al. 2003).

AD has sometimes been described as a diagnosis of exclusion. By ruling out identifiable medical causes of the syndrome, AD would be left as the likely diagnosis. However, current approaches to diagnosis focus on “ruling in” the disorder by identifying the characteristic clinical presentation and course of AD, which are somewhat distinct from other dementias. Also, since Alzheimer’s can coexist with other disease states, identifying other potential causes does not rule out AD. AD usually involves an insidious onset and gradual progression, typically over a period of years. Short-term memory impairment is a hallmark of AD. Diagnosis of AD involves interview and mental status of the patient as well as information from other informants, since AD is also characterized by a lack of awareness of the illness (APA 1997). In some patients, distinguishing the type of dementia is problematic. Individual patients may present atypically or several brain diseases may coexist (for example, AD with vascular lesions or Lewy bodies).

**Cognitive Assessment**

Assessment of dementia requires an evaluation of memory including immediate recall, short-term memory, long-term memory, and other memory functions. Speech and language are often impaired in dementia and should be characterized. Dementia evaluations also require an assessment of praxis, visuospatial ability, attention and concentration, and calculation. Executive functions such as planning and problem solving are often impaired in dementia and should also be assessed. ADL are progressively impaired in dementia. Neurovegetative functions such as sleep and appetite are usually affected by dementia as are neuromuscular functions such as gait and balance. These elements also require delineation. Psychiatric and behavioral symptoms are also quite common in dementia and will be discussed separately.

Brief cognitive rating scales are often used for screening purposes and to track the progress of the disease. The best-known scale is the mini-mental state exam (MMSE). The MMSE is a 30-point test of basic cognitive skills that measures orientation, immediate recall, short-term memory, attention, and concentration. It features questions on basic language, reading, writing, and following directions. The patient is also given a figure of two overlapping pentagons to copy (Folstein et al. 1975). Although relatively easy to learn and administer, the MMSE has some limitations. For example, the questions are limited to several cognitive domains and do not address ADL, neurovegetative symptoms, or behavioral aspects of dementia. Patients who receive a similar score may actually have answered individual questions quite differently. Highly intelligent or educated patients may continue to achieve a relatively high score despite having early dementia. The MMSE is difficult to administer and interpret for individuals with limited education, language proficiency, or motivation. Likewise, vision or hearing deficits limit the effectiveness of this test. The MMSE may overestimate cognitive deficits in such patients. For these reasons, the MMSE is neither sensitive nor specific enough to stand alone as a diagnostic instrument. A variety of alternatives to the MMSE have been devised in an effort to find a faster and more reliable measure, but any brief test of cognition involves some limitations. For the clock drawing test (Brodaty and Moore 1997), the patient is usually asked to draw the face of a clock including the numerals and hands to indicate a certain time. Several scoring methods are utilized, but typically the patient receives a point for drawing a closed circle, a point for including all 12 numbers, a point for placing the numbers correctly, and a point for putting the hands in the correct location. Thus, 4 is a perfect score. Any score less than 4 should arouse suspicion while a score of less than 3 is clearly pathological. The Mini-Cog test also involves four possible points. The patient is given a three-item recall task as well as a clock. In this test, one
point is received for each item correctly recalled and one point for a correct clock (Borson et al. 2000).

Impact on Caregivers
Management of dementia requires an understanding of the impact of the illness on the patient’s caregiver and entire family. Caring for the AD patient requires support, advice, and education for the caregiver as well. Helping the family understand and accept the illness is an important role of the psychiatrist. They often require practical advice on topics such as driving, behavior management, ADL, and timing of placement in a nursing home or other facility. Making the diagnosis as early in the disease process as possible is valuable not only for pharmacologic management, but also enables the patient and family to discuss issues such as estate planning, powers of attorney, nursing home placement, and end-of-life care while the patient is cognitively able to participate (McCurry 2006).

Driving and Dementia
Driving is a significant problem for dementia patients and their families. A few states have enacted laws restricting driving in patients diagnosed with AD or other dementias. However, at present most states have no such legislation. While patients with mild dementia can often continue to drive, moderate-to-severe dementia patients clearly have a higher risk of accidents and should not drive. Some patients may continue to drive if they can observe restrictions such as driving only during the daytime and in good weather, driving only in familiar areas and limited distances, and avoiding expressways. Some communities have evaluation programs designed to test drivers suspected of cognitive impairment. Many dementia patients resist giving up driving. They may fear loss of independence and may also fail to recognize their own illness. In such cases, the physician may have to take action to limit the patient’s driving (Spar and La Rue 2006a, 2006b, Wang et al. 2003).

Pharmacologic Management
Cholinesterase inhibitors (CIs) are widely used in the symptomatic treatment of AD. CI are typically prescribed early in the course of the disease and maintained as long as there are apparent benefits. The decision to stop CI is made on an individual case basis taking into account the degree of progression of illness, side effects, cost, and goals of treatment. While CI are prescribed primarily for cognitive benefits, they may also help behavioral symptoms, maintain functional abilities, delay nursing home placement, and reduce caregiver burden. However, the effects of CI are generally modest. Goals of treatment with CI include improvement, stabilization, or slower than expected decline.

Establishing the effects of CI may take several months of therapy and be difficult to quantify for an individual patient. While indicated by the Food and Drug Administration (FDA) for AD, CI are also sometimes prescribed for mild cognitive impairment or other forms of dementia. CI are believed to work primarily by blocking acetylcholinesterase in the brain, thereby increasing levels of the neurotransmitter acetylcholine, which is believed to be important for memory function. The three currently utilized CI (donepezil, rivastigmine, and galantamine) vary slightly in exact mechanism but are generally similar in clinical response. CI are not believed to influence amyloid plaques, neurofibrillary tangles, atrophy, or other basic manifestations of the disease. While generally well tolerated, CI may have a variety of side effects that primarily involve, cholinergic functioning. The most common side effects include gastrointestinal effects such as nausea, vomiting, and diarrhea. Less common side effects include muscle weakness, bradycardia, loss of appetite, and sleep or dream disturbance. CI should be used with caution in patients with a history of bleeding peptic ulcers (Takeda et al. 2006).

Memantine is an antagonist of the N-methyl-d-aspartic acid (NMDA) glutamate receptor and is believed to modulate neurotransmission. Clinically, memantine is indicated for moderate-to-severe dementia of the Alzheimer’s type (Reisberg et al. 2003) and is occasionally prescribed for other forms of dementia. Although its mechanism is quite distinct, the clinical effects of memantine are roughly similar to those of CI, including modest, symptomatic effects on cognition and behavior rather than curative or true disease-modifying effects. Memantine can be used alone or in combination with a CI. Evidence of a synergistic effect was found in a study of moderate-to-severe AD in which patients being treated with the CI donepezil were also given memantine (Tariot et al. 2004). The side effects of memantine are usually mild and may include constipation. Rarely, patients can experience increased confusion.

A variety of other treatments have been proposed for AD and other dementias. At present, none have been clearly shown to be beneficial. Antioxidants such as vitamin E have been widely discussed. One study of high-dose vitamin E showed benefit in function though not cognition (Sano et al. 1997). However, high doses of vitamin E have also been linked to negative health effects including increased cardiovascular mortality. Early studies of estrogen as well as nonsteroidal anti-inflammatories showed much promise, but subsequent research has not been confirmatory. More recently statins, oral hypoglycemics, lithium, and other medications have been proposed as preventives or treatments in AD but remain investigational. A variety of new medications are in development, including several types of antiamyloid drugs. At present, only the CI and memantine are clinically available. There is no known prevention for AD. Some authors have proposed increased mental or physical activity (Verghese et al. 2003, Larson et al. 2006). Dietary approaches such as red wine, antioxidant-rich diets, the “Mediterranean” diet (rich in fish, olive oil, and whole grains and low in saturated fat) have also been proposed (Scarmeas et al. 2006). Some authors have suggested a link between vascular disease or type II diabetes and AD. According to this viewpoint, managing blood sugar and vascular risk factors such as hypertension and lipids might be helpful in reducing the risk of AD (Haan and Wallace 2004).

Medical Comorbidity and Dementia
Many dementia patients have comorbid medical problems requiring care. Intensive medical evaluations and aggressive therapies for such conditions usually require a motivated and cooperative patient who can participate in his or her own care. As cognition declines, such an approach becomes quite difficult to apply. In advanced dementia, a palliative-care approach to management of pain and comorbid medical conditions may be appropriate. This approach emphasizes
relief of suffering and psychosocial support for the patient and family rather than intrusive or extensive medical interventions. Palliative care, along with hospice, have gained considerable acceptance in the medical community as well as the community at large. However, these approaches have been utilized primarily for those with terminal medical conditions such as AIDS or cancer. In recent years, some psychiatrists as well as palliative-care specialists have become interested in applying this approach more widely to dementia (Harris 2007). Most dementias can be thought of as terminal diseases, since the patient will continue to decline and will not recover.

Management of Behavioral Disturbance in Dementia

Clinical Presentation of Behavioral Disturbance

The great majority of persons with dementia suffer from some form of psychiatric or behavioral disturbance during the course of their disease (Cummings 2005, Lyketsos et al. 2000). Up to 50% are believed to suffer from psychotic symptoms including delusions or hallucinations. Despite these problems, behavioral disturbance in dementia (BDD) has not been a major focus of psychiatric research. Behavioral disturbance contributes greatly to reduced quality of life for the patient, their caregivers, and those around them. Hospitalization and placement of the patient in a long-term care facility is often prompted by BDD. Therefore, BDD drives much of the cost of caring for demented patients. As the problem becomes more prevalent, the most severely disturbed patients move back and forth between the hospital and nursing homes in a new form of “revolving door.” In the typical nursing home approximately 50% of patients suffer from dementia. Nursing homes are becoming de facto psychiatric facilities in the management of BDD, a role they are ill suited to play.

Virtually any psychiatric symptom can occur in BDD. Complex combinations of symptoms are common, which evolve over time. These symptoms may or may not resemble typical psychiatric syndromes. In early or mild dementia, anxiety or mood symptoms frequently occur. These symptoms may actually predate the onset of diagnosable memory symptoms of dementia. As dementia progresses through its stages, the earlier symptoms may persist while new symptoms develop.

Moderate dementia is often a challenging period in the management of BDD. Wandering, sleep disturbances, agitation, aggression, and combativeness may begin. Yelling or other vocalization syndromes present significant challenges in management (e.g., chanting, repeatedly asking the same question). Psychosis often begins and usually includes an element of paranoia, often focused on the caregiver or those nearby. When patients no longer recognize loved ones, the paranoia may take the form of delusions of impostors (Capgras syndrome). Hallucinations are less common but may be noted in Lewy Body and other parkinsonian dementias as well as delirium. Hallucinations are predominantly visual. Because of memory disturbance, confabulation, and communication deficits, psychosis can be difficult to diagnose in dementia patients. As dementia progresses, sleep usually becomes more erratic. Patients may not perceive this as a problem, but it is a significant issue for caregivers. Some patients become more agitated or psychotic later in the day or at night, a condition known as “sundowning” (Bachman and Rabins 2006). Disinhibition and inappropriate sexual behaviors may also occur. In late-stage dementia, agitation and aggression may be ongoing problems. Apathy, refusal of care, and eating problems may occur. In addition, behavioral patterns typical of infancy or childhood may reemerge (such a “shadowing” or following the caregiver and becoming distressed if the caregiver is not present).

Etiology of Behavioral Disturbance

The etiology of BDD is not well understood. It is almost certainly a heterogeneous, multifactorial problem. Preexisting psychiatric illness such as affective disorder, schizophrenia, or substance abuse may be a contributing factor in some cases. Some symptoms, such as anxiety, may be a direct result of cognitive loss. Dementia frequently contributes to stressful life situations such as loss of independence and nursing home placement. Dementia patients often deal with such stressors by acting out behaviorally. Many symptoms undoubtedly follow as a direct result of neurodegeneration. Dementia leads to changes in neurotransmitter function in key systems that impact thinking and behavior (such as acetylcholine, norepinephrine, dopamine, glutamate, and serotonin). Delirium from comorbid medical conditions or medication frequently contributes to BDD. Pain or physical discomfort can also contribute to problem behaviors, complicated by the patient’s difficulty in communication (Desai and Grossberg 2001).

The treatment of BDD must follow from a careful assessment of the patient. This assessment must include screening for medical conditions, which may be a source of delirium or pain. The entire medication list should be scrutinized, including over the counter medications. Polypharmacy is common among elderly patients and is frequently a source of confusion or behavioral disturbance. Dementia patients are particularly prone to negative effects from anticholinergic medications. Benzotropine, tricyclic antidepressants (TCA), hydroxyzine, and many others have significant anticholinergic effects. In addition, the patient’s environment may be an important factor in the development of BDD (Desai and Grossberg 2001).

Delirium and Dementia

Delirium frequently complicates dementing disorders and can be source of additional confusion, agitation, or psychosis. Such a delirium can be subtle and difficult to recognize against the backdrop of dementia. Even relatively minor medical problems such as a urinary tract infection may provoke a delirium in a dementia patient. Often the delirium occurs in the context of multiple medical problems. Medications, particularly anticholinergic medications, sedatives, or polypharmacy may also be source of delirium. Management of delirium primarily involves treating the underlying disorder or disorders. Prolonged or severe delirium may be a poor prognostic sign, indicating a failing ability of the organism to cope with stress (Casey et al. 1996).

Nonpharmacologic Management

Nonpharmacologic management of behavioral disturbances should be considered as the initial approach, and should be
physicians must be aware of the heightened requirements for documentation of the rationale for treatment and monitoring for adverse events. Informed consent is required, usually involving a surrogate rather than solely the patient (Barret et al. 2002).

The choice of a pharmacologic agent is largely empirical. The clinician attempts to match the drug to the target symptoms to be treated. However, medication effects are often nonspecific and highly variable among patients. The drug should be initiated at the lowest dose and gradually escalated to the dose required to manage the symptoms. Most BDD patients will be managed with low doses of medication, but individual patients may require higher levels. Polypharmacy should be minimized. The clinician must be alert to the possibility of side effects that may be obvious (e.g., sedation, extrapyramidal symptoms, ataxia) or subtle (e.g., apathy, swallowing difficulties). BDD patients are at risk for treatment-induced akathisia or delirium, which may be mistaken for the symptoms of the BDD itself. Patience is required, as the full effects of a new medication may take many weeks to be fully manifest. The overall goal of treatment is improved quality of life for the patient and caregivers rather than “cure” of the disease. Sedation is rarely a goal of treatment and typically reduces quality of life. Instead, reduction of agitation without undue sedation is desirable. Polypharmacy, rapid dose titration, and frequent medication changes can all contribute to poor outcomes (Maher 2004).

Medication management in BDD presents significant ethical challenges. At times, the interests of patients may not be identical to those of caregivers or others. For instance, providing sedation for sleep enables the caregiver to rest even though the patient may not perceive this as a problem. The nature of dementia often prevents the patient from participating in such discussions (Kim et al. 2005).

Pharmacologic management of BDD requires careful, ongoing monitoring. Behavioral symptoms evolve over time, requiring change in medication therapy. Especially close monitoring is required after initiation of a new treatment or dose change. Once patients have been stabilized, patients should be seen at regular intervals. Medications should be reviewed approximately every 3 months. When symptoms abate, consideration should be given to tapering and eventually stopping psychiatric medication.

### Alzheimer’s Medications and Behavioral Disturbance

CIs as well as memantine have been shown to affect behavior as well as cognition in patients with AD. These effects have been identified in a wide range of BDD symptoms. Generally, symptoms of BDD are lessened in AD patients taking these medications. Symptoms of BDD may be less likely to emerge in treated patients (treatment emergent effects). However, for patients who already have significant BDD these medications are usually not sufficient. Overall, the effects of these medications on symptoms of BDD are worthwhile but relatively modest. The CIs galantamine and rivastigmine are indicated for mild-to-moderate AD while donepezil is indicated for mild, moderate, or severe disease. Memantine is indicated for moderate-to-severe AD and may be used alone or in combination with a CI (Cummings et al. 2006, Cummings et al. 2006).

continued in the event medications are required (Table 123–4). A variety of interventions can be utilized. After identifying and quantifying the behavior to be addressed, the first step is to identify any environmental or interpersonal triggers that contribute to the behavior. Such triggers might include conflict with a caregiver or roommate, too much or too little stimulation, or variations in the daily schedule. At times, the behavior is reinforced by the responses of others. Dementia patients typically do best with a calm, orderly environment. A predictable schedule helps the patient maintain appropriate behavior. Some patients respond to alterations in the schedule with significant agitation. Since dementia patients cannot comprehend multistep commands, it is necessary to break tasks down into small components. The caregiver should try to “depersonalize” the dementia-related behavior and not respond emotionally. Rather than confrontation, which is rarely productive, dementia patients respond better to reassurance and distraction with alternative activities. A patient approach, respecting the patient’s need for time and space, will typically provoke much less agitation than a more forceful tone. Many dementia patients have a need to wander and will be less agitated if a safe wandering space is available (Cohen-Mansfield 2001, Teri et al. 2002).

### Pharmacologic Management of Behavioral Disturbance

Dementia patients suffer from many symptoms, usually in the context of an incurable disease. Treatment will not be able to address many of these symptoms. Therefore, it is important to have a specific goal or goals in mind when initiating treatment. Since the disease provokes strong emotional reactions in caregivers and often precipitates conflict over diagnosis or treatment, it is useful to try to achieve some consensus among key persons in determining the goals and means of treatment. It is often helpful to choose one or more “target symptoms.” These should be symptoms that are amenable to pharmacotherapy. In most cases, reducing the intensity of symptoms is a more realistic goal than complete eradication of a behavioral problem. Some means of quantifying the symptom and response is also necessary as the caregivers’ impressions may be at odds with one another and greatly influenced by their emotional responses to the patient’s illness. Medication therapy is best regarded as an adjunct to nonpharmacologic treatments that focus on modifying the patient’s environment (Maher 2004).

The US Food and Drug Administration (FDA) does not currently indicate any medication for BDD. Therefore, pharmacotherapy for BDD is off-label (other than dementia-specific drugs such as CIs and memantine). In such situations,
Antipsychotic Medications in Dementia

The "atypical" antipsychotics were introduced beginning in the 1990s and have largely supplanted the older "typical" or conventional antipsychotic medications. These older drugs (such as haloperidol and chlorpromazine) were noted to cause parkinsonian side effects such as rigidity and tremor. The designation "atypical" refers to the relative lack of these extrapyramidal side effects (EPS) with these medications. The atypical antipsychotics include risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, and paliperidone. Atypical antipsychotics have arguably become the most widely utilized type of medication for BDD (Table 123–5).

Alexopolous et al. (2005).

A number of studies have shown modest efficacy with reasonable tolerability for atypical antipsychotics in BDD. Many of these studies were small scale and open label in design. However, a small number of placebo-controlled trials have been published. For example, a 6-week study of olanzapine in dementia revealed efficacy for 5 or 10 mg doses but worsening of behavior at 15 mg per day (Street et al. 1998). A 12-week study of risperidone showed dose-related improvement in psychotic symptoms and agitation, but also revealed greater levels of EPS at higher doses up to 2 mg per day (Katz et al. 1999). A 52-week open-label study of quetiapine in elderly psychotic patients (with a mixture of diagnoses) revealed overall benefit as well as good tolerability with a mean dose of 138 mg per day (Tariot et al. 2000). Tariot et al. (2004) reviewed the literature and concluded that atypical antipsychotics in general are efficacious for agitation in dementia (with a less clear impact on psychotic symptoms) but have varying tolerability. Sink et al. (2005) reviewed the literature and concluded that treatment with olanzapine or risperidone leads to modest but significant reductions in behavioral symptoms. Sink also concluded that psychiatric medications as a group had limited efficacy, with perhaps the best results for the atypicals. Schneider et al. (2006) performed a meta-analysis of all 16 published placebo-controlled trials of atypical antipsychotics in dementia. They concluded that aripiprazole and risperidone showed efficacy, but not olanzapine. They also found smaller effects for outpatients (who were presumably less ill), those with less severe dementia, and those with psychosis. The overall dropout rate of about a third did not differ between subjects on active treatments and placebo. Adverse events were typically somnolence and urinary tract infection or incontinence across all drugs. EPS and gait disturbances were found with risperidone and olanzapine, but there was not increased injury, falls, or syncope. Cognitive scores were worse in patients on atypicals versus controls. There was an overall increased risk of cerebrovascular adverse events (CVAE), especially with risperidone.

Recently, the CATIE-AD, a large, double-blind, placebo-controlled study showed limited efficacy and generally poor tolerability of atypical antipsychotics in dementia (Schneider et al. 2006). The methodology of CATIE differs from most previous psychopharmacologic trials in using duration of treatment as the primary outcome measure (i.e., how long did the clinician and patient choose to maintain a particular medication). The study included olanzapine, risperidone, and quetiapine as well as placebo. Time to discontinuation for lack of efficacy favored olanzapine and risperidone over quetiapine and placebo. Time to discontinuation due to adverse effects favored placebo. There were no differences among the groups on the CGIC (Clinical Global Impression of Change), a rating scale measure of effectiveness. The authors concluded that “although the atypical antipsychotics were more effective than placebo, adverse effects limited their overall effectiveness, and their use may be restricted to patients who have few or no side effects and for whom benefits can be discerned.” Despite these results, it appears clear that individual patients may benefit from atypical antipsychotic therapy. The impact of BDD on quality of life is often so great that these risks are deemed acceptable given the benefits in these cases. Some authors have suggested that patients with risk factors for stroke, early development of side effects, the “old-old” (over the age of 85 years) and the frail are at greatest risk of negative effects from atypical antipsychotics.

In 2003, 2004, and 2005 the FDA issued several “black box” warnings addressing the use of atypical antipsychotics in dementia and suggesting caution in their use (U.S. Food and Drug Administration (2003/2004/2005). These warnings were issued to the medical community and the public in the form of advisories and also mandated labeling changes in the package inserts of the affected medications. The initial warning cited an increased risk of cerebrovascular adverse events such as stroke or transient ischemic attacks in patients treated with risperidone and olanzapine. The magnitude of the increased risk was estimated at roughly two- to three-fold. Later, aripiprazole was added to the warning. This FDA review was prompted in part by an Australian study of risperidone (Brodaty et al. 2003), which showed efficacy but an increased risk of CVAE in dementia patients. An additional warning published in 2005 (U.S. Food and Drug Administration (2003/2004/2005) addressed increased mortality (from all causes) in demented patients treated with atypicals as a class. This warning followed an FDA meta-analysis of all 17 placebo-controlled atypical trials available at that time, involving four different atypicals. This analysis revealed the death rate from all causes (principally cardiovascular diseases and pneumonia) to be 1.6 to 1.7 times higher among patients taking active drug versus placebo. These concerns come amidst other controversies surrounding the atypical antipsychotics, particularly their propensity to cause weight gain and increase the risk of type II diabetes and other metabolic problems. The FDA has also addressed these concerns with changes in labeling that are not specific to dementia patients. The methodologies used in determining these risks have been controversial. Nevertheless, these warnings are part of the FDA labeling of all atypical antipsychotics. These warnings, combined with the lack of an FDA indication, necessitate a special focus on documentation, informed consent, and monitoring for all dementia patients taking atypical antipsychotics. Ironically, the older, the so-called “typical” antipsychotics have not received a similar black box
warning despite abundant evidence that they have greater risks than the atypicals. A 2005 study revealed risks of death for dementia patients treated with conventional (typical) antipsychotics to be at least as great as that for atypicals. The authors advised against returning to the use of the conventional antipsychotics as a replacement for the atypicals (Wang et al. 2005).

Mood Stabilizers in Dementia
Mood stabilizers such as valproic acid (divalproex) have long been used to treat BDD, especially for agitation, aggression, mood lability, disinhibition, and manic-like symptoms. Studies of valproic acid have revealed a mixed picture. Several studies have shown benefit, but a large placebo-controlled study of nursing home patients failed to do so (Tariot et al. 2005). A meta-analysis of valproic acid in dementia concluded limited efficacy at low doses and problems with adverse effects at higher doses (Loneragan et al. 2004). Another review of the literature on divalproex revealed a conflicting picture of controlled trials with three studies showing some limited benefit while another did not (Porsteinsson 2006). Sink et al. (2005) concluded that the literature did not support the use of valproate. Carbamazepine showed modest but conflicting results in several studies, but concerns persist over its tolerability and side effects. Several reports have suggested some utility in managing sexually aggressive symptoms (Sink et al. 2005). Other anticonvulsant mood stabilizers have been used anecdotally. Lithium has not been well studied in BDD, but has generally been regarded as poorly tolerated in this population.

Antidepressants and Dementia
Antidepressants have been used to treat depressive symptoms, anxiety, and agitation in dementia. Older studies showed benefit for trazodone, especially for sleep. Several selective serotonin reuptake inhibitor (SSRI) including sertraline and citalopram have shown benefits in clinical trials. These drugs have shown some efficacy for depressive symptoms, anxiety, and modest evidence of utility in agitation in some studies (Pollock et al. 1997, 2002). Verbal aggression responded to citalopram in several small-scale studies. Other antidepressants including mirtazapine have been widely utilized though not thoroughly studied. Mirtazapine is sometimes used as a sleep or appetite aid (Watson and Steffens 2004). TCA should be avoided, primarily because of their anticholinergic properties.

Benzodiazepines
Benzodiazepines have been widely utilized in the treatment of BDD despite admonitions against their use. Anxiety, agitation, and sleep disturbances are common reasons for the use of benzodiazepines. They may be given orally or by injection. Recent concerns about atypical antipsychotics may have contributed to renewed interest in this class of medications. Objections to the use of benzodiazepines in elders include sedation, ataxia, falls, cognitive clouding, dependency, and paradoxical excitation. Despite these concerns, the use of benzodiazepines in BDD has not been well studied. Long-acting benzodiazepines such as lorazepam, chlordiazepoxide, or clonazepam have been shown to be poorly tolerated in elders. Generally, clinicians prefer short-term use of shorter acting drugs with few active metabolites, such as lorazepam or oxazepam. Sleep problems in dementia are common and persistent. Benzodiazepines or other hypnotics such as zolpidem have been used clinically. Benzodiazepines may occasionally prove useful in the treatment of catatonia, which can mimic or complicate dementing disorders (Alisky 2007). Melatonin has been used anecdotally, and melatonin agonist agents may prove useful, but have not been systematically studied in dementia. Buspirone, a nonbenzodiazepine antianxiety agent, has also been used in dementia but seems to have limited utility.

Summary of Pharmacologic Management of Dementia
Since cure is not possible, the treatment of BDD should focus on maintaining and improving quality of life for the patient as well as the caregivers and those around them (Burke and Morgenlander 1999). Environmental triggers should be identified and nonpharmacologic approaches considered before medication is prescribed. Frequently, these approaches are used alongside pharmacologic approaches. The treatment flows from a careful assessment considering preexisting psychiatric illnesses, current medications, and possible delirium or pain. The spectrum of symptoms needs to be identified and a target or targets for treatment identified. Pharmacotherapy then focuses on managing these targets, using some objective means of outcome measurement wherever possible. The Alzheimer’s medications including CIs and memantine can be useful in reducing symptoms. Informed consent (usually from a surrogate) should be obtained, keeping in mind the lack of FDA indication for psychiatric drugs in BDD, the nonspecificity of patient responses, and the concept of risk-benefit analysis. Use of multiple psychiatric medications should be avoided whenever possible. Psychiatric medications require close monitoring and a high index of suspicion for adverse effects, which can negatively impact quality of life. As the dementing illness progresses, the medication requirements evolve over time. Avoidance of anticholinergic medications deserves special emphasis.

The atypical antipsychotics have become a special area of controversy because of their wide use as well as ongoing concerns over limited efficacy, mortality, and side effects. Recent changes in labeling including FDA-mandated black box warnings have heightened these concerns. Although they continue to be prescribed, a clear consensus for how to utilize them is lacking. However, many BDD patients have serious behavior problems that have not responded to other measures and some individual patients have benefited from atypicals. Alternative treatments also have limited efficacy and potential side effect issues. In this setting, it might be prudent to limit antipsychotics to cases who have not responded to other treatments or have significant physical aggression or combativeness. The presence of demonstrable psychotic symptoms would seem to be a logical rationale for the prescription of these medications, although clinical trials have yet to show convincing evidence of their utility.

Management of Depression in the Elderly
Clinical Presentation of Depression in the Elderly
Depression is a common disorder among the elderly, especially those with significant medical illness or in long-term
care. Management of depression begins with recognizing the disorder and establishing the diagnosis. However, depression in the elderly is often overlooked in the context of physical symptoms or rationalized as a normal response to loss or aging (Charney et al. 2003, Katz 1996). The diagnosis may be further obscured when the patient presents with multiple diffuse symptoms, weight loss, or preoccupation with bodily functions (e.g., constipation, pain, insomnia, fatigue). Depressed elders may focus on anxiety rather than sadness. Some elders (especially men) may feel stigmatized by a psychiatric diagnosis, and resist being labeled as depressed (Cooper et al. 2003). Loss of function is also an important concern in the assessment of geriatric depression (Koenig and George 1998). Depressed elders may withdraw from activities and even become bedridden. Such patients can exhibit exaggerated helplessness, dependency, and negativism that can reach psychotic proportions. The degree of functional impairment in depressed elders can be similar to that seen in a serious medical illness (Casey 1994, Alexopolous et al. 1996, Unutzer et al. 1997). Diagnosis is also complicated when symptoms such as insomnia, low energy, and loss of appetite or weight could be explained as symptoms of either a comorbid medical disorder or depression. When depression is suspected, geriatricians generally “count” such symptoms toward the diagnosis, even when they may be multiply determined. Although major depression is obviously the most significant issue, elders have a high prevalence of lesser, but still important types of depression. The term “minor” depression has sometimes been used to describe this group. These patients may suffer from adjustment disorders, dysthymia, depression related to medical illness or other conditions that are disabling yet do not meet the full diagnostic criteria for major depression (Beekman et al. 1997, Lavretsky and Kuman 2002).

Loss and grief are virtually universal in the lives of elders and can be triggers for clinical depression. In fact, social isolation and loss are important risk factors for elder depression. Depressive illness must be distinguished from normal grief. Functional impairment in grief usually improves over a period of several months. After the first few weeks, sad mood in grief usually comes in waves. Prolonged, persistent sadness, especially coupled with hopelessness, guilt, or thoughts of death or suicide suggests the advent of an episode of clinical depression (Casey 1994, Serby and Yu 2003).

### Geriatric Depression and Medical Comorbidity

Geriatric depression often occurs in the context of significant medical morbidity such as stroke, cancer, chronic lung disease, arthritis, or Parkinson’s disease (Ranga et al. 2002). Depressed elders have a higher overall mortality than their peers (Black and Markides 1999, Schulz et al. 2002). Depressed, medically ill elders present a much greater burden on their caregivers (Sewitch et al. 2004). Geriatric depression is particularly prevalent in primary-care practices (Cronin-Stubbbs et al. 2000, Unutzer et al. 2003). Ischemic heart disease has a complex relationship with depression (Ariyo et al. 2000). These illnesses may not only coexist, but also interact in important ways. For example, depression commonly follows myocardial infarction (MI) and can increase post MI mortality. Medications prescribed for medical illnesses can also have effects on mood. Corticosteroids, antineoplastics, anti-parkinsonian drugs, metoclopramide, alpha interferon and others can contribute to depression. Some drugs cause fatigue or loss of appetite that can be confused with clinical depression. Depressed elders are heavy utilizers of general medical care (Katon et al. 2003, Lebowitz et al. 1997). A significant number of their doctor visits are for physical symptoms actually related to depression. Just as physical symptoms may be related to depression, depressive symptoms may be an indication of a physical disorder (Penninx et al. 1998). Assessment of depressive symptoms in an elderly patient requires a thorough medical work-up. Neurological disorders such as multiple sclerosis, AD, and others may present with mood changes or even full blown depression. Endocrine disorders such as hypothyroidism or deficiency states such as lack of vitamin B12 can contribute to depressive as well as cognitive symptoms. Failure of basic organ systems including renal failure or congestive hear failure can cause fatigue, loss of appetite and weight, and depressed mood. Cancers, especially pancreatic or small cell lung carcinomas, can present with depressive symptoms even before the patient is aware of the diagnosis (Ell 2006, Evans et al. 1999).

### Depression and Cognitive Impairment

Depression can coexist with cognitive impairment, including dementia. Severe depression may negatively impact cognition. Occasionally, such patients are described as having “pseudodementia.” However, when demonstrable, significant cognitive impairment is present, it is more likely that the patient has both depression and dementia (Reifler 1982). Apathy is a common symptom of dementia. This apathy may or may not be a part of a treatable depressive syndrome. Some researchers have suggested that late life depression, especially new onset depression may be an early indicator of AD. New onset depression in late life is often related to medical illness as well as loss or grief. In particular, late life onset depression has been linked to cerebrovascular disease (the “vascular depression” hypothesis) (Watson and Steffens 2004).

### Suicide in the Elderly

Elders have a high rate of suicide. Late onset, unipolar depression seems to be particularly correlated with elder suicide (Table 123–6). Some studies have suggested that the suicide rate is approximately two times that of the general American population. As in other groups, female elders have

a higher prevalence of depression and a higher rate of suicide attempts. However, males (especially white males) predominate in completed elder suicide. These elderly men typically choose highly lethal means of suicide such as gunshot wounds to the head or chest. Many of these patients have not been formally diagnosed or treated for depression. However, many of these patients have visited a physician within weeks of a suicide attempt. Physicians should have a high index of suspicion for suicidal thinking in depressed elders, even those who minimize or deny depressive symptoms. A serious medical illness, especially a terminal or painful illness should be regarded as a risk factor for suicide. Social isolation, the loss of a spouse, substance abuse, or previous suicide attempts should also be considered as risk factors for elder suicide (Casey 1991, Conwell and Duberstein 1995, Juurlink et al. 2004).

**Treatment of Depression in the Elderly**

Depression in late life is a very treatable condition. Successful treatment not only improves mood and reduces the chance of suicide, but can also dramatically improve functional deficits and improve quality of life for the patient as well as the caregiver. All treatment modalities for depression can be utilized for elders including pharmacotherapy, psychotherapies, social therapies, and electroconvulsive therapy (ECT).

Studies of pharmacotherapy for geriatric depression have documented the safety and efficacy of antidepressants, particularly the serotonin reuptake inhibitors (Sheikh et al. 2004). The use of older antidepressants, particularly the TCA, should generally be avoided because of concerns over side effects and toxicity. Anticholinergic and cardiovascular effects of TCA can be more problematic for elders than other populations. Approximately 60–80% of elders will respond to pharmacotherapy if carefully managed. However, only about half are likely to respond to the initial medication trial and response time is often longer than in other groups. Up to 8–12 weeks may be needed for maximal response (Thomas et al. 2002, Whyte et al. 2004). Although recent studies have suggested that combinations of antidepressants may be required for good response, geriatricians are generally conservative about such polypharmacy. Since elder depressives may emphasize their symptoms of anxiety, benzodiazepines are often prescribed instead of or in addition to antidepressants. Benzodiazepines are not adequate treatments for depression and are potentially problematic for elders. Careful attention to adherence is required in the management of geriatric depression as rates of noncompliance are high (Salzman 1995). Adherence improves when the patient is seen frequently and counseled about their illness and the need to faithfully take their medication. Despite evidence of their effectiveness, the majority of depressed elders do not receive antidepressant therapy (Dunner 2003, Lyness 2004, Taylor and Doraismwamy 2004).

**Psychotherapy for Elder Depression**

At one time, elders were considered to be poor candidates for psychotherapy. However, a number of studies have documented the utility of various psychotherapeutic approaches for geriatric depression, either alone or in combination with medication (Arean and Cook 2002, Gum and Arean 2004). In fact, combination approaches are becoming well accepted in the management of depression in the elderly (Arean et al. 2001). Cognitive therapy is perhaps the best studied psychotherapeutic approach and cognitive therapy manuals for geriatric depression have been prepared (Grant and Casey 1995, Thompson et al. 2001). Interpersonal therapy has also been studied, mostly in combination with medications (Miller et al. 2001). The descriptive literature also delineates psychodynamic and reminiscence approaches to the elderly psychotherapy patient. Reminiscence therapy is designed to allow the patient to review and take stock of their life experience.

**Electroconvulsive Therapy in the Elderly**

ECT is a valuable tool in the treatment of depression in the elderly. A substantial proportion of ECT patients are elderly. Several studies have shown the utility and safety of ECT in the elderly. ECT is typically done for treatment-resistant patients who have failed several previous medication trials. However, ECT should not be viewed solely as a treatment of last resort. Patients with catatonic or psychotic symptoms may benefit from ECT early in the course of their illness. Severe psychomotor agitation or retardation, anorexia, or marked suicidal thinking can also be addressed with ECT. Patients who have responded to ECT in the past may be better served by early intervention rather than a new set of pharmacologic trials. Much of ECT for elders is performed on an inpatient basis. Outpatient ECT may be difficult because of severity of medical and psychiatric illness, frailty, lack of social support, or cognitive impairment. Although initial response rates are high, many patients relapse. Maintenance ECT may provide an alternative, especially for patients prone to early relapse. Maintenance ECT may be performed on a scheduled basis (e.g., weekly) or based on early signs of relapse. Maintenance ECT represents a significant effort on the part of the patient as well as their caregivers, particularly for transportation and ongoing supervision. ECT patients receive general anesthesia as well as electrical stimulation. Therefore, a thorough medical evaluation is required prior to treatment. Physical examination, ECG, and basic laboratory evaluation (CBC and electrolytes) are advisable. In the past, neuroimaging and spine films have often been performed prior to ECT. However, these procedures are no longer considered mandatory and are done when an indication exists. Assessment of cardiovascular status is important since elderly ECT patients can be expected to have post-treatment tachycardia and hypertension. ECT is usually avoided in patients with recent MI or stroke as well as cardiovascular instability. However, the decision to perform ECT must always balance the risks against the urgency of the clinical need. Cognitive impairment is an expectable short-term outcome of ECT. Anterograde and retrograde amnesia as well as short-term memory impairment can occur, especially with bilateral ECT. Cognitive impairment can be more persistent with bilateral ECT. Despite these issues, ECT is generally well tolerated in elders (Casey and Davis 1996, Salzman et al. 2002).

Dementia patients who have comorbid depression may be candidates for ECT despite their ongoing cognitive impairment. Dementia patients receiving ECT may become confused. However, these effects are relatively time limited and do not influence the long-term cognitive symptoms.
of dementia. Occasionally, severely depressed dementia patients can experience improved cognition following ECT as the depression lifts.

Conclusion
As the number of elderly patients increases in the US and many other parts of the world, psychiatrists will need to enhance their skills in management of clinical problems common in this age range. Dementia and depression are particularly important syndromes in geriatric psychiatry requiring careful evaluation and management. Care of the geriatric patient requires an appreciation for the effects of the aging process and age-related illnesses on functional abilities. There is considerable overlap between geriatric psychiatry and geriatric medicine, so that psychiatrists must consider the effects of medical illness as well as medications when managing psychiatric illnesses. Psychiatric illnesses also complicate the care of medical conditions. Therefore, open communication among specialists is a necessary component of geriatric management. The role of patients in the family and community evolves as they age. Geriatric management involves an appreciation of the context of care, and cooperation with the patient’s caregivers.

Introduction
Torture History and Definition
Torture has always been a part of the history of mankind. Numerous accounts tell us how authorities have used torture as a means to deal with defeated enemies, to extract confessions, to show superiority, to humiliate the defeated, or to spread terror among the subordinates. The practice of torture knows no geographical or ideological boundaries, and has been used by all kinds of authorities whether military, clerical, monarchical, or political.

Historically, the French Revolution and the emerging recognition of human dignity and human rights are landmarks in the abolition of torture as an accepted official practice. Subsequently, many countries have taken a firm stand against the use of torture as a legitimate procedure. The awareness of the widespread use of torture and the recognition of the need for international declarations became very prominent following the revelations of the World War II concentration and extermination camps (Eitinger and Weisæth 1998). The adoption of the United Nations (UN) Universal Declaration of Human Rights in 1948 and several other major conventions against human rights violations reflect this. According to the Universal Declaration, “no one shall be subjected to torture or to cruel, inhuman or degrading treatment or punishment” (United Nations 1948).

The Geneva Convention (1949) protects those persons who are not taking an active part during war from “violence to life and person, in particular murder of all kinds, mutilation, cruel treatment and torture.” This includes soldiers who have “laid down their arms” (International Committee of the Red Cross 1987).

In 1984, the General Assembly of the UN approved the most important international legal instrument against the practice of torture, the Convention against Torture and Other Cruel, Inhuman or Degrading Treatment or Punishment. Article 2.2 of this states “No exceptional circumstances whatsoever, whether a state of war, internal political instability or any public emergency, may be invoked as a justification for torture.” As of December 6, 2006, 144 countries were parties to the Convention, obligating them to accept this principle (www.ohchr.org/english/countries/ratification/9.htm).

Nonetheless, torture has continued and remains a major problem around the world today, and pessimistic voices claim that we will never see an end to torture.

The term “torture” has been defined in various ways depending upon the defining organization and purpose. Among the definitions, two have gained particular importance, the UN’s definition from 1984 and the World Medical Association’s (WMA) definition, also called the Tokyo Declaration, from 1975.

According to the UN Convention (1984), “For the purposes of this Convention, the term “torture” means any act by which pain or suffering, whether physical or mental, is intentionally inflicted on a person for such purposes as obtaining from him or a third person, information or a confession, punishing him for an act he or a third person has committed or is suspected of having committed, or intimidating or coercing him or a third person for any reason based on discrimination of any kind, when such pain or suffering is inflicted by or at the instigation of or with the consent or acquiescence of a public official or other person acting in an official capacity. It does not include pain or suffering arising only from, inherent in, or incidental to lawful sanctions” (United Nations 1995).

The WMA states, “For the purpose of this Declaration, torture is defined as the deliberate, systematic or wanton infliction of physical or mental suffering by one or more persons acting alone or on the orders of any authority, to force another person to yield information, to make a confession, or for any other reason” (Amnesty International 1994).

In comparison, the WMA definition is broader as it does not require the perpetrator to be affiliated with any government or to act in any official capacity, and it may also include suffering caused by ritualistic or criminal acts.
torture is widespread. The AI Report (Jaranson 1998). The UN definition, on the other hand, limits torture to acts that are perpetrated by persons in “an official capacity.”

From a therapeutic point of view, the two definitions dictate differential approaches. The WMA definition recognizes the severity of the suffering irrespective of who caused it. Since such suffering may lead to mental health consequences, whether or not the torture was officially sanctioned, this definition may favor a broader approach to identification and treatment. The UN definition recognizes the legal and political responsibilities of governments in causing severe suffering. Consequently, this definition may be used as a stepping stone to create therapeutic interventions to alleviate the sequelae due to the suffering. For example, helping a survivor return to political activism may be a component of treatment.

Prevalence of Torture
Repeated reports by Amnesty International (AI) state that torture is widespread. The AI Report (2006) documents the occurrence of human rights abuses in 150 of the 193 countries around the world (http://web.amnesty.org/report2006/index-eng). As torture is frequently carried out under clandestine circumstances, reliable estimates are very difficult to get, not least due to the political sensitivity of the issue. The AI figures, thus, conservatively estimates the actual situation.

Torture seems particularly common in regions characterized by political unrest, riots, civil war, rebellion, and other social or political conflicts, but is not restricted to those regions (Basoglu et al. 2001). In view of the political nature of torture, certain groups are more likely to be exposed to torture, such as political activists, asylum-seekers, refugees, and persons who have been detained. It is well-known that torture is also used extensively in police custody and in correctional services, including regions that are not afflicted by war. Torture does not exclusively take place in countries with nondemocratic governments.

Democratic governments are also at risk for allowing torture during detention of prisoners. The recent focus on terrorism has been used as a reason to accept the use of “mild” torture in such situations. The long-standing controversy in the United States about which specific interrogation techniques are allowed by the Geneva Convention is one example.

Prevalence rates in non-Western countries range from 8 to 26% in national random samples, 3 to 16% in refugee camps, and an extremely high range of 85 to 100% for detainees remaining in their countries of origin (Quiroga and Jaranson 2005). With nearly 21 million refugees, asylum-seekers, internally displaced persons (IDPs), returnees, and stateless persons reported for 2005 by the United Nations High Commission for Refugees (UNHCR), millions of torture survivors exist worldwide (UNHCR 2006). This, however, includes only those under the responsibility of UNHCR and millions more are not officially recognized, such as those who have sought refuge in the West.

In Western settings, prevalence of torture ranges from 7–8% in general primary care clinics and up to 70% in refugee psychiatric clinics (Quiroga and Jaranson 2005). Among a select group of refugees and asylees in the US and Europe, prevalence rates of torture between 6 and 55% (Quiroga and Jaranson 2005) have been reported. Even when using a conservative estimate, we are facing an issue of enormous dimensions from both human rights and therapeutic perspectives, an issue that until recently received limited psychiatric attention.

Estimates of the prevalence of torture vary due to methodological issues, such as the selective delineation of the study populations, restricted access to torture survivors, lack of validated assessment instruments, and reluctance of survivors to reveal their torture experiences. Most studies have been carried out on persons in exile, a selected population, and few studies have used structured procedures in the assessment. Silove et al. (2002) have delineated some of the problems in studies investigating the conditions following severe man-made traumata. These problems include: (1) poor definition of the boundary between torture and other severe trauma; (2) the higher demonstrated prevalence of PTSD in refugee populations although the distinction between torture and other trauma is unclear; (3) small sample sizes; (4) possible selection bias, especially of populations referred to treatment; and (5) lack of precision regarding diagnostic methods. Furthermore, the usual lack of control groups, the absence of follow-up studies, and uncertainty whether the questions may have potential negative impact on the critical legal and psychiatric state of the persons, add to the difficulties. A critical review (Hollifield et al. 2002) of trauma measurements in refugees concluded that the majority of 394 publications about refugee trauma or health in refugees are either descriptive or include qualitative data from instruments that have limited or untested validity and reliability in refugees.

Methods of Torture
Methods of torture vary over time and across regions. Torture methods are frequently divided into physical and psychological methods, and attempts have been made to develop algorithms in order to facilitate comparative studies of torture experiences (Bojholm et al. 1992). Perpetrators constantly develop and refine their methods in order to avoid leaving traces. There are, however, commonalities in the use of methods, and several studies report nonsystematic beatings as the most common form of torture, while various kinds of deprivations are also frequent (e.g., Olsen et al., in press). Techniques include beatings to specific parts of the body, such as falanga (to the soles of the feet) or telefono (to both ears); suffocation (such as submarino, or placing the person’s head in liquid until near suffocation), suspension in contorted positions or electrical torture to body parts (such as genitalia). Mutilating injuries consist, e.g., of amputation of limbs or other body parts. Sexual torture is reported among a high percentage of torture survivors, not only women.

Torture almost always includes psychological dimensions, alone or simultaneously with the physical torture. Psychological methods, which are generally more difficult to trace, range from general humiliation and threats to mock executions and witnessing the torture of loved ones. Cultural and social differences regarding what is considered shameful or violating are important in psychological torture. As an example, Indian Hindu authorities have used cutting the hair of Sikh men as a method of psychological torture specifically for that group (Wenzel et al., in press).
**Medical Aspects of Torture**

**Physical Effects of Torture**

The sequelae of torture are both immediate and long term. Therapists in the West rarely encounter the immediate consequences, and it should be remembered that many victims with the most severe immediate health effects may not have survived (Skylv 1992). The survivors who have been encountered in Western health settings may have undergone torture years prior to receiving treatment and represent a selected group.

Ample documentation shows that many torture survivors primarily have somatic complaints but that many subjective physical symptoms are rarely matched with objective signs. Many survivors have been subjected to multiple forms of torture with subsequent overlapping injuries (Basoglu 1992). Thus, it may be difficult to trace signs of a particular form of torture. Among the most prevalent physical sequelae are complaints from the musculo-skeletal system (Rasmussen 1990). Electrical torture will result in characteristic skin changes. Dental torture together with poor dental hygiene during imprisonment may lead to loss of teeth, gingivitis, or dysfunctional temporomandibular joints. Sexual torture is usually revealed late, and leaves not only injuries to the genital organs, sexual dysfunction, and sexually transmitted diseases, but also pain in the lumbar region.

There is an increasing focus on the chronic pain experienced by a large proportion of torture survivors, linking it to the kinds and amount of torture (Olsen et al., in press). Pain is typically localized to the musculo-skeletal system, accompanied by fibrositis and myofascial pain (Amris 2000). Headache is also very common. Falanga may result in pain, primarily in the tibial region and near the joints, damaged heels, and impaired walking (Skylv 1992). Suspension may give rise to joint pain, and trigger points are frequent in the shoulder musculature (Skylv 1992).

Despite presenting physical complaints, psychological problems are frequently revealed later (van Ommeren et al. 2002). The impairment following torture experiences is caused by combinations of both physical and psychological factors, and torture survivors are more than twice as likely as nontorture survivors to have impaired physical and social functioning due to the trauma resulting from the torture (Wenzel et al. 2006).

**Psychological Effects of Torture**

Until the first half of the twentieth century, the prevailing notion was that the traumatic life events per se did not result in lasting consequences for the mental health of the individuals affected. In instances where persons nevertheless developed more chronic conditions, they were perceived as having a particular vulnerability. Such vulnerability could be interpreted from two different perspectives, one using a genetic frame of reference, the other psychoanalytic. In the first case, the mental health consequences were seen as a reflection of a premorbid biological weakness; in the latter, consequences were caused by psychological damage in early childhood (Sonnier and Geneke 1986).

Investigations of holocaust survivors (Eitinger 1980) changed this assumption. These investigations described a population that to a great extent had long-lasting psychological sequelae, following the extreme traumatic events in concentration camps. Scandinavian studies of war sailors from World War II (Askevold 1980) revealed similar findings. In both cases, there was no indication that these populations had a higher presence of psychopathology prior to the traumatic experiences. Such findings seem to indicate that exposure to continuous extreme stress, if the stressor is sufficiently severe, may induce mental health consequences in individuals with previously normal mental health. Following World War II, similar findings were found in populations exposed to, among other things, the taking of hostages or rape.

Due to such findings, a hypothesis has been proposed that exposure to different forms of stress may result in sequelae that, irrespective of culture or setting, are comparable. Rasmussen (1990), who analyzed the medical aspects of torture in his dissertation, concluded that various stressors seem to overlap with respect to consequences, and that there is good reason to believe that we are dealing with similar mechanisms.

In the 1970s (AI 1977), the Danish Medical Group in A1 published some of the first systematic investigations of the immediate consequences following torture. At a very early stage, it was recognized that the psychological consequences were extensive and, in many ways, far more long lasting than the physical consequences.

Studies of some of the first patients seeking treatment at rehabilitation centers for torture victims show similar results (Sonnier and Geneke 1986). The psychological problems when compared to the physical complaints showed a higher prevalence among those investigated. The psychological problems were severe and resulted in a significant reduction in the level of functioning. The most frequently reported complaints included anxiety, memory problems, concentration problems, depression, changes in personality, and nightmares (Sonnier and Geneke 1986). Fatigue, sexual problems, and headache were also frequently seen. These findings have been confirmed in a number of investigations on torture survivors from all regions of the world (e.g., Allodi et al. 1985) and it seems that, irrespective of cultural background, there are a number of common traits in the symptomatology manifested.

---

*A 35-year-old woman, MH, from Bosnia grew up in a well-functioning middle-class family. During the civil war, her father was taken away and presumed killed in a massacre. Her mother died shortly after. MH stayed with her grandmother during the war in Sarajevo, suffering severe deprivation, hunger, and constant bombing. She was raped by soldiers but kept this secret from her grandmother. She fled the country and obtained asylum in the country of exile. MH managed to get a higher education there, learnt the language, got a job, and developed a network. After eight years, she began to have difficulty in concentrating, suffered from flashbacks and nightmares, had attacks of anxiety, and became very sensitive to noise. She could no longer manage her job, and gradually, she became isolated and lost all interests. MH had been under psychiatric treatment for some time, combining pharmacological and psychotherapeutic treatments, and was very grateful, for this treatment relieved some of her anxiety and flashbacks. Her disorder had been assessed as chronic, and she thus received some economic compensation that gave her some rest and removed part of her hopelessness.*
In uncontrolled studies, the most prevalent complaints include: (1) psychological symptoms (e.g., anxiety, depression, emotional liability, irritability); (2) cognitive symptoms (e.g., confusion, difficulty with concentration and memory); and (3) neuro-vegetative symptoms (e.g., lack of energy, insomnia, sexual problems) (Goldfeld et al. 1988). Reviews, however, of the psychological effects of torture (Somnier et al. 1992) report significant shortcomings in many of the studies due to their uncontrolled design. Some studies include only refugees, and most consist of treatment populations that show some degree of selection.

A controlled study of Spanish torture survivors showed higher prevalence of depressive symptoms, anxiety, insomnia, concentration, and memory problems than the nontortured controls (Petersen and Jacobsen 1985). Tortured political activists in Turkey were compared with a controlled group of nontortured political activists without political involvement. The torture survivors had significantly more lifetime and current PTSD than the controls (Basoglu et al. 1994a). Among East African refugees in Minnesota, 25% of those exposed to torture met the criteria of suspected PTSD (with a cutoff PCL-C score of 50 or more) compared to 4% of those traumatized in ways other than by torture (Jaranson et al. 2004).

A recent review of surveys of PTSD among traumatized persons documented that PTSD exists across cultures ranging from 9 to 37% (Modvig and Jaranson 2004). Many factors influence the emergence of mental health problems including awaiting asylum, loss of meaningful activities, language inadequacies, and marital conflict (Saraceno et al. 2002).

Identifying Consequences of Torture and Need for Treatment

Diagnostic Considerations

Over time, several attempts have been made to delineate phenomenological descriptions of the mental health consequences of severe trauma. The diagnostic considerations of persons exposed to severe trauma may be seen as a continuation of the discussions related to the mental health problems of immigrants and refugees.

In the nineteenth century, an early conceptualization of the reactions to trauma were derived from perspectives of the medical knowledge at that time. Diagnoses such as tunnel disease and railway spine disorder were used. Subsequently, the syndrome was seen as closely related to the context forcing the reaction, e.g., soldier’s heart, nervous exhaustion, shell shock, and combat neurosis (Baex and Kastrup 2002).

In the 1930s, Ödegaard (1932) showed that immigrants from Norway had a higher rate of “insanity” than the native Minnesota population. Subsequently, Eiting (1980) showed a higher incidence of mental illness in World War II refugees compared to their Norwegian counterparts, and found a high proportion of schizophrenia and the so-called “reactive psychoses.” Ödegaard and Eiting made their empiricism based on the local diagnostic criteria and nosology of their time. The question is whether the conditions viewed as psychoses in those days would, in fact, have been diagnosed as PTSD had that diagnostic category existed.

As previously mentioned, the so-called “war sailor syndrome” (Askevold 1980) in the post World War II period showed similarity to the concentration camp syndrome described by Hermann and Thygesen (1954). Conversion to these descriptions was an initial interest in organic brain symptoms and what, in those days, was called asthenia.

The Vietnam War gave rise to an interest in describing and diagnostically categorizing the consequences of trauma. PTSD first appeared as an independent nosological entity in the American Psychiatric Association’s DSM-III in 1980, and may be seen as an attempt to unite various response syndromes.

Subsequently, the condition has shown a prevalence ranging from 9% among unselected Vietnamese refugees in Norway to 86% in Cambodian refugees in USA (Andersen 1998). After exposure to a significant trauma, approximately 20–45% of those unprepared will at some time develop PTSD (Andersen 1998). The wide range in these figures can mainly be explained by methodological, conceptual, selective, or investigative difficulties.

Later editions of the DSM classification (DSM-IV-TR) (American Psychiatric Association, 1994) have made certain modifications of the original diagnostic criteria, but the assumption remians that different types of traumatic events have similarities in psychopathological profiles. In the DSM-IV-TR (309.81), the stressor (Criterion A) includes not only those who have experienced torture and other extreme trauma, but those who have witnessed or been confronted with “an event that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others” (p. 427). In addition, the person’s response must involve “intense fear, helplessness, or horror” (p. 428). Other criteria include the symptom clusters of reexperiencing (Criterion B), avoidance (Criterion C), increased arousal (Criterion D) related to the traumatic event, duration greater than one month (Criterion E), and significant distress or impairment (Criterion F). Duration and onset of symptoms may be specified as acute (less than three months), chronic (lasting three months or more), or delayed (onset at least six months after the trauma). The DSM-IV-TR includes one related diagnosis, acute stress disorder (308.3), which occurs within a month after exposure to an extremely traumatic stressor.

Disorders of extreme stress not otherwise specified (DESNSOS) were considered for inclusion in the DSM-IV-TR classification but not accepted.

In the WHO (1992) International Classification of Diseases (ICD-10), the definition of posttraumatic stress (F 43.1) has criteria very similar to those of the DSM-IV-TR. PTSD is a delayed and protracted response to a stressor, which is exceptionally threatening or catastrophic and likely to cause distress in almost anyone. The diagnosis should not be given unless the symptoms occur within six months of the trauma and no alternative disorder is likely. Reexperiencing is required for diagnosis, while avoidance, although common, is not essential. Autonomic and behavioral disturbances or mood disorder contribute to diagnosis, but are also not essential. The ICD-10 also contains broader diagnostic categories, such as dissociative and somatoform disorders under the “neurotic, stress related and somatoform disorders” and recognizes posttraumatic “enduring personality changes after exposure to catastrophic events” (F 62.0). Consequently, ICD-10 includes two diagnostic categories covering consequences of traumatic stress. Chronic traumata may give rise to personality changes...
including a tendency for somatization, affect lability, difficulty in social relationships, lack of ability to trust others, and a feeling of having changed. The ICD-10 category F 62.0 better fits these symptoms.

**Torture Syndrome**

PTSD was never meant to include the entire range of responses following torture (Jaranson et al. 2001). Rasmussen et al. (1977) proposed the existence of a specific “torture syndrome” in 1977 and a lively debate about whether torture results in a predictable phenomenology ensued during the following years. The concept of “torture syndrome” was subsequently discussed by at least two groups (Allodi and Cowgill 1982, Abildgaard et al. 1984) but both primarily listed symptoms found among torture survivors, and they did not examine whether these symptoms would cluster as a syndrome (Turner and Gorst-Unwowrth 1993). Those in favor of a torture syndrome claimed that the infliction of deliberate violence on one human being by another has a decisive influence on the formation of symptoms (Sommier et al. 1992). It has been suggested that symptoms reflect the method of torture used, and that isolation, blindfolding, impact, or other forms of physical torture may give rise to intrusion symptoms of PTSD, whereas persons exposed to sexual torture more frequently complain about avoidance symptoms (Vesti and Genefke 1998).

Basoglu et al. (2001) pointed out that the existence of a torture syndrome will require evidence of a causal connection between torture experience and symptoms, a meaningful grouping of symptoms, and a comparison of symptoms with established diagnoses, such as PTSD. Turner and Gorst-Unworth (1993) concluded that the attempts to describe an independent torture syndrome have not been very convincing, and Mollica and Caspi-Yavin (1992) also found that it has not been possible to delineate a torture syndrome but that symptoms among severely traumatized refugees were closely associated with the PTSD diagnosis. Investigations have not been able to support the theory of a specific torture syndrome that is different from PTSD (Shresta et al. 1998), and a survey of recent publications carried out by Basoglu et al. (1994b) seems to suggest that we presently do not see a syndrome (Turner and Gorst-Unworth 1993). Those in favor of a torture syndrome claimed that the infliction of deliberate violence on one human being by another has a decisive influence on the formation of symptoms (Sommier et al. 1992). It has been suggested that symptoms reflect the method of torture used, and that isolation, blindfolding, impact, or other forms of physical torture may give rise to intrusion symptoms of PTSD, whereas persons exposed to sexual torture more frequently complain about avoidance symptoms (Vesti and Genefke 1998).

The diagnosis of complex posttraumatic disorder has been suggested by Herman (1995) and continuous traumatic stress response by Dowdall (1992), taking into consideration more complicated reactions observed in persons who have been subjected to prolonged and repeated forms of violence compared with the single exceptional event in the PTSD criteria.

Increasingly, the classification committees have considered including the diagnosis of DESNOS. DESNOS includes damaged affect regulation, chronic self-destructive behavior, amnesia and dissociation, changes in the relationship to self, distorted relationships to others, and loss of faith (Berliner et al. 2005).

**PTSD Symptomatology and Comorbidity**

Frequent misdiagnosis of pathology occurs with refugees. Diagnostically misleading suspiciousness and paranoia are prominent across diagnostic categories within most refugee populations, and psychotic and paranoid symptoms are often misdiagnosed as schizophrenia. Brief, reactive psychoses occur more frequently than schizophrenic disorders. Flashbacks, hallucinations, and dissociative phenomena typical of PTSD may be erroneously interpreted as symptoms of schizophrenia (Baez and Kastrup 2002). Very often, PTSD accompanies a major depressive disorder, a combination suggesting a more serious clinical picture and a less favorable outcome than if either disorder occurs alone.

Evaluation for organic impairment is another area of confusion among practitioners assessing refugees. Head trauma is common during torture, as evidenced by Mollica et al. (1993) finding among Cambodians that most torture involved beatings to the head. A torture survivor who has suffered head trauma might be affected cognitively because of this antecedent. This situation could lead to diverse degrees of confusion, memory impairment, and disorientation, contributing to the stigmatization of refugees or asylum-seekers as malingerers. Since cognitive impairment, especially with memory, can also be found in PTSD and depression, the differential is complicated and difficult.

**Clinical Vignette 2**

JH is a 53-year-old man from Croatia, who lived a productive life as a migrant with his own firm, family, and friends until the civil war broke out in the former Yugoslavia. JH was referred from neurologists, who had not been able to alleviate his chronic severe headaches and memory problems. He had no previous psychiatric history. During the war, JH decided to return to his country to fight. There he was involved in several battles, experienced atrocities, and was forced to participate in acts that he is unable to forget. He suffered psychological torture including severe humiliation, mock execution, and witnessing the torture of others. He was beaten on the head and was unconscious for a brief period of time.

Returning to his country of migration, JH found that his firm was bankrupt, and his wife divorced him and left with their children. He lived on welfare and, since he could not tolerate noise, had few social contacts. Despite his chronic PTSD—which improved little with psychopharmacological treatment—cognitive difficulties, and persistent headaches, JH expressed great willingness to work again and hoped that his condition will improve. He was very motivated for and compliant with the treatment.

Substance abuse is frequently comorbid among other populations with PTSD but relatively uncommon among refugee torture survivors. However, this varies considerably by factors such as culture and gender. For example, Farias (1991) has documented alcoholism as relatively common among Central American refugee males, khat has been abused by East Africans, and opiates by Southeast Asians. Substance abuse comorbidity with PTSD is more often seen in men than women (Kastrup and Arcel 2004).

**PTSD Issues**

From a clinical perspective, the diagnostic category PTSD is generally seen as meaningful, and an argument emphasizing...
the universal aspects of PTSD relates to the research findings on the biological aspects of PTSD (Friedman and Jaranson 1994). Jaranson et al. (2001) mention that the hyperarousal, seen as the startle response, can be interpreted as one of the findings that very strongly support the existence of a universal posttraumatic stress syndrome.

The presence of PTSD is, however, not a necessary consequence of stress and trauma. A large proportion of traumatized or tortured persons develop posttraumatic stress symptoms, whereas others do not. The exact proportion is unknown.

The study of resilience factors is important and still insufficient. However, currently more attention is being paid to understanding the protective aspects in different populations, lessening the focus on the negative impact of trauma. An important area of needed study is identifying factors of resilience that may reduce or modify the development of PTSD, irrespective of the survivors’ perceived or experienced traumatic events.

Perceived stress, rather than the objective severity of the stress, has been correlated with the development of PTSD. It is still unknown whether certain types of trauma are more likely to induce PTSD. Many factors, including age, personality, political or ideological inclination, quality of support after exposure to stress, may all influence the development of PTSD (Vesti and Genefke 1998).

Measurement Issues

In consonance with the increasing emphasis on valid and reliable measurements and evidence-based interventions, the study of torture increasingly recognizes the need to pay more attention to the development of valid and reliable instruments for assessing, e.g., PTSD symptoms, trauma history, and level of social and biological functioning (Marsella 2001).

Particularly pertinent in the study of torture is ensuring the cultural equivalence of the instruments used. In general, Western researchers have developed psychometric tests and structured interviews with little attention to their applicability and acceptability in other cultural settings. Some concepts in a given scale may have differing connotations depending upon the cultural group. Despite shortcomings, quantitative measurements like rating scales and structured interviews may be very useful in the management of torture survivors, but combining them with qualitative measurements may add further insight into the comprehensive situation (Marsella 2001).

All of these factors contribute to the need for culturally informed quantitative instruments that are designed to be linguistically and visually acceptable, universally applicable, and understandable across cultures and settings. There is still a need to encourage studies that combine the intensive narrative approach of the anthropologists with the large-scale surveys of the epidemiologists (Kleinmann 1988).

Conceptual Models

A number of conceptual models have been developed to explain different aspects of the etiology and course of the human response to traumatic events (Fairbank et al. 2001) (see Table 124–1). Two models dominate: the psychosocial and the neurobiological.

| Table 124–1 Conceptual Models of Response to Traumatic Events |
|---|---|---|
| Models | Theory | Characteristics |
| Psychosocial | Learned helplessness | Apathy, passivity, impossibility of escaping future traumatic events |
|  | Information processing | Recall of information linked to traumatic events |
|  | Classical conditioning | Increased cardiovascular and sympathetic nervous system activity upon exposure |
|  | Neurobiological | Overstimulation of memory for the same traumatic event |
|  | Overstimulation of stress-response neuro-modulators | Explains memory and reexperiencing symptoms |
|  | Hypocampal damage | |

Among the psychosocial models, Seligman’s theory (1975) of learned helplessness explains how exposure to trauma that is impossible to avoid may lead to apathy, passivity, and a conviction that escaping future traumatic events is also impossible. Information processing theory explains how information linked with traumatic events is recalled (Fairbank et al. 2001). Research (Basoglu and Minetka 1997) has shown how preparedness for trauma might alleviate the severity of later symptoms. In classical conditioning theory, exposure to trauma-related stimuli in persons with PTSD may lead to cardiovascular and sympathetic nervous system activity (Fairbank et al. 2001).

Increasing research into the biology of PTSD suggests that persons with PTSD respond to a variety of stressors with heightened catecholamines compared with controls, and that they show abnormal reactivity in response to stressors that resemble the trauma but not to generic stressors (Southwick and Friedman 2001). A possible explanation may be that stressful events result in an overstimulation of the endogenous stress–response neuro-modulators, thereby overstimulating the memory for the same event (Southwick and Friedman 2001).

Modern brain imaging techniques show that PTSD symptoms may have alterations of the brain such as a reduced hippocampus, as well as functional alterations, and that the hippocampal damage may explain the memory problems and the reexperiencing symptoms of PTSD (Southwick and Friedman 2001).

General Therapeutic Considerations

Approaches to Treatment

The enormous global public health problem of torture in many ways still remains neglected, and many challenges face survivors (see Table 124–2). First, of course, is to survive the immediate consequences of torture. The next steps include escaping the torture setting, successfully settling in a country of exile, finding treatment facilities there, and finally receiving treatment. But remaining as a displaced person in your country of residence may make it difficult to access treatment.
Populations entering treatment are characterized by their cultural diversity, necessitating development of culturally competent health care systems. This requires flexibility in approach and problem solving. Ultimately, the aim of the intervention should be to enable the survivor, irrespective of cultural background, to become a productive, or at least participatory, member of society (Quiroga and Jaranson 2005).

When dealing with traumatized patients, certain general principles should be taken into consideration (Jaranson et al. 2001). Therapists should above all do no harm, focus on the primary problems when the patient is ready, and support all needs that the patient expresses. One primary care person should offer regular meetings in an atmosphere of trust, providing continuity of care and awareness of cultural differences and religious beliefs. Both pharmacotherapy and other therapies should be considered, as well as the need to maintain a therapeutic relationship over extended periods. Posttraumatic stress symptoms wax and wane over time, often they can be exacerbated by environmental stressors, and can show persistent chronicity.

**Communication with Patients**

Working with torture survivors frequently means that therapist and patient have different linguistic backgrounds, thereby challenging the skills of the therapist. The patient rarely masters the language of the therapist fluently, and may have difficulty expressing emotions in detail or lacks terms for crucial concepts. Such cases easily give rise to misunderstandings that can have serious consequences for the therapeutic alliance.

In many settings, the use of interpreters is inevitable. Caution should be expressed regarding the use of nonprofessional interpreters, in particular the family members, who may not be able to keep their distance and get emotionally involved in the session. Working with interpreters requires the therapist to have the special skills of building a relationship with the interpreter as a third party and creating a safe environment. There are many pitfalls working with interpreters, including the reluctance of the patient to accept a given interpreter. Such reluctance may be related to issues like confidentiality or the sex and social background of the interpreter. On the other hand, some patients may express a preference for the presence of a third person of the same cultural background, stating that this provides a sense of security.

**Therapist–Patient Relationship**

Serious damage to a person’s feeling of safety is central to most traumatic experiences, and reestablishment of basic safety is a prerequisite of any therapeutic intervention (van der Weer and van Waning 2004). The primary need of traumatized persons consists of physical and emotional safety as well as predictability of relationships. The therapist may play a critical role in all of these issues (Kinzie 2001). The insecurity may be particularly common among refugees who experience unpredictability regarding future legal status or economic security, lack of integration into their final resettlement country, or bad news from home.

The patient may look for support to solve the current stress factors and put them in the foreground during therapy. As a therapist, it is essential to recognize and respect this need. (Kastrup and Arcel 2004). Recreating a safe place can be seen as the first step in the therapeutic process and the basis for developing a sustainable therapeutic alliance.

The needs of the survivors are frequently multiple, including medical, psychological, social, and legal. But the urgent needs to be met before any therapeutic intervention are, e.g., finding appropriate shelter, food, some kind of income if not employment, as well as access to basic medical care. Furthermore, child care and access to schooling may be needed.

**Clinical Vignette 3**

A 34-year-old physician, GH, escaped her native, Afghanistan, following jailing and torture at the hands of the Taliban for her treating of both male and female patients. As a result of this brutal violence, which included having her earring ripped from her ear and acid thrown on her, she suffered somatic pain, nightmares, insomnia, hyperarousal, and other symptoms of PTSD. The treatment center provided a psychological and medical affidavit of support for her asylum claim, as well as child care and interpreters for her asylum interview. She was secured primary care and social service assistance for herself and her young daughters, as well as ongoing individual therapy with a Farsi-speaking clinician. After she was granted asylum, GH received postasylum benefits counseling, and received mentoring and information on recertification as a physician directly from the treatment center’s Medical Director. Her husband and son were on their way out of hiding to the United States, and GH was looking forward to practicing medicine once again.
As pointed out by van der Weer and van Waning (2004), safety for a patient means a feeling of not being intimidated or threatened, which implies understanding the nature of the therapeutic intervention, its goals, and the rules guiding it.

Successful communication requires the therapist to have a respectful curiosity and willingness to learn more about the cultural values of the patient, as well as self-awareness of cultural biases, stereotypes, and values. Refugees frequently have a story fraught with betrayal and persecution. The therapist has an important role to recreate a feeling of trust in fellow men and to contain emotions of anger and grief expressed by the patient. The therapist should work to understand the depth and meaning of the patient’s losses and the shared powerlessness to undo these losses (van der Weer 1999).

**Treatment Interventions**

The applicability of different psychotherapeutic approaches has been widely discussed in the treatment of torture survivors. It is characteristic for the field that most therapeutic approaches are rather pragmatic and do not base themselves on one consistent theory but combine different elements based upon clinical experiences. Over time, several treatment modalities have emerged, and the choice of treatment in a given setting has to a large extent been formed by the professional orientation of the therapists at a given setting (Jaranson et al. 2001).

The severity of torture predicts PTSD, whereas lack of social support relates to depression but not PTSD. As a consequence, measures on social support may have little effect on PTSD (Basoglu et al. 1994b). Most treatment modalities include the telling of the traumatic events, sometimes in the form of imaginal exposure (Jaranson et al. 2001). Despite the communalities in the various treatment approaches, we still have insufficient evidence for the specific effective elements of the interventions (Jaranson et al. 2001). Retelling the traumatic event may cause abreaction, but the risk has not been confirmed in controlled studies (Jaranson et al. 2001). If follow-up intervention is not provided, this technique may cause more harm than problem solving (Quiroga and Jaranson 2005).

**Clinical Vignette 4**

AT is a 60-year-old man from Chile who has lived in the United States for thirty years but not made any contact with the treatment center until this year. He was one of the military officers loyal to Salvador Allende who were imprisoned and tortured in the wake of the coup in 1973. He suffered beatings, electric shocks, and psychological torture during interrogations, and was subsequently sentenced to several years in prison. His wife recalled during an interview with the treatment staff that she did not recognize him when she first saw him again after his arrest because he had lost so much weight. The center helped Mr. AT to document the psychological consequences of his experiences as he and many others were working toward obtaining proper recognition from the Chilean government. Mr. AT desired to become an active volunteer with the center and assist other survivors through his professional experience as a social worker.

**Cognitive–Behavioral Therapy (CBT)**

In recent years, interest in the cognitive approach to treatment of traumatized refugees has increased. CBT has already been shown effective in the treatment of depression and anxiety. CBT’s premise is that the way one sees and interprets the surrounding world strongly influences one’s actions and emotions. The assessment prior to therapy is essential since cognitive therapy presumes that the client is willing and able to participate actively in the treatment (Basoglu 1998) and has basic security (Varvin and Hauff 1998).

In the treatment of torture survivors, it is important to get an overview of the life difficulties, negative thoughts, and assumptions behind these (Berliner et al. 2005). The first step is prioritizing the problems and subsequently facing the negative assumptions lying behind them. The cognitive approach provides the patient with the tools to use in order to change these assumptions and, through assignments, change dysfunctional behavior (Berliner et al. 2005). Berliner et al. (2005) point out that cognitive therapy has certain shortcomings, since it presumes that the thought patterns are dysfunctional and need change, whereas thoughts may be normal reactions without a need to restructure.

**Psychodynamically Oriented Therapy**

Psychodynamic psychotherapy has been and is still one of the most frequently used psychotherapeutic approaches in the management of torture survivors, and several overviews of psychotherapeutic interventions have been published (e.g., Vesti and Kastrup 1992, Somnier et al. 1992, Varvin and Hauff 1998, Gurr and Quiroga 2001, Quiroga and Jaranson 2005). Psychoanalytic therapy focuses on the unconscious representation of the traumatic event and its interaction with other life events (Varvin and Hauff 1998).

Psychodynamic therapy is characterized by its structured frame, typically a contract between therapist and client. The establishment of a sustainable mutually trusting relationship is key. Torture places a person in a situation of helplessness and destroys a person’s internal enduring universe that the therapy aims to restore (Varvin and Hauff 1998). The client is encouraged to retell the traumatic experiences. Suitability for psychodynamic intervention includes the patient’s motivation for change, ability to introspect, ego strength, and choice of defense mechanisms, frequently dissociation, somatization, and derealization.

Torture survivors frequently suffer from very complex and chronic posttraumatic reactions. As a consequence, there are special concerns to consider before starting a psychotherapeutic intervention. Among such considerations are (Drozdek and Wilson 2004):

- The therapy must start at the right time.
- Decision must be made as to whether the therapy should be initiated or not.
- Decision must be made as to whether the therapy should be an individual or a group intervention. Group treatment provides a possibility to identify with others and share experiences, but for many torture survivors, disclosing personal violations, especially of a sexual nature, may be counterproductive.
- A proper therapeutic approach must be chosen. The more supportive therapies aim to help victims cope with
their current situation and modify the effects of the trauma in order to manage their daily life.

In contrast, the “uncovering” insight-oriented approach will face the trauma, and aim to provide the victims a deeper understanding and insight into the experiences they have undergone and their reactions. In general, it is wise to let the person’s ego strength be a decisive factor in the choice of therapy: The stronger the ego, the more likely that the person will be able to benefit from an uncovering approach (Varvin and Hauff 1998).

In many settings, a multiphasic model is recommended. One of those is the Five Phase Model described by Drozdek and Wilson (2004). Phase 1 establishes a sustainable therapeutic alliance. Phase 2 focuses on the trauma and the life story of the patient. Then Phase 3 deals with the telling of the trauma story, including the exposure and restructuring. In Phase 4, the focus is on relating the past, present, and future of the patient and, finally, Phase 5 focuses on working with the termination of therapy and future relapse prevention.

Psychopharmacological Treatment

The previous reluctance in many settings to use pharmacotherapy to avoid undue medicalization of torture is no longer prominent. Increasing evidence supports the use of psychotropic medication to reduce symptoms of PTSD, to help control loss of temper and aggression, to facilitate the psychotherapeutic intervention, or to treat some of the comorbid symptoms of anxiety or depression (Kinzie and Friedman 2004) (see Table 124–3). A combination of psychotherapy and pharmacotherapy is practiced in many settings.

Tricyclic antidepressants (TCAs) in randomized controlled trials have shown a moderate effect in alleviating PTSD symptoms, but today the SSRIs have replaced TCAs as the medication of choice. The SSRIs show a positive effect on the numbing and arousal symptoms of PTSD and on the comorbid symptoms of anxiety and depression (Jaranson et al. 2001).

Antiadrenergic drugs such as beta-blockers have been considered helpful by reducing noradrenaline release and global PTSD symptoms, especially intrusive thoughts, hyperarousal, and nightmares (Kinzie and Friedman 2004). Antipsychotic medication is not the recommended treatment for PTSD symptoms. For those reporting psychotic symptoms, the atypical antipsychotics may prove useful (Kinzie and Friedman 2004).

Anxiolytics may reduce anxiety that is so prevalent among torture survivors, but due to danger of addiction, these medications are rarely indicated.

Since insomnia is such a frequent symptom among torture survivors, agents to reestablish sleep patterns are often prescribed. Many psychiatrists in the field use nonaddictive but sedating medications, such as antidepressants in small doses (e.g., trazadone) or antiadrenergics (e.g., clonidine), for this problem.

Cultural factors and attitudes toward medication may influence compliance, and attention should be paid to explaining the importance of following the prescription instructions. Many torture survivors may stop their medication as soon as they experience a positive effect on their symptoms or stop because they either cannot wait for an effect or they experience side effects.

Other Treatment Models

Several other therapeutic approaches have been developed over time (Vesti and Kastrup 1992). The testimony method focuses on the detailed written account of the experiences that the survivor has undergone. Nonverbal techniques such as relaxation therapy have been used, especially when verbal therapies are not possible. Family and group therapy is particularly useful when the acceptance of individual therapy is limited. Recognizing the physical complaints of the torture survivors, physiotherapy has played a role as an integrative part of rehabilitation programs, and physiotherapy may be effective in reducing the distress and the chronic pain that is increasingly seen as a major contributor to suffering.

The narrative method consists of listening to the story of the client, trying not to make a psychological problem out of the story, but instead finding ways to actively change the future (Berliner et al. 2005). This method has little theoretical background and/or demonstrated effectiveness in the treatment of torture survivors.

Eye movement desensitization and reprocessing (EMDR) is increasingly used to relieve the effects of single traumatic events by combining components of exposure and cognitive therapies, but there is little documentation of their effectiveness in torture survivors (Quiroga and Jaranson 2005).

Psychosocial treatment emphasizes psychosocial factors, community activities, and self-help groups. When refugees arrive in a foreign environment, not only their health needs require reevaluation, but also their health promotion, empowerment, and quality of life. Cultural,

socioeconomic, and sociopolitical factors are important, as migrants undergo severe social changes in the host country (Ekblad and Jaranson 2004). A large proportion of torture survivors are in need of extensive social support, particularly with legal issues, housing, economic support, and access to treatment in countries of resettlement. Adjusting to a different and frequently hostile new environment adds further stress.

In many countries, entire communities have been exposed to organized violence. Here community intervention may be the solution, but limited evidence-based data on the effectiveness exist. According to WHO (2003), it is important to reestablish possibilities for religious, spiritual, and cultural activities, thereby strengthening traditional ways of handling sorrow and loss. Support programs should respect the local culture and preferably integrate local helpers. Individual counseling may not be possible if the person has no social network, but may be combined with community or family support (Madsen 2005). Goals for intervention are to heal the painful experiences, develop skills for coping with the present situation, and rediscover resources within a network (Madsen 2005).

**Organization of Care**

**Rehabilitation Models**

Since the 1980s, a large number of rehabilitation programs have emerged around the world and are still expanding. In a recent overview (Quiroga and Jaranson 2005), 235 programs or centers were identified by the International Rehabilitation Council for Torture Victims (IRCT).

Some programs may serve multiple needs of the survivors, be they medical, psychological, social, or legal, whereas the other programs specialize. The Global Directory of Centers and Programs (2003–2004) reflects the diversity of services offered by the different institutions, most emphasizing counseling or psychological services and, to some extent, medical services (www.irc.org). The Global Directory also reflects that pathways to care for survivors of torture depend upon the region in which they live. There are a variety of models of care: some are free of charge for those seeking help, and others have to be paid for by the survivors. Economic limitations are a major obstacle to appropriate care, since many torture survivors may be unable to afford any therapeutic intervention. In many regions, availability of appropriate care is limited. This means either that torture survivors do not receive any care, or that the available treatment settings have long waiting lists. Over time, treatment centers have been organized in different ways, recognizing that centers of expertise may be appropriate for some regions. In other areas, where entire populations have been exposed to organized violence, a community-oriented approach may be more appropriate. Mainstreaming the treatment and increasing the competency of mental health professionals may allow the treatment to take place within general mental health services and expand the availability of interventions. Historically, many programs were initiated by nongovernmental organizations (NGOs) in recognition that the official health services did not offer adequate care for this population. Gradually, expertise has been assembled around these programs. Subsequently, in many settings, the expertise has been transferred to and integrated with mainstream services, thereby rendering it possible for the mainstream to offer such treatment.

A bio-psycho-social approach is the philosophy behind many rehabilitation programs for torture survivors. This comprehensive approach to treatment typically provides support on a daily basis aimed at fulfilling many needs, with an awareness of the patient as a client (Berliner et al. 2005).

**Specific Populations and Issues**

**Influence of Culture and Sociopolitical Context**

Alldi (1991) has described the importance of geographical region from a developmental point of view in the management of care. In the North, i.e., the Western world, where disease classifications have been developed, the approach to treatment and diagnosis is individualistic and based upon a medical model. In the South, i.e., the developing world, this approach frequently meets resistance. For example, PTSD is often viewed as a Western ethnocentric concept that does not take into consideration the socio-political and cultural context.

This discussion has continued, emphasizing that symptom manifestation of PTSD may have different meanings depending upon cultural factors. Torture, however, is a trauma of such horrific dimensions that it essentially overrides the importance of cultural differences. This does not imply that culture has no impact, but rather that cultural differences may appear in the way the traumatized persons express their symptoms and interpret the trauma they have experienced (Jaranson et al. 2001).

The relationship between traumatic experiences and outcome is not clear-cut. Summerfield (1999) finds it problematic when Western researchers believe that PTSD, a Western diagnostic category, captures the essence of response to traumatic events. Applying diagnostic checklists without taking into consideration the cultural and political context may overestimate the need for treatment and render the problem as well as the solution individualistic.

Summerfield (1999) states that refugee beliefs of causation, such as the supernatural, may override the Western understanding of illness as situated in the individual’s body or mind. PTSD symptoms after war or torture fail to explain why many survivors of organized violence have nonetheless been able to think and act appropriately.

According to Kleinman (1988), the cultural dimension is increasingly valued, but that psychiatrists tend to exaggerate what is culturally universal in psychiatric disorder and deemphasize what is culturally particular. Disease entities are meaningful across cultures, and comparative studies across cultures with respect to certain diagnoses are therefore feasible.

Mirdal points out (2001) that there is a tendency to use the term “culture” as an explanation when dealing with “the others” behaving strangely, not when “we ourselves” do it. Culture is used as an explanation when Mustapha behaves aggressively or Fatima complains of respiratory distress, but less likely so if Maria is depressed or John drinks excessively (Mirdal 2001). Culture is a category used as a background factor in dealing with other persons’ sufferings but rarely with our own. This also is relevant to the discussion about the mental health aspects of severe trauma.
**Gender Issues**

There is a growing concern for the particular problems of female refugees. Research on the role of gender in the experience of torture has focused on individual vulnerability, and studies focusing on gender differences are rare, even though refugee women face multiple difficulties in exile (Kastrup and ArCel 2004). Refugee women risk sexual assaults, and may be forced to provide sexual services to secure survival for themselves and their dependents. Refugee authorities, e.g., UNHCR, recognize that gender aspects are important when considering refugee laws. Women, even as refugees and torture survivors, continue their role as nurturers and providers of emotional support. They have a key role in providing care and frequently have little time to consider their own needs due to their preoccupation with the needs of their immediate families. This may lead to anxious and depressive disorders, particularly in women with young children (Kastrup and ArCel 2004).

When referred to therapy in the country of resettlement, certain issues should be considered in order to provide gender-sensitive treatment. Many women with somatic complaints hope for a rapid improvement and have little knowledge about and confidence in psychotherapeutic interventions. The lack of social independence experienced by many refugee women may imply that their families do not see psychotherapy as an appropriate treatment and even question its legitimacy. Social control is generally stricter among refugee women in the host country, since male relatives may feel threatened by the autonomy and lifestyle of Western women (Kastrup and ArCel 2004). Therapists must consider such issues when establishing a therapeutic alliance. In addition, therapists should respect the values of the refugee women, as well as encourage involvement in decision-making regarding their own lives and survival in a new environment with little support from family. Social networks may be a valuable substitute for the extended family.

**Clinical Vignette 5**

YC was raped by members of Guatemalan military at the age of 15, forced to witness her mother's rape by those same soldiers, and entrapped for several years in a domestic violence relationship. She came to the treatment center suffering from severe PTSD and depression, with nightmares, headaches, and inability to sleep. The center provided YC with a psychological evaluation for her asylum case, represented by a local legal organization. The center also arranged for YC to begin seeing a primary care physician and begin free English classes, since she could not read or write in any language. Following her granting of asylum, the center secured YC job placement services, cash assistance, and medical insurance. YC reported success in all of these areas, and has referred several friends to treatment at the center.

**Survivor Issues**

Those who have been subjected to torture are frequently referred to as “victims.” By using this term, there is not only a focus on the human right violations that they have undergone, but also on the severe consequences. The term signals that they have been violated and left in a defeated position. Many have objected to be classified as “victims,” and there is an increasing tendency to replace that term with “survivors,” focusing on the resilience that the group has manifested, that they have managed to survive in spite of it all.

Several survivors of World War II concentration camps have shared their experiences with the world, and the writings of Primo Levi and Bruno Bettelheim are outstanding examples. Such testimonies provide us with an insight into the universe of those who have lived through atrocities. Other survivors (Ortiz 2001) have emphasized that it is not understandable that mental health professionals provide survivors with diagnoses without thoroughly understanding the ordeals of the survivors. Many object to psychiatric labels, stressing that they are normal persons who have experienced abnormal situations. They do not accept being called “sick” or “in need of treatment” and are concerned with the risk of being “guinea pigs.” Therapists have to be aware of this in order to avoid retraumatizing those who seek help.

**Educational Issues**

Many mental health professionals who work with severely traumatized persons experience profound reactions. Confrontation with the consequences of torture or strict asylum procedures challenges the neutral therapeutic approach. Some therapists become overinvolved with the patient’s situation and lose professional boundaries. Others may intellectualize and avoid the emotional aspects of the traumatic events revealed to them (Kinzie and Engdahl 2001). Bouts of hostility toward the patients and feelings of disillusionment or loss of neutrality may be seen. None of these reactions are healthy and may be related not only to the experience and personal qualities of the therapists, but also to their training.

In order to minimize such reactions, it is essential to provide training and adequate resources to the mental health staff working with such populations. Continuous supervision with discussion of these issues should be part of daily clinical practice. Caring for caregivers has consequently become necessary for the work in all torture rehabilitation centers.

Most centers provide special training for professionals who wish to work with torture survivors. Formal and informal exchanges of personnel within geographical regions of the world, supported by the IRCT, have also provided opportunities for training. On a more global scale, the IRCT, WMA, PHR, and the Human Rights Foundation of Turkey have collaborated to train mental health professionals, as well as doctors and lawyers, in assessment of torture survivors by implementing the Istanbul Protocol mentioned earlier in this chapter. Currently, the project has been piloted in ten countries.

**Ethical Issues**

According to the UN Convention Against Torture, countries that have ratified the Convention have also agreed to take steps to redress the consequences of torture. Thus, there is an ethical obligation to create such possibilities for those who have suffered torture.

International law provides the right to be free from torture. From a preventive point of view, it is important to investigate allegations of torture with respect to certain
principles as outlined, e.g., by AI and, in particular, by the Istanbul Protocol (UN 2001). This protocol provides minimum standards for assessing and reporting on examinations of torture survivors based on the accumulated experience worldwide. Subsequently, training manuals have been developed in several languages including a manual developed by the US Physicians for Human Rights, which emphasizes US asylum laws.

Conclusions

Torture is one of the most traumatic experiences a human being can suffer, often causing long-term physical or psychological consequences. Torture occurs worldwide to an extent that the world has only recently acknowledged, creating a difficult public health situation.

The challenges for psychiatrists and other mental health professionals are enormous, but the reward for rehabilitating survivors can be equally great. Only a small number of survivors overcome the obstacles to receiving treatment. When they do, the assessment, often using interpreters, is complicated by the extreme sensitivity required to elicit a history of torture and the necessity of assuring a sense of safety for the survivor.

Although symptomatology shows many similarities across cultural and gender boundaries, diagnostic questions about the validity of PTSD and the effect of head trauma on cognitive impairment still persist. Many approaches to rehabilitation have been used but evidence-based treatment is minimal. Cognitive therapy has been documented as an effective treatment for anxiety and depression. Pharmacotherapy has been effective in reducing PTSD and other symptoms. A bio-psycho-social approach with a multidisciplinary team of providers may be the best model for addressing the many needs of survivors.

Physical and sexual abuse and rape are prevalent in all current societies and are often followed by serious physical and psychological disturbances. Women, men, and children may be affected from all walks of life: rich and poor, across ethnicities, from the developed and developing world, and in peace and conflict zones. The common theme throughout is the use of violence as an expression of power, control, and domination.

Throughout the vast literature exploring these issues, there are many definitions of physical and sexual abuse and rape. The World Health Organization (WHO) (1996) subsumes physical and sexual abuse and rape under the category of interpersonal violence and defines violence as:

“The intentional use of physical force or power, threatened or actual, against oneself, another person, or against a group or community, that either results in or has a high likelihood of resulting in injury, death, psychological harm, maldevelopment or deprivation.”

Physical abuse involves contact intended to cause pain, injury, or other physical suffering. Examples include hitting, punching, pushing, pulling, pinching, kicking, burning, and strangling. Sexual abuse includes unwanted or forced sexual acts and is most often applied as a term in situations where an individual is, or has been, repeatedly victimized. Rape is defined as unwanted or forced sexual (vaginal or anal) intercourse, but sexual assault is a broader term that covers other unwanted sexual acts that do not include penetration. Any of these acts may include use of a weapon either as a coercive mechanism or as physically a part of the abuse or assault. There is overlap between these groups.

It is outside the scope of this chapter to discuss the acute management of child physical and sexual abuse. The objective of this chapter will be to focus on the psychiatric management of interpersonal violence and sexual assault and its sequelae in adults in nonconflict zones.

Victims of interpersonal violence will be divided into: (1) victims of childhood physical and sexual abuse. (2) those experiencing physical and sexual abuse as adults. (3) victims of rape or sexual assault. The first section of the chapter will review the prevalence of these problems and describe who are at risk. In the second part of the chapter, we will outline management issues on initial presentation that include medical stability and safety as well as early psychological intervention. Attention will then be directed to long-term mental health sequelae for victims in all three groups, with a specific focus on posttraumatic stress disorder (PTSD). Although victims of physical and sexual abuse and rape can present with symptoms of almost any mental disorder, symptoms of hyperarousal, reexperiencing of traumatic memories, and avoidance behaviors are very common and fall into the category of PTSD and related disorders. The goal of the last part of the chapter will be to review in detail the management of PTSD and related syndromes in victims of physical and sexual abuse and rape.
**Epidemiology**

**Adult Survivors of Childhood Physical and Sexual Abuse**

The US Department of Health and Human Services estimated the rate of child maltreatment in 2001 to be 12.4/1000 or over 903,000 children (US Department of Health and Human Services Administration on Children, Youth and Families 2003). Of these cases, 19% were physically abused and 10% suffered sexual abuse. Gorey and Leslie (1997) calculated the prevalence of child sexual abuse at 16.8% for girls and 7.9% for boys after adjusting for sample variation, response rates, and definition differences in 16 North American community studies. In general, it is estimated that up to 90% of cases of sexual abuse are not reported (Horner 2002).

**Physical and Sexual Abuse of Adults**

The most common type of ongoing physical and sexual abuse in adults is intimate partner violence (IPV). This includes acts of physical aggression, psychological abuse, forced intercourse and other forms of sexual coercion, and various controlling behaviors such as isolating a person from family and friends or restricting access to information, finances, and assistance. Elder abuse and maltreatment of persons with intellectual disabilities are also significant problems in which the intimate partner is not necessarily the perpetrator.

**Intimate Partner Violence**

**Case #1 — Mary**

Mary, age 28 years, is referred by her primary care physician with a history of depression and anxiety for 6 years. She is the mother of two daughters aged 5 and 3 years and has been married for 7 years to a police officer. Her husband, John, comes to the psychiatric consultation and says Mary is too upset to answer questions, so they would like to be seen together. Mary nods her head in agreement. You agree to see them together initially and advise them that you will need to see Mary alone in the latter part of the consultation.

You note that when they are together, John does most of the talking but occasionally says “isn’t that so?”, and Mary nods her head in agreement. You then ask to see Mary alone and John replies, “can’t you see she’s not up to answering questions?” You thank him for his helpful information and insist that you need to spend some time with Mary alone. As he reluctantly leaves the room, he stares at Mary and says, “I’ll be right outside, don’t be long.”

Once alone with her, you ask Mary how she feels. She begins to cry and wring her hands. You gently ask if she feels safe and she shakes her head “no.” You quietly ask if anyone has threatened her or hurt her physically, and she nods affirmatively and then abruptly says, “I can’t talk now.” You ask why and she points to the door. You ask if it is safe for her and her children to be at home tonight and she nods yes. You give her the number for the police and an emergency abuse shelter helpline, assure that she has a means of transportation, and arrange for her to return the following day by herself to get further information and decide together on the best plan.

The literature supports the idea that IPV is a prevalent problem with serious consequences. The FBI reports that 30–40% of female murder victims and 4% of male murder victims each year are killed by their partners or ex-partners (Barrier 1998). In the US population-based National Violence against Women (NVAV) survey, IPV was defined as physical or sexual assault and/or rape by an intimate partner (a current or former cohabitant, at least some of the time). In this study, 22% of women and 7% of men reported lifetime IPV (Tjaden and Thoennes 2002). In the WHO multicountry study on violence against women, there were wide variations in prevalence by country and by area within countries (i.e., urban or rural). Women who experienced sexual or physical violence from an intimate partner ranged from a low of 15% in urban Japan to a high of 71% in rural Ethiopia. Generally, rates of IPV were higher in rural than in urban areas of countries (WHO 2005).

It has been well established that most acts of IPV are not reported to police and are underreported in health-care settings. The data reported from epidemiological studies may be a gross underestimate (Cherniak et al. 2005).

**Risk Factors**

**Sex** Data from the NVAV survey suggest that women who cohabitate with women incur less IPV than women overall (11% vs. 22%) and that men who live with men incur more IPV than men overall (15% vs. 7%). However, women are more likely to be chronically assaulted with more injurious consequences. For example, in the NVAV survey, women averaged 6.9 assaults by one partner, whereas men averaged 4.4. During their most recent assault, 41.5% of women were injured, compared to 19.9% of the men (Tjaden and Thoennes 2002).

**Socioeconomic Factors** Many studies have examined risk factors for IPV (For a review, see Acierno et al. 1997). Although there have been differences in rates of IPV in various racial and ethnic populations (usually with ethnic minorities at greater risk), IPV affects all parts of society. Racial and cultural differences are often eliminated when controlling for socioeconomic status where lower income women are at greater risk than higher income women. However, even women from middle and higher socioeconomic families may have no access to cash, credit cards, or bank accounts, as abusive partners often carefully control these by preventing access.

**Relationship-Specific Characteristics** Worldwide, violence is linked to emotionally abusive and controlling behavior in the home. In the NVAV survey, having a verbally abusive partner was associated with the having twice the odds of experiencing IPV. A particularly at-risk time may be directly after one member of the couple has left the cohabitation environment. Unmarried cohabitating female partners (but not males) tend to be at greater risk than married couples. Couples where there is greater financial or educational disparity are at greater risk. For men, being a different race from the other partner is a significant risk factor for abuse. Alcohol and drug abuses are also significant risk factors.

**At-Risk Populations** Individuals who experienced assault as children are more likely to be victimized as adults (Bohn and Holz 1996). Persons with a disability (in particular those with intellectual disability) are at higher risk. It is estimated...
that up to 20% of women are beaten during pregnancy, and there are reports that ongoing violence escalates during the pregnancy and postpartum periods (Cherniak et al. 2005). However, it is controversial whether pregnancy itself is a risk factor for IPV. Women are at highest risk of domestic abuse when they are of child-bearing age, and the most consistent finding in the literature is that women who experience IPV during pregnancy have suffered abuse prior to pregnancy (Bowen et al. 2005).

Elder Abuse

Although the elderly can also experience IPV, they are also at risk of physical and sexual abuse from other sources. Perpetrators include nonpartner family members (often trans-generational) and, if the individual is institutionalized in a nursing home, can include nursing home staff or strangers. In addition to the types of physical abuse commonly seen in adult IPV, in the elderly physical abuse can include force feeding, improper medicating, or improper use of physical restraints (particularly in institutional settings). It is thought to account for about 14% of all elderly trauma. Estimates from the US National Center for Elder Abuse (2005) are that 2–10% of community-dwelling elders are victims of maltreatment (which includes neglect, psychological and financial abuse, as well as physical and sexual abuse). The National Center for Elder Abuse (1996) estimates that physical abuse accounts for 14.6% and sexual abuse for 0.3% of the total. In institutional settings, the prevalence is thought to be much higher. One survey in the USA of nursing home staff found that 10% of nurses’ aides reported that they had committed at least one act of physical abuse in the preceding 12 months (Pilemer and Moore 1989). However, elder abuse is thought to be widely underreported, with as many as five in every six cases going unreported (National Center for Elder Abuse 2005). This may be for many of the same reasons as underreporting in IPV, with the additional provision that there is more likely to be physical dependency on a perpetrating caregiver. As well, some elderly victims may feel that their allegations will be dismissed due to ageism or attributed to declining cognitive functions.

Risk Factors (Collins 2006)

Risk factors for physical and sexual abuse of the elderly include age >75 years, female, social isolation, living with or close to the perpetrator, and being dependent on the perpetrator (physically and financially), Cognitive, physical, and functional impairment; incontinence; and nursing home placement all increase risk of abuse. In addition, a history of physical or sexual abuse in the home increases the risk of recurrence in the elderly (even if the elderly victim was historically a perpetrator).

Rape and Sexual Assault

In the USA, the estimated prevalence for rape in women is 9–13% and 0.7–5% for men (Spitzberg 1999). The prevalence of sexual assault is even higher, with estimates as high as one in three for women. Data from the National Centre for Victims of Crime and Crime Victims Research and Treatment Centre (1992) reports that 1.3 women are raped every minute in the USA. Rape and sexual assault are epidemic in some countries and may be used as a weapon of war to demoralize large sectors of society. In the WHO multicountry study on violence against women (WHO 2005), rates of rape and sexual assault in women >15 years perpetrated by nonpartners were highest (between 10% and 12%) in rural Peru, Samoa, and Tanzania, with the lowest levels reported in rural Bangladesh and Ethiopia (<1%).

In recent years, there has been the advent of “date rape” drugs, such as the benzodiazepine flunitrazepam (rohypnol) and the GABA-agonist gamma-hydroxybutyrate (GHB). The existence of these drugs obscures prevalence estimates of rape because the drugs leave the victim without memory of the assault.

Clinical Pearl

Flunitrazepam can go undetected if added to any drink, has an onset of action within 30 minutes with peak at 2 hours, and can exert its effects for up to 8–12 hours. Along with the well-known effect of associated amnesia, there is somnolence, muscle relaxation, and profound sedation (Kaplan et al. 2001).

Risk Factors

Young women appear to be most vulnerable to rape. In 1987, Koss et al. conducted a national survey of college women and found that 1 in 4 women had a lifetime history of rape or attempted rape. More than half of all rape and sexual assault victims in the NVAVW were women under the age of 18 (Tjaden and Thoennes 2002). Men appear to be most at risk in the prison population where it is estimated that up to 14% of inmates are raped (Dumond 2003).

In general, strangers account for 22% of rapes; partners or dates for 19% and 38% are perpetrated by family members (Tjaden and Thoennes 2002). In the Koss et al. (1987) study of the college students, 84% of women knew their attacker. In older adolescents, date rape appears to be most common, whereas with younger adolescents, perpetrators tend to come from the victim’s extended family (Kaplan et al. 2001).

Management—Acute Presentations of Physical or Sexual Abuse and Rape

Acute presentation of physical and sexual abuse or rape may be to primary care, specialist, or emergency room settings.

Adult Physical and Sexual Abuse

Presentation

Any type of injury can be sustained from physical abuse. Risk of injury is associated with threats to harm or kill, use of a weapon, and substance use (Tjaden and Thoennes 2002). Injuries may include contusions, abrasions, lacerations, fractures, or sprains. It is important to consider that head injury can also occur (Dutton et al. 2006). This has been referred to as “shaken adult syndrome” and may be manifested by symptoms such as blurred vision, vomiting, confusion, and headaches. There may be presentation after choking including loss of consciousness and seizure.

Victims may also present with exacerbations of chronic health conditions (e.g., diabetes and cardiac disease) because the abuse has interfered with their ability to manage these conditions. They may present with chronic pain or other somatic symptoms, eating and sleep disturbance, substance
use disorders, mood and anxiety disorders, and suicidality (Cherniak et al. 2005).

**IPV**

Clues to the presence of IPV in the clinical setting are outlined in Table 125–1. It should be noted that some of these behavior patterns such as avoidance of eye contact, refusal to completely disrobe, or a male partner refusing to have his female partner seen alone by a male physician may actually be normative in some cultures.

**Clinical Pearl**

Abusive partners are often overcontrolling and may find many reasons to not allow the patient to be interviewed privately. It is essential to find a way to speak with the patient without the partner, even if it requires obtaining a nonfamily interpreter and moving the patient briefly for “a test” where family is not permitted to enter (remember Mary from Case #1).

**Elder Abuse**

Clues to the presence of elder abuse are similar. Injuries in the elderly to areas not commonly affected during daily activities are most worrisome: bruising on inner thighs, pinna of the ear, and patterns that might indicate that physical restraint was used (over abdomen, wrists, or ankles).

**Case #2—Harry**

Harry, age 75 years, has advancing Alzheimer’s disease and has been in a nursing home for 6 months. You are asked to see him because his primary care doctor thinks Harry is also depressed and agitated.

Harry is tearful and looks frightened but is unable to give a coherent history. His daughter reports that he is losing weight and is apathetic and many of his personal items including his radio, wedding ring, and watch are “lost.” His daughter also reports that Harry is poorly groomed and his clothes are often soiled with food or urine. During a visit to Harry, his daughter reports that she used her father’s washroom and overheard an aide speaking angrily to her father about needing a shower again. On emerging from the washroom a few moments later, the daughter saw her father on the floor being dragged down the hall for a shower by one arm. She is afraid to complain because she is fearful her father will be discharged from the nursing home or treated worse.

You speak with the primary care doctor and together with Harry’s daughter you meet with the nursing supervisor in the home and express your concerns. To your surprise, she reports that she has been suspicious of the aide’s behavior for some time but has not had grounds to dismiss her.

Harry’s daughter later writes you a note to tell you that her father is gaining weight and is much less agitated and depressed since the aide no longer works at the home.

**Case Identification**

As noted, victims are often hesitant to disclose. Identified barriers include shame, embarrassment, and fear of retaliation from partners. There may be economic constraints, child custody concerns, or cultural pressure not to disclose abuse. However, disclosure occurs more when questions about abuse or assault are asked.

**Clinical Pearl**

A major barrier to case identification is lack of comfort and knowledge about what to do subsequent to disclosure on the part of clinicians. It is important that frontline clinicians be apprised of resources available to assist victims of physical and sexual abuse and rape in their communities. Physicians need to remember that they do not have to manage every aspect, and referrals to social workers are usually available.

Useful principles to facilitate disclosure include a non-judgmental, empathic, and respectful clinical environment. “How” the questions are asked (i.e., with sensitivity) matters more than the exact wording of the questions.

- Clinicians must give the message that abuse is a health issue and that they are capable of dealing with “taboo” subjects. This communicates that the problem is not too irrelevant, insignificant, deviant, or shameful to talk about. It may be helpful to normalize the situation (e.g., this is a question that I ask all patients). Good areas to place information about abuse and assault are in waiting rooms and private examination rooms. Restrooms are a great place for posters about abuse, as they are private and the partner is not usually present.
- **Show concern.** The goal is to communicate that discomfort and reactions are understandable.
- **Show an ability to help.** This communicates that the situation is not hopeless.
- **Show an interest in helping, communicating that the victim is not to blame.**
- **If a patient initially denies abuse, this could mean that he or she does not yet feel safe to disclose the abuse, does not consider abuse behaviors as abusive, or may not have suffered abuse. It is important to accept this response, provide education around abuse in general, and consider asking again in the future.**

There have been studies investigating the utility of universal screening for ongoing physical and sexual abuse; however, there is little evidence that universal screening is effective either at identifying abuse or at reducing it. Therefore, targeted screening is recommended. Some healthcare providers do include screening for violence at annual health examinations, or in the assessment of new patients.
The American College of Obstetricians and Gynecologists (ACOG 2006) recommends that all pregnant women should be screened for abuse at the first prenatal visit, once per trimester, and at the postpartum visit.

Figures 125–1 and 125–2(a) and (b) offer methods for asking about IPV called the “partner violence screen (PVS)” (Feldhaus et al. 1997), the “antenatal psychological health assessment” (ACOG 2004), and the widely used “abuse assessment screen” (McFarlane et al. 1992). Questions detailing specific behaviors (e.g., slap, hit, and unwanted sexual intercourse) are more sensitive than using the words “abuse” or “assault.”
Initial Management Plan

Once physical or sexual abuse has been disclosed, the first task is to ensure the physical safety of the victim. For example, will emergency accommodation be needed? Is there someone who should or should not be contacted? Are there children involved requiring the assistance of child protective services? Then, it is important to assess the victim's motivation for change in the situation. Many victims are fearful of retaliation or feel bound by financial constraints; children; and familial, cultural, or religious expectations to remain in their current situation. No assumptions should be made about the assistance that the victim wants. Interventions should be targeted to match the victim's readiness for change. For example, if the victim is in a stage where he or she is minimizing the problem, forming an action plan for leaving the relationship would not be appropriate—and would not likely be successful.

Steps in management of physical and sexual abuse:

1. Ensure and explain limits of confidentiality (in most jurisdictions there is no legal responsibility on the part of the health-care professional to report IPV).
2. Document abuse in victim’s words, using diagrams or photographs if possible.
3. Physical examination if appropriate (and document when physical examination seems inconsistent with mechanism of injury).
4. Medical stabilization if necessary (e.g., if victim is in your office, does he or she need to go to the emergency department for X-rays, stitches, or investigation of internal injuries?).
5. Validate victim’s right to live without abuse.
6. Discuss safety and develop a safety plan (for immediate or later use). This can include planning an escape route from home, strategizing ways to reduce harm done during the abuse or ready important documents and necessities should the victim decide to leave in a rush, before, during, or after an assault.
7. Consider need for child protection (including need for reporting to child welfare authorities if child danger or abuse is suspected).
8. Assess motivation for change and tailor subsequent interventions accordingly.
9. Make referrals to social and legal services as indicated—physicians should realize that they do not need to manage all aspects by themselves.
10. Make referrals to mental health professionals as indicated.
11. Ensure a follow-up appointment.

Management considerations for the long-term mental health consequences will be discussed in detail in subsequent sections.

Rape

Rape or sexual assault leaves both men and women at risk of physical injury and sexually transmitted infection, with women at risk of (unplanned) pregnancy. Men are more likely to suffer physical harm, as they are more likely to have had multiple assailants and it is more likely that weapons were used. Rape and sexual assault are massively under-reported. In particular, adolescents tend to delay seeking care longer than adults and tend to press legal charges less frequently than adults, with males underreporting more than females (Kaplan et al. 2001). Proposed reasons for under-reporting include shame, fear of retribution, lack of confidence in police, as well as a desire to forget the event. Many victims of rape or sexual assault may be reluctant to disclose this information and may present instead for STI testing, contraception, or needing treatment for other injuries.

Clinical Pearl

Sexual assault or rape may be present in cases of IPV or elder abuse.

Disclosure

It is well established that case identification improves in settings where clinicians directly ask about the possibility of sexual assault. This happens most often in clinical settings in which clinicians are encouraged to ask, and studies show that most patients do not mind being asked. In order to ensure that the disclosure of information about sexual assault can occur, it is extremely important for the clinician to be explicit about confidentiality and allow for privacy, safety, and adequate time for the victim to tell his or her story. It is important to be nonjudgmental and to acknowledge how difficult it may be for the victim to disclose. It is important to acknowledge that feelings of fear, shame, or guilt are common and to begin to correct any cognitive misattributions such as self-blame.

Clinical Pearl

First disclosure is not the time for determining the accuracy of the allegations. The task of investigating the assault will be that of the police, if the victim chooses to pursue this avenue.

Acute Management of Sexual Assault or Rape

Case #3—Felicia

An 18-year-old college student named Felicia arrives in the Emergency Room tearful and mute. You are asked to see her for a psychiatric consultation.

You notice that Felicia appears dazed and has a swollen, bleeding lip. You ask her what happened and she shrugs her shoulders and cries. You offer her a tissue that she uses on her eyes and lip and then begins to rock back and forth in her chair. You gently comment that you can see she is very distressed and if she can tell you why, perhaps you can help.

She eventually appears to collect herself and reports that she went out with a friend to celebrate her 17th birthday and drank too much. One of the men in the bar stopped her as she was entering the women’s washroom at the end of the long hall in the basement. He punched her in the face and threatened to kill her if she did not cooperate and have sex with him. Following the assault, he told her that if she talked he would “come after her” and anyway he knows she was drinking underage and the police would charge her. She tearfully says, “It’s all my fault, anyway. There is nothing anyone can do now.”
You tell her that no one deserves to have this happen and that sexual assault is illegal. There is something that can be done. You encourage her to allow the sexual assault team to examine her and make sure that she is physically okay, by testing for sexually transmitted diseases and taking pregnancy precautions if necessary. Her options for reporting to the police can be considered. You inform her about common psychological symptoms after sexual assaults and discuss possible ways of coping. You enquire if she has a safe place to stay with family or friends. You offer her a follow-up appointment for further assessment and management the following day.

Once again, the first task is to ensure the physical safety of the victim. For example, will emergency accommodation be needed? Who should or should not be contacted for support? In some jurisdictions, it will be possible to refer to a sexual assault center where the staff is expert at the medical, forensic, and psychological evaluation of acute sexual assault. For example, in the USA, many facilities have begun to use the Sexual Assault Nurse Examiner (SANE) program, which encompasses the principles discussed below (Ledray 1999). However, there are many places where such a specialized service is unavailable and acute management will be referred to the general emergency department team.

Clear documentation is vital, particularly if the victim decides to report the rape to police. Informed consent for each stage of the management plan is essential.

**History**

1. A brief history of the assault is needed.
   (a) What orifices were penetrated?
   (b) Was barrier contraception used?
   (c) Were any weapons used?
   (d) Are there characteristics of the perpetrator known that would help inform risk assessment of STI or HIV status?
   (e) Does the victim suspect that drugs were used unknowingly?

2. Take the victim’s medical history (including pregnancy status and date of last menstrual period if applicable), psychiatric history, medications, and allergies.

3. It is helpful to know the victim’s initial thoughts about reporting the abuse or assault to the police. This can help direct the clinician in terms of what protocol to follow for DNA and other specimen. However, victims often change their minds with time, so ensure that proper specimens are collected.

**Physical Examination**

Physical examination should involve a general examination that includes a screen for external injuries as well as a genital examination for both men and women. When using a proctoscope (anal examination) or speculum (vaginal examination), special care should be taken to explain to the victim exactly what is being done and the reason for it. It can be very important to give feedback about genital damage, as patients may be worried that future partners may be able to see or somehow know that they have been raped. Details for physical examination and documentation are outlined in an American College of Emergency Physicians’ Handbook “Evaluation and Management of the Sexually Assaulted or Sexually Abused Patient” (ACEP 1999).

**Laboratory Investigation**

Investigation for pregnancy and sexually transmitted infections should be done according to need. Investigations and proposed follow-up are outlined in Table 125–2.

**Forensic Referral**

DNA samples for forensic evidence can be collected up to 10 days after assault (particularly if the samples have been stored in a nondamp environment). It is important to ask victims not to wash themselves or the clothes that they were wearing during the assault prior to forensic investigation. If the victim has changed clothes prior to presenting for treatment, then usually only the undergarments are collected. Local sexual assault response teams will have specific protocols for forensic documentation. Even if the victim is undecided about whether he or she will report the assault,
forensic evidence can be collected and stored until such a decision is made.

**Medical Treatment**

**Pregnancy Prophylaxis** Postcoital contraception can be used up to 72 hours after rape. There are two main methods: progesterone only (two 750 μg tablet given 12 hours apart) or the Yuzpe method where 2 50 μg estrogen birth control tablets are given 12 hours apart. Progesterone only is the preferred method, as it is just as effective with fewer side effects (Mein et al. 2003).

**STI Prophylaxis** The Centre for Disease Control and Prevention (ACEP 1999) recommends:

1. Prophylaxis for chlamydia, gonorrhea, trichomonas, and bacterial vaginosis.
   - (a) ceftriaxone 125 mg IM (intramuscular) once and
   - (b) metronidazole 2 g p.o. once and
   - (c) azithromycin 1 g p.o. once or doxycycline 100 mg p.o. BID for 7 days.
   - Note that some centers will substitute cefixime 400 mg p.o. once for ceftriaxone.
2. Hepatitis B immune globulin (400 IU IM) and hepatitis B vaccination if not immune.

**HIV Considerations** for HIV exposure prophylaxis involve weighing the risk of infection with that of treatment. It is important to consider the time since exposure occurred, the likelihood of transmission, the probability that the perpetrator is infected with HIV, the efficacy and side effects of the proposed regimen, and the expected patient compliance. In Canada, the British Columbia Centre for Excellence in HIV/AIDS recommends that patients who are sexually assaulted receive postexposure antiretroviral therapy. There are no data on postexposure prophylaxis after rape; however, in cases of occupational needlestick injuries or perinatal transmission, postexposure prophylaxis reduces risk of infection by approximately 67% (ACEP 1999). Risk of HIV transmission in various situations is summarized in Table 125–3.

**Early Psychological Treatment**

Although many victims are in shock and sometimes denial at the outset, initial dissociative and numbing responses have been associated with later mental health difficulties. Therefore, referrals for counseling should be offered at onset. To ensure continuity of care, patients should also be referred back to their primary care physician for ongoing monitoring.

Initial psychological intervention should be individual, supportive, and educational in nature about the effects of trauma and rape. It is important to acknowledge with the patient that any reaction he or she might be having is acceptable and that it is normal to need support. Also, it will be difficult for the patient to process and assimilate general information about rape or specific information about his or her own physical health concerns until there is a sense of psychological safety. Ensure that the patient recognizes that he or she is now in a safe place and that the assault is over. Sometimes dissociative phenomena can be observed in the emergency room. One can assist the patient by providing “grounding strategies” such as touching a table or other object in the examination room. In situations where the victim’s symptoms are so overwhelming that they preclude psychotherapeutic support of any kind, pharmacotherapy may be indicated, either with short-term use of benzodiazepines or with the institution of SSRI or SNRI medication to treat the severe anxiety. Any person being started on medication should be closely monitored. Once the patient is feeling safe enough to assimilate information ensure that he or she obtains specific information about health status and educate about the risks of future health problems (victims will often be very concerned about contracting sexually transmitted infections).

**Involvement of Family or Friends** Social support is crucial to help restore effective coping. However, the clinician should gain the patient’s involvement in deciding who to contact. There is evidence that negative social support (blame, criticism, etc.) can lead to worse mental health outcomes (American Psychiatric Association 2004). In addition, due to the high prevalence of known assailants, one should take care to ensure that the perpetrator is not mistaken for the intended support system. It can be helpful to discuss the acute and potential longer-term effects of rape with family. Education about sleep disturbance, irritability, hyperarousal, and reexperiencing phenomena can help to ensure a safe and supportive environment, as well as early referral to mental health treatment if symptoms persist. Education of family members about potential misattributions can also help reduce the victim’s experience of shame or self-blame.

**Clinical Pearl**

It is important to give written instruction, as patients may not be able to store verbal information in the overwhelmed state subsequent to an assault.

**Clinical Pearl**

Victims’ sexual partners should know that unusual responses to sexual advances after rape are universally experienced and do not reflect on the partner him- or herself.

**Debriefing** There is no evidence for “debriefing” groups where the victim is asked to describe his or her experience. There is in fact some concern that this might be detrimental for some...
patients, exposing them to triggers of reexperience unnecessarily and possibly causing them to redefine their own rape experience as more horrific in light of hearing others’ experiences (American Psychiatric Association 2004).

**Long-Term Mental Health Sequelae of Physical and Sexual Abuse and Rape**

**Adult Survivors of Childhood Physical and Sexual Abuse**

Abuse in childhood leads to significant biological, psychological, and social consequences. Adult survivors of childhood physical and sexual abuse often have profound mental health sequelae and frequently present for psychiatric treatment. Adult consequences of physical and sexual abuse in women include lower perceptions of overall health, greater physical and emotional disability, more physical health symptoms and a greater number of health-risk behaviors (e.g., physical inactivity, smoking, drug abuse, and prostitution). Risk is at least doubled for psychiatric sequelae of PTSD, major depressive disorder (MDD), anxiety disorders, and somatization (including gastrointestinal, gynecological, and neurological symptoms). Risk is significantly increased for substance abuse, dissociation, aggressive behaviors, and personality disorders.

Although mental health sequelae of childhood sexual abuse in males have been less well studied, there is an increased prevalence of PTSD, depression, anxiety disorders, eating disorders, substance use disorders, personality disorders (borderline and antisocial), poor self-image, future sexually related problems, legal difficulty, and attempted suicide. Men who were abused as children have even greater rates of psychological distress (e.g., up to fourfold increased risk of major depression), substance abuse, and sexually related problems compared to men who were not abused as children than do women who were abused compared to those not abused (Holmes and Slap 1998). For depression, this may reflect the lower baseline prevalence of depression in males. However, it may also reflect the impact of societal beliefs about abuse in males that affects disclosure, feelings of self-blame, and sense of masculinity.

**Risk Factors for Long-Term Mental Health Sequelae of Childhood Maltreatment**

In discussion of risk factors for long-term mental health sequelae of child maltreatment, it is very important to note that child sexual and physical abuses are strongly associated with mental health sequelae regardless. The following factors may mediate or increase risk, but their effect is small relative to the association between abuse and mental health sequelae in general.

**Social Factors**

The majority of the research on risk factors for long-term sequelae of abuse has been focused on the characteristics of the abuse. Individuals who suffer multiple types of maltreatment (i.e., physical and sexual abuse as opposed to one or the other), perpetrators and incidents have a higher risk of developing mental health symptoms than those who experience a single type of maltreatment, perpetrator, or incident. The risk of developing psychiatric difficulties is also increased with longer duration of abuse and earlier age of onset.

In addition, it has been suggested that “invasiveness” of the abuse (i.e., penetration vs. noncontact and violence or injury resulting from abuse result in more serious mental health consequences. Studies have shown that having a closer relationship to the perpetrator is also a risk factor, but this is complicated by the fact that a closer relationship (e.g., father–daughter incest) may mean an earlier age of onset, multiple incidents, and longer duration (Lesserman 2005).

Additional traumatic experiences may also be risk factors. In some environments where childhood maltreatment occurs, there is also familial dysfunction and there may be other traumas (e.g., witnessing abuse). Such adverse child experiences, particularly in the absence of protective factors that would help a child develop stable emotional resources, may be mediating factors in the development of long-term mental health sequelae. In addition, for women, at least, there are higher levels of psychiatric symptomatology among those revictimized in adulthood than among those women abused only as adults (Arias 2004).

**Psychiatric History and Comorbidity**

Psychological manifestations such as depression or anxiety in childhood at the time of the abuse may increase the risk of future mental health complications. The development of drug and alcohol use disorders is associated with poorer mental health outcomes for abuse survivors. In addition, early childhood abuse may interfere with the establishment of basic trust, an essential ingredient to later stable interpersonal relationships. An important question for the future is whether childhood intervention can prevent the development of long-term mental health sequelae.

**Neurobiology**

There is some evidence to suggest that individuals with a history of sexual abuse may actually have measurable hypothalamic–pituitary–adrenocortical (HPA) axis dysregulation and greater autonomic activation (e.g., higher catecholamines) both at baseline and in response to stress. In those with depression, anxiety, or PTSDs as adults, the HPA axis dysregulation and autonomic reactivity are greater. More research needs to be done in this area to determine whether the neurobiology could usefully predict who will develop psychiatric sequelae of childhood trauma (Lesserman 2005).

**Physical and Sexual Abuse of Adults**

Over the long term, individuals exposed to IPV report more physical symptoms than those not exposed (Dutton et al. 2006). Common somatic symptoms are headaches, insomnia, choking sensations, hyperventilation, gastrointestinal symptoms, and back, chest, and gynecological pain. Chronic pain syndromes are common in women who report histories of abuse. They also report poorer health status than those not exposed (Campbell and Soeken 1999). In addition, there is a higher risk of engaging in negative health behaviors such as smoking, alcohol and drug use, unsafe sex, and poor eating behaviors. There is a higher risk of HIV or other sexually transmitted infection (Zierler et al. 1996).

At the center of the psychological response to interpersonal trauma is the experience of intense fear, helplessness, or horror. IPV disrupts an individual’s sense that the world is a safe place and that others can be trusted. It disrupts an
individual’s sense of him- or herself. One of the first conceptualizations of the psychological effects of IPV was the “battered woman syndrome” (Walker 1991). Symptoms included anxiety, depression, posttraumatic stress, helplessness, passivity, and low self-esteem. It was thought that many of these symptoms arose from the chronic, unpredictable nature of the violence. It is more common now to avoid the use of this term in favor of a DSM-IV-TR diagnosis.

Mental health consequences of physical and sexual abuse in adults include PTSD, depression, anxiety, alcohol and drug abuse, attempted suicide, and suicide. In a review by Golding (1999), victims of IPV had a 3–5 × greater likelihood of the above than non-victims. It has been suggested that rates of MDD in physically abused women range from 66% to 80%. It is also important to note that subthreshold symptoms of depression and PTSD are common in this group and can cause significant functional impairment (Hegadoren et al. 2006).

Sexual Assault and Rape

Similar to the evidence in IPV, the effects of rape can be mediated through health behaviors. In a cross-sectional survey of adolescent girls in Massachusetts (Silverman et al. 2001), physical and/or sexual abuse by a dating partner resulted in increased substance use, unhealthy weight control behaviors, sexual-risk behaviors (including earlier age at first “consensual” intercourse), and pregnancy.

In 1974, Burgess and Holstrom (1974) described the “rape trauma syndrome,” which consisted of two phases. First is the acute stage immediately after a rape where symptoms include disorganization, denial, and shock. The reorganization stage occurs weeks to months later. Symptoms of this second stage typically included anxiety (fear and avoidance), depression, emotional and social withdrawal, sleeping and eating disturbances (including nightmares), self-blame, shame, guilt, somatization, and sexual dysfunction. These two stages are most similar to the DSM-IV-TR diagnoses of acute stress disorder (acute stage) and PTSD (reorganization stage). There is evidence that dissociation in the peritraumatic phase characterized by the acute stress reaction may be a risk factor for the subsequent development of PTSD. See Figure 125–3 for DSM-IV-TR diagnostic criteria for acute stress disorder. Note the time period requirements for acute stress disorder, and the symptoms must occur within 4 weeks of the trauma and last for between 2 days and 4 weeks.

The US National Comorbidity Survey (Kessler et al. 1995) found that 49.5% of women and 65% of men who experienced rape met DSM-IV-TR criteria for PTSD. PTSD does not only occur in the acute time after a rape, but many victims continue to suffer for months, if not years subsequent to an assault. Major depression is purported to be higher in rape survivors, although some authors suggest that this is more of a factor in individuals who have experienced repeated sexual trauma. Once again, symptoms that do

A. The person has been exposed to a traumatic event in which both of the following were present:

(1) the person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others

(2) the persons response involved intense fear, helplessness, or horror

B. Either while experiencing or after experiencing the distressing event, the individual has three (or more) of the following dissociative symptoms:

(1) a subjective sense of numbing, detachment, or absence of emotional responsiveness

(2) a reduction in awareness of his or her surroundings (e.g., “being in a daze”) (3) derealization

(4) depersonalization

(5) dissociative amnesia (i.e., inability to recall an important aspect of the trauma)

C. The traumatic event is persistently reexperienced in at least one of the following ways: recurrent images, thoughts, dreams, illusions, flashback episodes, or a sense of reliving the experience; or distress on exposure to reminders of the traumatic event.

D. Marked avoidance of stimuli that arouse recollections of the trauma (e.g., thoughts, feelings, conversations, activities, places, people).

E. Marked symptoms of anxiety or increased arousal (e.g., difficulty sleeping, irritability, poor concentration, hypervigilance, exaggerated startle response, motor restlessness).

F. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning or impairs the individual’s ability to pursue some necessary task, such as obtaining necessary assistance or mobilizing personal resources by telling family members about the traumatic experience.

G. The disturbance lasts for a minimum of 2 days and a maximum of 4 weeks and occurs within 4 weeks of the traumatic event.

H. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition, is not better accounted for by Brief Psychotic Disorder, and is not merely an exacerbation of a preexisting Axis I or Axis II disorder.

Management Considerations for Long-Term Psychiatric Sequelae of Physical and Sexual Abuse and Rape

As discussed in previous sections, individuals who have been victims of physical and sexual abuse and rape are at increased risk of various psychiatric syndromes, including depression, anxiety, substance abuse, and somatization. In general, the recommended pharmacotherapeutic and psychotherapeutic treatments of these conditions are not different for individuals who have experienced sexual abuse and rape. However, it is essential to recognize the connection between the presenting symptoms and the traumatic experience(s) and to consider the individual’s behavior and symptoms in the context of traumatic reenactment. The following are some important factors to consider in the general management of psychiatric illness in individuals with a history of interpersonal trauma:

1. Safety: It is important to consider that sometimes the psychiatric difficulty cannot be resolved if the abuse is ongoing—no matter the treatment.
2. Comorbidity: In many cases, there will be a number of different problems or symptoms that will need to be targets of treatment. As always, a comprehensive assessment is vital and comorbidity needs to be addressed. It will be difficult to ameliorate symptoms in one area without addressing the others.
3. Difficulties with interpersonal relationships and affect regulation: Many victims of abuse and rape have been unable to develop and/or maintain stable emotional resources, resulting in affective instability and difficulty sustaining interpersonal relationships. This will have significant implications for the therapeutic relationship that may challenge therapists in the areas of countertransference and boundary or limit setting. It may also present a clinical dilemma of how to address the trauma history during the treatment of a psychiatric disorder. With significant affective symptoms, particularly if the patient always feels “in crisis,” it is vital to equip the patient adequately to address the trauma background. Early on, it is important to help improve daily functioning and relationships while acknowledging that trauma has occurred. Exploration of the trauma itself should only begin after optimal symptom control has been achieved, there is a strong and reliable therapeutic relationship, and there has been some work in the area of expressing and processing emotions in a safe way (i.e., not using substances or self-harm to regulate affect).

While the above points apply to all psychiatric illnesses, there are some considerations specific to individual disorders. This section will review specific considerations for treatment of depression, anxiety, substance use, and somatoform disorders in individuals with a history of interpersonal trauma. The concept of posttraumatic stress is especially relevant for discussion in a chapter on management of victims of physical and sexual abuse and rape. Therefore, the phenomenology and management of PTSD in victims of abuse and rape will be discussed in detail in a subsequent section.

Depression

There is evidence that abuse influences the expression of mood disorders. There are higher levels of depressive and psychotic symptoms and suicide attempts, as well as more comorbidity with personality disorders, eating disorders, and substance abuse. Individuals with a childhood history of physical and sexual abuse are more likely to present with “atypical” depression as identified by reverse neurovegetative symptoms (e.g., increased appetite and sleep instead of decreased appetite and insomnia) than individuals without interpersonal trauma histories (Levitan et al. 1998). In assessment of a mood disorder in an individual with a trauma history, it is vital to consider symptoms in the context of the history. For example, “body memories” or “voices” may be incorrectly labeled as psychotic phenomenon when in fact they may be more accurately labeled “reexperiencing phenomena”.

Furthermore, individuals with “atypical” depression have earlier ages of onset with a more chronic course of depression—more frequent mood episodes and longer duration of episodes (Zlotnick et al. 2001). In tailoring a management plan for these patients, all of the general considerations apply, but there will almost certainly be a need for fairly intensive and multimodal treatment that might not be necessary in the management of an uncomplicated major depressive episode.

Anxiety

With respect to anxiety disorders, panic disorder and PTSD are the two types most commonly seen in individuals with history of interpersonal trauma. PTSD will be discussed subsequently and panic disorder will be addressed here.

There is evidence that individuals with a history of trauma (particularly as children) may be particularly predisposed to panic disorder, given the high degree of autonomic reactivity that can result in HPA axis dysregulation. From a cognitive perspective, panic disorder is characterized by high levels of fear of anxiety sensations. It is the fear of these anxiety sensations that contributes to the maintenance of panic disorder. In trauma, the original anxiety sensations signaled impending severe trauma, so the connection between the anxiety sensation and the cognitive perception of danger is very strong (Safren et al. 2002).

Therefore, management implications include attention to severe physiological symptoms that will often require pharmacotherapy (i.e., SSRIs). With respect to cognitive-behavior therapy, it will be important to understand the thoughts associated with panic attacks in the context of
the trauma history, addressing cognitive distortions and forming exposure therapy hierarchies with this in mind.

Substance Abuse and Dependence
In the treatment of substance use disorders in victims of interpersonal trauma, it is important to consider two main points:

1. Memories of the trauma may be triggers for substance use. Use may be a way of coping with the emotional pain of the trauma, although cravings later become associated to drug or alcohol cues as well.

2. As patients start to cut down or become abstinent from substances, feelings and memories may surface about past trauma(s). Therefore, it is essential to continually reassess individuals in treatment for substance use for comorbid depression or posttraumatic stress symptoms that may emerge. If these go unmanaged, the person may not be able to maintain or continue recovery.

Specific therapies for PTSD co-occurring with a substance use disorder have been developed. Techniques are mainly cognitive and behavioral, and the focus is on stabilizing the substance use disorder while developing coping skills to manage symptoms of hyperarousal and reexperiencing of trauma. Pharmacotherapeutic recommendations are the same as for treating these disorders individually, although it may be advisable to avoid the use of benzodiazepines for anxiety symptoms in this population due to the potential for developing dependence.

Somatization
There is not a large literature on the management of somatic symptoms in individuals with a history of physical and sexual abuse and rape despite the plethora of evidence that somatization is prevalent in this population. The prevailing theory is that exposure to physical and sexual abuse or rape may predispose individuals to respond to stress somatically—perhaps as a result of heightened somatic perception (Stuart and Noyes 1999). Unfortunately, somatization is a maladaptive communication of distress because healthcare providers and other potential sources of emotional support may focus only on the physical symptoms and not be responsive to the individual’s emotional distress. Particularly when no physiological etiology of the symptoms is found and the level of concern by the health-care provider is lessened, the patient may have feelings of abandonment and despair (leading to a corresponding increase in somatization). Implications for management, therefore, include an empathic and consistent therapeutic environment, whereby, although the health practitioner may set limits on the number of medical investigations that are to be done, he or she remains emotionally available to the patient.

Posttraumatic Stress
Herman (1992) conceptualized the response to trauma as a spectrum, from an acute stress reaction on one end to “complex PTSD” at the other end, with “simple” PTSD somewhere in the middle. Changes to a person’s psychological schema, as well as to his or her neurobiological systems (mediated by the effects of norepinephrine and cortisol), can result in a characteristic response pattern that has been labeled in the DSM-IV-TR as PTSD. Symptoms of PTSD are clustered into three categories—hyperarousal, intrusion, and constriction/numbing. Diagnostic criteria are labeled in Figure 125–4. Hyperarousal refers to the tendency to startle easily, be irritable, and sleep poorly. Intrusion refers to the flashbacks or nightmares or reexperiencing of traumatic memories. Constriction refers to the numbing and avoidance response that is like dissociation from the pain of the trauma. (See Figure 125–4 for DSM-IV-TR diagnostic criteria.)

Complex PTSD or “disorder of extreme stress, not otherwise specified” (DESNOS) (van der Kolk et al. 2005) is thought to arise in individuals who have suffered severe, prolonged, and repeated interpersonal victimization. This includes extended child abuse, chronic spousal abuse, or the effects of forced prostitution or sex trafficking. The repeated nature of the trauma is linked to cognitive, somatic, and dissociative disturbances as well as difficulties in affect regulation, boundary awareness, interpersonal problems, and identity disturbance. Although complex PTSD/DESNOS is not considered a distinct DSM diagnosis, it is widely used by researchers and clinicians who deal with individuals exposed to recurrent trauma, as it may better characterize their symptomatology than any specific DSM-IV-TR diagnosis (see Figure 125–5 for proposed diagnostic criteria).

Risk Factors for Developing PTSD
Not every victim of physical or sexual abuse or rape develops PTSD, and it is clear that the pathway to the development of PTSD is multifactorial. Greater severity and chronicity of the violence, life threat, use of a weapon, and sexual violence have all been shown to contribute to a higher risk of PTSD. Risk varies with victim-specific factors (e.g., female sex, socioeconomic status, past psychiatric history, less functional coping styles, family psychiatric history, and prior trauma history) as well as the sociocultural environment in which the violence takes place. For example, it has been shown that criticism, blaming responses, or stigmatization strongly predict poor mental health outcome (Briere and Jordan 2004).

Management
Case #3—Felicia (continued)
Felicia, who you assessed in the emergency room, did not keep her follow-up appointment the day following the assault. You next see her 14 weeks later in the outpatient department. She reports that she tried “to forget the assault by pretending nothing had happened.” She has not told anyone about it and returned to classes the next day.

She has recurrent nightmares of the assault, flashbacks, episodes of tearfulness, exaggerated startle reactions, and anxiety. She has avoided all social contacts and has started skipping classes. She feels that she has brought all these events on herself as a result of her bad judgment.

You again affirm that no one “deserves” to be raped. You explain the symptoms and causes of PTSD. You discuss the proposed treatment plan outlined in Figure 125–6 and the following pages.

The American Psychiatric Association (2004) published guidelines for the treatment of PTSD, many principles of which are applicable to treatment of PTSD in the population
of victims of physical and sexual abuse and rape. The goal of treatment is to reduce anxiety, fears, and avoidance behaviors, ultimately to return the patient to good functioning and prevent relapse. It is important to note that the psychotherapeutic treatment options described below have been studied in samples where the victim is in a safe physical environment. They are not meant to be delivered in an acute setting, prior to the medical stabilization of the individual. Principles of the assessment and treatment can also be applied in the setting of acute stress disorder and in individuals with subsyndromal posttraumatic stress symptoms.

Assessment
First, a full psychiatric interview should be undertaken with exploration into symptoms of posttraumatic stress and their temporal relationship to the trauma(s). Some aspects of the full psychiatric assessment may need to be deferred if the patient is still acutely disturbed from the assault. The general aim is to confirm diagnosis, identify comorbidity, and document baseline functioning and available resources (e.g., stability of housing, social support network, and financial resources). A psychiatric history should be taken with special attention to history of past physical and sexual abuse or rape. There should always be a thorough safety
assessment that includes assessment of suicidality, homicidability, and the safety of the current environment.

**Rating Scales**

The clinician can combine the clinical interview with rating scales such as the PTSD Checklist (Weathers et al. 1994), the Impact of Event Scale (Horowitz et al. 1979), or the Davidson Trauma Scale (Davidson et al. 1997). This will help to assess the full range of symptoms and functional impairment and provide a baseline for comparison during treatment.

**Choice of Treatment** This may depend on the severity, recency, or ongoing nature of the trauma. For example, it may not be the right time to begin cognitive-behavior therapy for PTSD in the case of a woman who continues to fear for her safety at the hands of an abusive domestic partner. In such a case, supportive intervention and resource mobilization would be more appropriate.

Choice of treatment may also depend on the severity of the symptoms, medical and psychiatric preexisting or comorbid illnesses, or patient preference. Cultural factors should always be considered. For example, cultural norms may contribute to support of a person who has suffered abuse or rape or may contribute negatively through communication that rape is shameful or that interpersonal violence should not be discussed outside the family or community.
Specific Pharmacotherapy There is no evidence for prevention of PTSD or ASD using pharmacotherapy. Studies of pharmacotherapy in PTSD have been limited, but there are data to support the use of SSRIs or venlafaxine as first-line treatment. SSRIs (citalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline) have been shown to reduce symptoms in all three symptom clusters characteristic of PTSD: hyperarousal, reexperiencing, and numbing/avoidance (e.g., Marshall et al. 2001, Connor et al. 1999, Brady et al. 2000). Venlafaxine has been shown to reduce symptoms in all three clusters and induce remission better than placebo in 12-week studies. One recent study of venlafaxine vs. placebo that included follow-up for 6 months revealed continued efficacy of venlafaxine overall, however not for symptoms of hyperarousal (Davidson et al. 2006).

The use of other antidepressants including monoamine oxidase inhibitors is supported by moderate clinical evidence for PTSD, but there are no trials specifically in interpersonal trauma survivors (Baker et al. 1995). Tricyclic antidepressants have been found to be helpful primarily with male combat victims, but not with individuals who have experienced chronic physical and sexual abuse or rape (Kosten et al. 1991, Davidson et al. 1990, Reist et al. 1989).

Benzodiazepines are not recommended as monotherapy due to the possibility of dependence and the withdrawal effects from use. However, they may be useful as temporary adjuncts to treatment, especially in the acute phase.

There are no good clinical trials to support the use of second-generation antipsychotics; however, these medications may be of some use for associated psychotic symptoms. Most anticonvulsants have not been shown to be of benefit for symptoms of PTSD, but there are some preliminary data to suggest that lamotrigine may be helpful in reducing symptoms of “reexperiencing.”

Adrenergic inhibitors are theoretical treatments in that alpha-2 adrenergic agonists decrease central adrenergic activity (possibly being effective at reducing symptoms of hyperarousal and anxiety). There are no controlled trials, but there have been open-label studies showing some efficacy for clonidine and prazosin. There is some evidence that propanolol (a beta-adrenergic blocker) may reduce later symptoms of PTSD if administered after acute trauma (Vaiva et al. 2003).

Psychotherapy There is good evidence (level I) for the effects of cognitive-behavior therapy. There is some evidence (level II) for the effectiveness of eye-movement desensitization and reprocessing or eye movement desensitization and reprocessing (EMDR). There is also some evidence that stress inoculation, imagery rehearsal, and prolonged exposure-based techniques may be helpful in PTSD symptom reduction. It appears that the common element to these therapies is that they all offer controlled exposure to traumatic memories in a safe environment. Theoretically, this allows for the victim to be reminded of the trauma while in a setting that is not dangerous and therefore allows him or her to learn to discriminate between remembering the trauma and actually being there (i.e., being in danger). In essence, the goal is to break the conditioned association between various stimuli and danger.

Cognitive-Behavior Therapy The principles of cognitive-behavior therapy for PTSD are described in Figure 125–6. It is important to consider that short-term treatment may be appropriate for those who have experienced a single traumatic event and are suffering from ASD or acute PTSD. However, individuals who are suffering from chronic PTSD or who have history of repeated trauma may require longer-term therapy.

Stress inoculation, Imagery Rehearsal, and Prolonged Exposure These concepts are closely related to cognitive-behavior therapy. Unfortunately, studies on the efficacy of these treatments have been small and relatively short term. Stress inoculation involves breathing exercises, relaxation, thought stopping, role playing, and cognitive restructuring without any exposure to imagined or real stimuli and has been shown to be effective on its own in reducing overall PTSD symptoms. Prolonged exposure involves imagined or real-life exposure to situations that are being avoided due to association with trauma and has demonstrated effectiveness in reducing symptoms of anxiety and avoidance. Imagery rehearsal is a type of prolonged exposure where only imagined situations are used. There is evidence to support a decrease in overall PTSD symptoms and nightmares with this technique.

Eye Movement Desensitization and Reprocessing EMDR is a therapy that involves multiple, brief, interrupted exposures to memories and images of trauma combined with rapid lateral eye movements. The eye movements are thought to help with reprocessing of the event, allowing for modification of affective and cognitive responses (Shepherd et al. 2000). There have been several small trials of EMDR that suggest some efficacy in victims of abuse and rape. However, some opponents argue that the eye movements themselves are not necessary for treatment and attribute benefits to the cognitive-behavioral techniques inherent in the therapy (Davidson and Parker 2001).

Psychodynamic Psychotherapy Although psychodynamic psychotherapy has not been studied systematically in the treatment of PTSD, it may be useful to aid with developmental, interpersonal, or intrapsychic issues that impact on function. Approaches outlined in the literature involve classical, object relations, and self-psychological understandings. Essentially, all approaches are useful in helping patients identify the disruptions in their assumptions about themselves, others, and the world around them that stem from, or were exacerbated by, their trauma experience. From a classical perspective, therapy can help the patient understand his or her defenses and coping abilities in the context of prior psychological conflicts, development, and relationships. From a self-psychological perspective, the focus is on how trauma has affected prior self-object experiences and overwhelmed a person’s sense of safety, security, and self-esteem, leading to difficulties with maintaining a cohesive self. Psychodynamic interventions will have to be both supportive and expressive, as indicated by the capacities of the individual at given points of treatment.
Supportive Interventions
Continued supportive interventions, including case management as clinically indicated, have been shown to improve functional outcome and to aid in symptom reduction.

Nonresponse to Treatment
In the case of nonresponse to treatment, it is important to review the items in the initial assessment and the original goals of the treatment and wonder about barriers to treatment adherence (if this appears to be a factor). Attention should be paid to any difficulties in the therapeutic alliance and the contribution of previous trauma or comorbid psychiatric axis I (e.g., substance abuse) or axis II (personality) disorders.

Conclusions
Physical and sexual abuse and rape are all common and may be followed by serious physical and psychological disturbances. They are often unreported and should always be considered in assessing individuals for psychiatric disorders or emotional perturbations. A confidential, nonblaming, empathetic line of enquiry is essential for mental health professionals during short- and longer-term management of victims of violence. The treatment, as always, will be determined by the past history, symptoms, coping mechanisms, vulnerabilities, and resilience of the individual patient and the availability of affordable skilled providers.

**Epidemiology of Mental Illness in Correctional Populations**

According to the Bureau of Justice Statistics (November 2005), by 2004, there were approximately 7 million individuals under the supervision of the local, state, and federal correctional systems of the United States (Table 126–1). This represents a nearly fourfold increase since 1980. Mental health problems are common among correctional populations. While it can be difficult to obtain data regarding the prevalence of mental illness among correctional populations, recent research has improved our understanding of the rates of mental illness within correctional populations, the role of mental illness in leading individuals into the correctional system, and the aspects of the correctional environment that alter the presentation of mental illness within correctional settings.

The United States Department of Justice, Bureau of Justice Statistics (BJS), has conducted two landmark studies examining the prevalence of mental health needs among detainees, prisoners, and offenders on probation in the community. In the first study, BJS identified an estimated 16% of jail and prison inmates and detainees who reported suffering from mental health problems (Ditton 1999). This study identified people as having mental health needs if they responded positively to one or more of the following questions:

1. Do you (or have you been told by a mental health clinician that you) have a mental or emotional condition?
2. Because of a mental or emotional problem, have you ever
   a. taken a medication prescribed by a psychiatrist or other doctor?
   b. been admitted overnight to a mental hospital or treatment program?
   c. received counseling or therapy?
   d. received any other mental health services?

No attempt was made in this initial study to objectively identify inmates’, detainees’, or probationers’ psychiatric conditions; the study relied entirely on the self-report of the study subjects.

To remedy this deficit, BJS conducted a second study (James and Glaze 2006) in which investigators conducted computer-assisted interviews of jail and prison inmates using a modified structured clinical interview for the DSM-IV-TR. Probationers were not included in this second study. Some of the key results of this investigation are summarized in Table 126–2.

*Source: Adapted from James and Glaze (2006).*
Notably, the prevalence rates of serious mental illness are remarkably high in this study: between 9 and 18% of individuals endorsed symptoms consistent with a manic episode, between 16 and 30% endorsed symptoms consistent with a depressive episode, and between 10 and 24% endorsed at least one psychotic symptom. Other important findings from this study are increased rates of many problems for inmates with mental illness than for those without mental illness. For example, inmates with mental illness had higher rates of substance use or dependence (62–63% among those with mental illness compared to 42–49% of those without mental illness), higher rates of homelessness in the year prior to arrest (13–17% vs. 6–9%), increased likelihood of a history of physical or sexual abuse (24–27% vs. 8–10%), an increased likelihood of being charged with rule violations in both prisons (58% vs. 43%) and jails (19% vs. 9%), and an increased likelihood of having been injured in a fight while incarcerated in prisons (20% vs. 10%) and jails (9% vs. 3%). Other data support the findings of BJS. For example, Teplin (1990) and Teplin et al. (1996) found that 6.4% of male jail detainees and 15% of female jail detainees had severe psychiatric disorders.

High rates of mental illness are found in prisons and jails in other countries as well. For example, in England, Gunn et al. (1991) reported that about 37% of male inmates had a mental disorder. A survey of a sample of male detainees in England found that 63% had some type of mental disorder, including 5% with psychosis (Brooke et al. 1996). A more recent study (Brugha et al. 2005) found that there was a greater than tenfold increased prevalence rate of psychosis in English prisons (52 per 1,000) when compared to the community (4.5 per 1,000). Similarly, elevated prevalence rates have been found in France, where between 4 and 6% of surveyed inmates were diagnosed with schizophrenia, and 18–24% were diagnosed with major depression (Falissard et al. 2006).

Data from less developed countries is much more difficult to obtain. International advocacy organizations such as Human Rights Watch (www.hrw.org) and Amnesty International (www.amnesty.org) tend to focus on issues related to detention without due process. While organizations such as Mental Disability Rights International (www.mdri.org) focus specifically on individuals with mental illness, their focus tends to be on individuals who are housed in hospitals or asylums with poor conditions and inadequate or cruel treatments provided. Given attention to the larger issues, little attention has been focused on people with mental illness who are detained in jails and prisons in these countries. Most countries in Latin America “are still struggling to enter into a more dynamic reform of outdated institutionally-based care. From the point of view of prisons, in those countries where data on prisons are available, no tracking mechanisms exist to determine the number of individuals with psychiatric illness in these institutions” (Arboleda-Flórez, J, personal communication, November 25, 2006. Professor Arboleda-Flórez (http://meds.queensu.ca/medicine/psychiatry/faculty/arboleda.html) is Emeritus Professor and Head. Department of Psychiatry, Queens University, Kingston, Ontario, Canada). This is not meant as a critique of these organizations or these countries, but is included only to note that in most areas of the world, the plight of individuals with mental illness in the criminal justice system does not attract attention.

Jails, defined as locally run detention facilities housing pretrial detainees and individuals serving short sentences, are known to house a disproportionately large percentage of individuals with mental illness. In some places, jails are the housing option of last resort, despite the obvious inadequacy of such a housing “placement” (Roskes and Osher 2006). There are multiple reasons for the overrepresentation of persons with mental illness in local jails, including societal intolerance of unusual behaviors, resistance of persons with mental illness to traditional interventions, and inadequate training of law enforcement officers regarding the ways in which mental illness can lead to unwelcome behaviors.

Because individuals with mental illness may be less able to mount effective defenses, they may be more likely to receive longer sentences, resulting in a high prevalence rate of mental illness in state and Federal prisons. In a study of service utilization, the BJS reported that 13% of inmates in state prisons were receiving mental health therapy or counseling, and that 10% of state inmates were receiving psychiatric medications. In addition, about 1.6% of state inmates (about 10% of those with mental illness) were housed in special housing or psychiatric treatment facilities within the prison system (Beck and Maruschak 2001).

Assuming a flat rate across all parts of the criminal justice system, applying the 16% prevalence rate from the first BJS study to the overall correctional population leads to the fairly conservative conclusion that approximately 1.1 million individuals with mental illness were under some form of criminal justice sanction (incarceration or community supervision) as of 2004. Using the more recent BJS finding that between 45 and 64% of jail and prison inmates and detainees have symptoms of mental illness, the disturbing conclusion is that about 1 million of the 2.1 million currently incarcerated suffer from symptoms of mental illness. The high prevalence of mental illness among correctional populations, when combined with the rapid increase in overall correctional population, means that the overall population of inmates and detainees with mental illness is increasing as well. However, the services infrastructure is not meeting the need. Recently, Manderscheid et al. (2004) demonstrated that “the growth in prison facilities and the growth in prisoner populations are outstripping the more meager growth in mental health services.”

Numbers are more difficult to obtain for individuals under any form of community supervision, including parole, probation, or pretrial release. It has long been recognized that individuals with mental illness are less likely to be permitted community release for similar crimes committed by those without mental illness, meaning that it might be expected that these groups will have a lower prevalence rate of mental illness as compared with incarcerated populations. This has become increasingly true over the past two decades, during which legislatures have eroded discretionary release authority of parole boards in favor of guideline-driven sentencing (see Council of State Governments 2002, Chapter 19). However, BJS (Ditton 1999) found a 16% prevalence of mental illness among probationers, very similar to the rate for jail and prison inmates, indicating that judges, at least, continue to permit community release options to individuals with mental illness.

Mental retardation is also overrepresented in the correctional system. Accurate prevalence data are much harder to obtain, but estimates as to the prevalence range from 2 to 10% (Human Rights Watch 2001). While most people with
mental retardation, like most people with mental illness, do not break the law, those who do are more likely to be caught, more likely to confess (even to crimes they did not commit), less likely to be granted parole, and likely to serve more time than nonretarded individuals with similar sentences. In addition, because of difficulties with interpersonal skills management and cognitive limitations, these inmates are more likely to find their way to higher security levels due to an inability to comprehend and follow the complex rules of a correctional institution.

The Insanity Defense
Most US states have some version of an insanity defense, under which an individual found not to be criminally responsible is diverted from the criminal justice system into mental health care and custody. For example, in Maryland, a defendant found “not criminally responsible” is criminally committed to a state hospital until he is no longer dangerous due to mental disorder or mental retardation (Eligibility for Release n.d.). Because, in general, states may elect to retain people in secure hospitals far longer than they might have served had they been convicted (see Jones v. US 1983), the vast majority of defendants who have committed minor crimes may legitimately elect to forego an insanity defense based on their belief that they will not receive long sentences. Under Frendak v. US (1979), the Court may not impose an insanity verdict on a competent defendant who elects not to enter an insanity plea.

The insanity defense is a very unusual outcome even in states like Maryland with a fairly liberal two-pronged American Law Institute test for insanity (Test for Criminal Responsibility n.d.). Janofsky et al. (1996) found that in Baltimore City, only about 1 in 10,000 indictments resulted in an outcome of “not criminally responsible,” and that in the vast majority of cases, this outcome is not contested by the prosecution.

Thus, for the small minority of defendants who elect to enter an insanity plea, there is a chance for diversion out of the criminal justice system. While this represents a diversion of these few cases from the correctional system, the insanity defense will not dramatically alter the number of individuals with mental illness who become involved in the criminal justice system.

Criminal Justice/Mental Health Collaborative Interventions
Individuals with mental illness are frequently in contact with law enforcement. For example, Deane et al. (1999) reported that among 174 big city (>100,000 population) police departments, 7% of all police contacts involved persons believed to be mentally ill. Homelessness appears to be a prominent risk factor for criminal justice involvement as well: Martell et al. (1995) reported that the rate of offending behavior was 35 times higher among homeless mentally ill persons than among domiciled mentally ill persons.

Research is beginning to demonstrate directly that individuals in our community mental health systems often have a history of involvement with the criminal justice system. For example, Theriot and Segal (2005) found that 45% of new admissions at community mental health centers and self-help programs in Northern California had a history of at least one contact with the criminal justice system prior to their contact with the program. Thirty-six percent had at least one prior conviction; half of these were for a felony offense. A prospective population-based study (Fisher et al. 2006) demonstrated that, on 10-year follow-up, 28% of individuals who had received publicly funded services in Massachusetts had been arrested at least one time. Arrest rates were higher for individuals who were younger and non-White, as is the case in the general population. Men were arrested at twice the rate for women; this represents an attenuation of the risk for men in the general population, who have a nearly fourfold risk of arrest as compared to women (Federal Bureau of Investigation 2005). The most common causes of arrest were crimes against public order (representing about 58% of all arrests), followed by serious violent personal crimes (49%), nonserious property crimes (38%), serious property crimes (34%), and motor vehicle offenses (29%). Notably, about 10% of the arrests were for assaulting a police officer. These findings lend support to much of the focus on diversion of individuals charged with minor offenses, though the prevalence of serious personal and property crimes highlights a significant public policy blind spot regarding work with serious offenders who are mentally ill. In addition, just as is the case in the general population, a small number of individuals accounted for a disproportionate number of the arrests, indicating a need to attend to highly recidivating individuals.

Police retain substantial discretion regarding the decision to arrest individuals engaging in socially unpleasant behaviors: essentially, they can interpret such behavior as a crime or as a nuisance. Police have been described as “front-line, around-the-clock, emergency responders, mediators, referral agents, counselors, youth mentors, crime prevention actors and much more” (Council of State Governments 2002). When an officer is faced with a situation that does not present an easy, community-based resolution, especially in communities in which urgent or rapidly responsive mental health care is difficult to access or unavailable, the officer may rely on a “quality of life” law to remove the individual with mental illness from the situation. Unfortunately, this response initiates criminal justice procedures rather than a mental health intervention.

Increasingly, police-based interventions are demonstrating effectiveness at reducing this “inflow” of people with mental illness into the criminal justice system. For example, Lamb et al. (1995) reported that of patients referred to a joint police–mental health team, only 2% were arrested at the time of the referral, though after 6 months, 22% had been arrested for subsequent offenses. In a review of three types of police response models, Steadman et al. (2000) found arrest rates ranging from 2 to 13%. The use of specialized police intervention models, which require advanced training of law enforcement officers regarding mental illness, has been demonstrated to reduce the criminalization of individuals with mental illness. Dupont and Cochran (2000) reported that tactical unit (“SWAT team”) callouts fell by over 50% after the initiation of the Crisis Intervention Team police intervention model in Memphis, Tennessee. Similar system interventions to assist police in diverting suspects with mental illness into the mental health system have been developed in a variety of jurisdictions in the United Kingdom (Cavadino 1999).

An open question is whether individuals with mental illness involved in criminal justice supervision are at higher risk of violations of the supervision conditions and resultant
Mental Health Care in the Correctional Setting

Standards

A number of organizations have adopted the concept of minimum standards by which correctional mental health services would be judged. These organizations include the American Correctional Association (see http://www.aca.org/standards/healthcare), the American Psychiatric Association (2000), the American Psychological Association, the American Public Health Association, and the National Commission on Correctional Health Care (see http://www.ncchc.org). NCCHC also offers accreditation to correctional facilities based on its standards. These standards attend to the following key issues.

Screening

Jails and prisons routinely must assess newly arrived detainees and inmates regarding many issues. All of the above-referenced standards setting bodies require a screening process for mental health issues. Typically, this is a brief procedure carried out by a correctional officer who poses a series of yes/no questions to the new arrivals. This process may also consist of a questionnaire to be completed by the inmate. These basic questions usually include historical queries (e.g., “Have you ever had mental problems?” “…taken psychiatric medications?” “…been in a mental hospital?”) as well as queries related to current mental status (e.g., “Are you hearing voices?” “…feeling like you want to hurt/kill yourself?”). In the past several years, screening systems have been studied and validated in correctional settings (see, e.g., Steadman et al. 2005).

Assessment and Evaluation

Inmates who screen positively for mental illness are to be referred for a more in-depth assessment by a mental health provider. In some cases, this may be a two-step procedure, with a brief assessment to rapidly rule out false-positives from the screening process, followed by more sophisticated full psychiatric or psychosocial evaluations of those individuals still of concern. In other settings, these two steps may be combined. The decision as to how best to conduct this step is dependent on availability of personnel and other resources (e.g., special housing settings). Often, various providers, including psychiatrists, psychologists, social workers, and nurses, conduct different parts of this assessment. In some instances, the first provider is a nonpsychiatric clinician such as a registered nurse or a physician assistant.

Individuals determined to need rapid psychiatric assessment due to acute presentations should be housed in a special unit designed for safe monitoring and should be prioritized for urgent psychiatric care. Many correctional facilities may not have settings specifically designed for this purpose and may simply house people in a medical clinic setting or in a “segregation” or “lockdown” setting. In addition, small facilities may not have the capacity for urgent psychiatric assessment and may need to rely on local emergency departments or community hospitals, where staff often have very limited understanding of what can and cannot be provided in the correctional setting.

Treatment and Management

Once the evaluation is complete, individuals who have been determined to require mental health care and treatment should be housed in an appropriate setting for their needs. There are a variety of levels of care and services that may be provided in a correctional system, depending on the size and location of that system (Table 126–4). Large jail and prison systems may include all of these levels of care, while smaller jails may not have any of them and may rely on outside agencies (such as a community mental health center or a state or county hospital) to provide these services (Maier and Miller 1989). Because of their shorter-term mission, jails may not provide all of the services below but may focus instead on identification of individuals with mental illness and may choose to refer them for treatment. Consistent with this mission, many larger jurisdictions are focusing increasingly on options for “diversion” of individuals with mental health problems, partnering with the courts and with the prosecution and defense bars to seek alternatives to incarceration for these individuals, especially those charged with relatively minor offenses.

It is important to keep in mind that correctional administrators struggle with finding a balance between their very real budgetary restrictions and the requirement to meet all of the needs of the prison or jail on the one hand, and the requirements of courts vis-à-vis standards for mental health care on the other. What is presented here is to some extent an ideal: many systems struggle to meet this ideal. Further discussion of the economic constraints faced by corrections administrators will be presented below.

“Outpatient” Care
As described above (Beck and Maruschak 2001), 13% of state prison inmates in 2000 were receiving therapy or counseling, and 10% were receiving medication. The majority of these inmates were housed in general population settings (i.e., they did not require specialized housing within the prison). Typically, these inmates are seen periodically by a therapist and/or a psychiatrist. In addition, services may be provided on an as needed basis. This level of care resembles outpatient care provided to individuals in the community who are not hospitalized.

Special Housing
Many large correctional institutions and systems provide special housing units for individuals who are found to have mental illness and who may not be manageable in general population. For example, the Baltimore City Detention Center, with a total male population of around 3,000, includes a 65-bed residential unit for individuals with mental illness. Detainees who are known to have or who are identified as having problems managing jail life in general population due to mental or behavioral disorder, but who are not so ill as to require inpatient care, are housed on this unit. The unit is staffed by a psychologist who conducts rounds every day, and the inmates on this unit have regular access to a psychiatrist. In addition, correctional staff have been assigned to work in this unit and have developed an improved understanding of the mental health needs of the detainees housed there. Other large jail systems have similar models.

“Inpatient” Care
Large institutions and systems may also provide their own inpatient treatment facilities. Some systems (e.g., the Maryland Department of Public Safety and Correctional Services) have created a specialized prison designated as an inpatient facility for seriously mentally ill and behaviorally disturbed inmates. Other systems have established collaborations with health care entities to provide secure inpatient units. For example, the New York City Department of Correction operates units within several City hospitals for the inpatient management of seriously ill inmates and detainees (see http://www.ci.nyc.ny.us/html/doc/html/hospital.html#hospital).

Medication Management
As outlined by the US District Court in Ruiz v. Estelle (1980), one of the services to be provided to inmates suffering with mental illness is medication management. At a minimum, this should include rational prescribing following appropriate diagnosis, with adequate monitoring and ongoing reevaluation of ongoing therapy. A significant issue in many correctional systems is the limited formulary, usually imposed due to economic constraints, as discussed further below. Psychiatric medications should never be used simply for sedation or “chemical restraint” in the absence of an appropriate psychiatric diagnosis and treatment plan.

Psychotherapy
Many inmates with mental health problems are appropriate for brief or ongoing psychotherapy, often provided by psychologists and social workers in an individual or group setting. These services may begin upon intake or in response to a crisis during an incarceration. Typical problems include adjustment to incarceration, reactions to family problems outside the prison, as well as psychiatric illnesses that may be responsive or partially responsive to psychotherapies.

Many prison systems provide psychotherapy targeting specific issues. For example, the majority of inmates with mental illness have a co-occurring addictive disorder. Many prison systems offer substance abuse treatment. Typically, however, there are an inadequate number of treatment slots for the population, and mental illness may be used as an official or unofficial exclusion criterion. In addition, some of the treatments offered (e.g., therapeutic communities) may be seen as inappropriate for those with serious mental disorders.

Sexual disorders are increasingly the focus of psychotherapeutic approaches in prison settings. An increasingly common phenomenon is the “diagnosis” of “sexually violent predator.” Washington State in 1990 was the first jurisdiction to pass a law regarding such individuals, which requires the civil commitment at expiration of a criminal sentence.
of individuals meeting the definition of “sexually violent predator.” A “sexually violent predator” is defined under Washington law as “any person who has been convicted of or charged with a crime of sexual violence and who suffers from a mental abnormality or personality disorder which makes the person likely to engage in predatory acts of sexual violence if not confined in a secure facility.” Under this law, the person who is found to meet this definition “shall be civilly committed to the custody of the department of social and health services for placement in a secure facility…” either until he no longer meets the definition or until a less restrictive alternative placement is found (Washington State Legislature n.d.). Mental health providers in prisons in states with similar laws may be asked to perform evaluations of inmates based on this or similar definitions. In addition, during an incarceration, inmates may request psychotherapy in an attempt to avoid civil commitment at end of sentence.

Release Planning
Over the past decade, attention has focused on the needs of the inmate with mental illness nearing the end of his/her term of incarceration. Historically, correctional providers have overlooked this important clinical responsibility. However, transition planning increasingly is seen as an important element of the provision of care to incarcerated individuals with mental illness (Council of State Governments 2002, Chapter 20).

A key case in this area is *Brad H., et al. v. City of New York, et al.* (2000). Filed as a class action in 1999, this case was settled in 2003. In the settlement (Stipulation of Settlement 2003), the City agreed to provide eligible individuals with discharge planning services to include referrals to mental health providers (or appointments where a release date was known in advance), medications and prescriptions upon release, applications for medical assistance and public assistance, referrals for supportive housing services, access to shelter placements where necessary, and transportation services. In addition, these individuals would no longer be released in the middle of the night. The case currently is subject to a monitored consent agreement.

A second key case is that of *Wakefield v. Thompson* (1999). In this case, an inmate with a psychotic disorder was provided with a prescription for his antipsychotic to be dispensed on release. The correctional staff failed to provide the inmate with the prescription, and the inmate became psychotic and violent just 11 days after his release. The inmate sued the prison system. In overturning the District Court’s dismissal of the case, the Ninth Circuit held that the state must provide an outgoing prisoner who is receiving and continues to receive medication with a supply sufficient to ensure that he has medication available during the period of time reasonably necessary to permit him to consult a doctor and obtain a new supply. A state’s failure to provide medication sufficient to cover this transitional period amounts to an abdication of its responsibility to provide medical care to those, who by reason of incarceration, are unable to provide for their own medical needs.

The *Wakefield* principle has since been applied to a jail case in which a detainee was released on bond in an effort to evade county responsibility for the detainee’s medical bills (*Marsh v. Butler County* 2000) and to a case involving the need for ongoing medical procedures and care upon release from prison (*Lugo v. Senkowski* 2000). The spirit of *Wakefield* is evident in the *Brad H* Stipulation of Settlement as well.

Community Treatment of Offenders
Increasingly, attention has been focused on the treatment needs of individuals under criminal justice or correctional supervision in the community. These individuals may be released pending trial under the jurisdiction of a mental health court, or they may be adjudicated as guilty and given probation in lieu of incarceration. Alternatively, they may have served a partial sentence having been released early under parole supervision. At times, the releasing authority imposes special conditions of treatment, or the supervising agency of its own accord may recommend that the individual seek treatment. Various diversion models have been piloted in jurisdictions across the United States (Council of State Governments 2002). Similarly, in the United Kingdom, efforts have been made toward the diversion of individuals with mental illness from the criminal justice system into appropriate mental health services (Badger et al. 1999, Cavadino 1999). Community providers can effectively work with such individuals in a variety of settings (Roskes et al. 1999, 2005, Roskes and Feldman 1999). In addition, it is important that the providers maintain a clinical focus and avoid becoming an extension of the monitoring entity.

Special Topics and Challenges in the Correctional Setting

Refusal of Treatment
In all correctional settings, the inmate or detainee with mental illness who refuses treatment poses a special problem. In addition to the usual balancing of individual rights versus public safety, the correctional environment poses special challenges to providers and correctional managers when faced with a refusing inmate. Clearly, the overarching issue is whether inmates and detainees have the right to provide consent (assuming competence to do so) to recommended treatment. Assuming that the provision of relevant information regarding the treatment proposed is considered a part of standard care, then competent inmates and detainees in theory have as much right to refuse treatment as any other patient.

However, in the correctional setting, such refusal may adversely affect other inmates or detainees. Consider an individual with a psychosis that includes symptoms of paranoia and threats toward other inmates and staff. These potential victims cannot distance themselves voluntarily from the ill person, as they might do in the community. The potential victims have a right to a safe environment, either as inmates (under the Eighth Amendment) or as staff of the institution (under Occupational Safety and Health Administration and similar state codes). Some states have resolved this problem by creating an administrative process that requires a finding that, untreated, the mental illness will cause the inmate to be “gravely disabled or dangerous” (*Washington v. Harper* 1990). While this may superficially resemble civil procedures for forcibly medicating committed inpatients, it differs in
that there is no constitutionally mandated requirement for judicial oversight of the decision. In states without such a statute, the only alternative available is the civil commitment of such inmates to a secure hospital where they might undergo medication over objection proceedings.

Comorbidity and Mistrust
As a rule, individuals with mental illness in the correctional system usually have multiple co-occurring problems, including substance abuse, medical problems, developmental disorders, and personality disorders. These multiple comorbidities render treatment very complicated. Superseding the complications of treating any person with complex comorbidity is the mistrust that inmates often have in dealing with correctional-based clinicians. Often, inmates and detainees see the provider as part of “the system” and will not accurately report symptoms. A high level of skill is required to make accurate psychiatric diagnoses of patients in this system, some of whom will falsely report symptoms that are not present in order to obtain medications for abuse or sale, others of whom will falsely report lack of symptoms in order to remain unobtrusive and “low profile.” Maintaining an appropriate level of suspicion can be difficult (Roskes and Osher 2006).

Offenders who have been released also have some difficulty engaging in community-based treatment. Community psychiatrists and other mental health providers must be aware of this difficulty and work to overcome the added mistrust that individuals with criminal justice histories may have. Specialized training programs have been developed for both providers and patients, in learning to work with each other after an individual has been released (Rotter et al. 2005).

Seclusion and Restraint
In correctional settings, the use of seclusion and restraint for individuals with psychiatric disorders is confounded by the routine use of nontherapeutic restraints by corrections and law enforcement staff for security reasons. While efforts toward the reduction of seclusion and restraint are proceeding in community settings (see, e.g., SAMHSA 2006–2007), such efforts have not yet made their way into correctional settings. In instances where seclusion or restraint are ordered in correctional settings. In instances where seclusion or restraint are ordered with therapeutic intent, such decisions should be made by appropriate clinicians, and the inmate subject to such interventions should be monitored closely.

In addition to standard therapeutic types of seclusion and restraints, all corrections agencies have a system of custody levels, ranging from low security (e.g., prerelease or work release), through minimum, medium, and maximum up to “supermax” levels. Inmates are classified based on a variety of factors including the instant offense (the offense leading to the current incarceration), prior criminal record, and institutional adjustment factors. Inmates with persistent difficulty adjusting to the prison setting tend to rise in classification level, ultimately arriving at supermax. Because mental illness and mental retardation may result in difficulty adjusting to prison, it is imperative that administrators have in place a system for the evaluation of inmates for “suitability” for placement in these ultrahigh security settings, which may involve total isolation from other inmates and near-total isolation from staff. Such isolation has been asserted to lead to worsening psychosis in predisposed individuals (see, e.g., Grassian 1983). Ironically, in most correctional institutions in the United States, all forms of psychological and social treatment cease when an inmate is sent to segregated settings due to rule infractions (Toch and Adams 1990). Therefore, inmates for whom difficulty in adjusting is believed to be due to mental illness or retardation should be referred instead for special housing units or treatment/habilitation programs designed to help them accommodate to the prison setting, rather than being placed in higher security levels for punitive purposes. Although this sounds simple in theory, it can be extremely difficult in practice, given the complex diagnostic comorbidities among the correctional population.

Dual Agency
A frequent dilemma faced by psychiatrists and other mental health professionals working with correctional populations is the problem of dual agency. Familiar to forensic psychiatrists, this issue may present problems for the novice in this area. Providers of services to individuals under correctional supervision have two consumers of their services: the patient and the correctional manager or supervising agent (Packard 1989). These potentially conflicting obligations may arise under varying circumstances. For example, a clinician may be asked to perform a specific forensic evaluation, if a patient under his/her care is accused of a new crime, or if a patient under his/her care is a “sexually violent predator” subject to potential civil commitment at expiration of sentence.

Perhaps a more frequent occurrence is an institutional need: should an inmate under a clinician’s care be absolved of responsibility for a rule infraction due to mental illness? If not, should that inmate be placed on segregation (as a punishment) or moved to a higher security level (as a management strategy)? These are examples of common questions posed to the correctional mental health provider that may place the patient’s interests at odds with the needs of the institution.

Economics and Correctional Mental Health Care
Correctional administrators struggle with limited budgets, imposed by the legislature which is ultimately responsible for funding the correctional system. Within their budget, these administrators are responsible for managing all aspects of their institutions—staffing, infrastructure, security, and inmate services. Health care is but one part of the overall set of services provided to inmates, and mental health is but one part of the overall health care service.

Recruitment and retention of mental health providers within correctional settings is a challenge, and often prisons and jails have inadequate numbers of mental health staff. These jobs are perceived as dangerous and unpleasant and hence are not attractive to job seekers. In addition, prisons are often located in rural areas which are underserved by mental health providers in general. Providers working in such settings often feel compelled to play roles in containment and discipline, which may disrupt their ability to establish and maintain a traditional therapeutic alliance.

Correctional providers often outsource the problem of staffing by contracting with private companies who agree to provide health care services in the jail or prison system.
Because these contracts usually operate as a capititated system of care, the contractor is at risk for all costs and therefore may be incentivized to cut costs in a variety of ways. As in the private sector, one of the most common cost saving mechanisms is a restricted formulary. Some jurisdictions have responded to these concerns by establishing independent oversight boards, by offering training to officers, and by seeking accreditation.

**Conclusion**

The number of individuals with mental illness or mental retardation in the criminal justice system continues to increase. The US Supreme Court has established a constitutional right to treatment for prisoners, rendering the incarcerated the only group in the United States for whom there is a constitutionally mandated right to health care. However, many correctional systems struggle to meet this requirement due to inadequate resources and staffing, or because of a lack of vision and understanding regarding the importance of providing such care. The situation is similar in other developed countries, while in the developing world, data regarding the prevalence of mental illness in prisons are unavailable. Only when individuals with mental illness are identified can adequate treatments be provided, and prompt provision of appropriate mental health services may lead to improved outcomes. The recent Criminal Justice/Mental Health Consensus Project (Council of State Governments 2002) provides a series of overarching policy recommendations that may be used by jurisdictions interested in improving the services they provide, or by advocates (including psychiatrists) seeking to raise the profile of this important issue in their communities.

Introduction
Violence is a major and growing public health problem globally according to a World Health Assembly Resolution (WHA49.25) (World Health Organization 2002).

The World Health Organization defines violence as

The intentional use of physical force or power, threatened or actual, against oneself, another person, or against a group or community, that either results in or has a high likelihood of resulting in injury, death, psychological harm, mal-development or deprivation. (WHO Global Consultation on Violence and Health, 1996)

This definition implicitly includes all acts of violence, private or public, proactive or reactive, planned (deliberate) or unplanned (impulsive), criminal or noncriminal.

Given an overall age-adjusted rate of 28.8 per 100,000 population, World Health Organization (WHO) data (World Health Organization 2002) on estimates of mortality and nonfatal violence indicate that in 2000, an estimated 1.6 million people died globally from self-inflicted, interpersonal, or collective violence. Underreporting, cultural sanction of violence, poor study design, and inadequate surveillance make accurate estimates of violence difficult. Available estimates rely on surveys and special studies, often examining crime rates or injury rates. Violence also varies with age, gender, between and within regions, and among different racial and ethnic groups.

Most violence is caused by persons without mental illness (Appelbaum 2006). Nevertheless, violence and aggression are frequent reasons why a person may present to a psychiatric emergency service. Psychiatric inpatients may become violent. For example, in a study (Barlow et al. 2000) examining inpatient aggression, 13.7% of patients were recorded as being aggressive over an 18-month period, and most of the aggression occurred within two days of admission. Violence can also be seen among outpatients (Steadman et al. 1998). It is, therefore, incumbent on mental health clinicians to have a sound understanding of the assessment of violence risk among patients. In addition, it is important to know about treatment approaches utilized to help manage violence risk.

Violence is not only multidimensional but also multifactorial. In particular patients, manifest reasons for violence or aggression (such as a dispute with a family member or active manic symptoms) may be apparent, but underlying factors (such as genetics, environment, culture, personality) may also play a contributing role. Therefore, even well-established associations between violence and any mental disorder should not be mistaken for demonstrated causal links. The reverse is also true: failure to conclusively demonstrate a causal link between a specific disorder and a specific type of violence does not mean that none exists or that the knowledge of predictable associations may not be of clinical use, even if the true cause of the relationship is unknown.

In this chapter, we provide an overview of the literature related to violence and its underpinnings. This chapter will review relationships between biological factors and violence and describe pharmacological and nonpharmacological strategies to assess and treat aggression.

Assessment of Violence Risk in Clinical Settings
As with suicide, a general query as to whether a given patient has ideas of harming or killing anyone is often the mainstay of a brief screening assessment. More open-ended screening questions may yield additional information related to more general violence risk. Examples of areas of exploration in screening questions are listed in Table 127–1.

When screening questions yield a history of violence and/or active violent ideation or intent, or when the facts
related to the reasons for presenting for clinical care warrant concern, clinicians should conduct a more thorough violence risk assessment. General risk assessments involve a careful review of the patient’s historical, situational, and clinical factors that may contribute to violence risk. Individuals may provide a great deal of important information related to their violence history, with collateral records and conversations with other people who know the patient supplying additional useful information (Steadman et al. 1998). Actuarial and structured clinical risk assessment instruments continue to be developed, though their general applicability in non-forensic settings has not been fully established. For a more thorough review of violence risk assessment, see Borum et al. (1996) and Pinals et al. (in press) for examples.

### Classification of Violence

Attempts have been made to classify violence but none of these has been as comprehensive as the WHO classification (World Health Organization 2002). This classification categorized violence into three broad categories based on the characteristics of the perpetrators of the violent acts (Table 127–2). The categories include:

1. Self-directed violence
2. Interpersonal violence
3. Collective violence

This chapter addresses interpersonal violence, and in particular, interpersonal violence that can become the focus of treatment. Early studies examining the relationship between violence and mental illness have been criticized for the lack of specificity regarding what is meant by violence. One of the first studies to offer a careful distinction between types of violence under study was that of the MacArthur group, whose significant methodologically sound investigation divided violence generally into serious “violence” (defined as battery resulting in injury, weapon use, sexual assault) and “other aggressive acts” (defined as battery without injury) (Steadman et al. 1998). A widely used classification of aggression (Dodge 1991) distinguishes between reactive aggression, which is described as anger motivated and impulsive; and proactive aggression, which is comparatively unemotional and deliberate (for the types of characteristics, see Table 127–3). These types of aggression have also been described as affective and predatory types.

In clinical terms, the words aggression, agitation, and violence are sometimes used interchangeably, though they are not synonymous and doing so can lead to confusion and inaccuracies. For clinical purposes, it is much more useful to describe specific behavior before assigning more general labels. These distinctions help in treatment planning and risk management.

### Link Between Anger and Aggression

Recently “anger” has received increased attention, demonstrated for example, by the widespread establishment of “anger management” groups. Anger is an emotion while aggression is behavior. Anger is an emotion associated with a person’s aim to increase the probability of success in the pursuit of ongoing desires and competition for resources (Panksepp 1998). Though not all aggression is caused by anger.

Chronic anger can be debilitating. Research affirms the negative influences of anger on health (Siegman and Smith 1994), work effectiveness (Folger and Baron 1996), and interpersonal relationships (Jacobson and Gottman 1998), and an increase in propensity to aggression and violence (Baumeister et al. 1996).

The **Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)** (American Psychiatric Association 2000) lists five diagnoses (Intermittent Explosive Disorder, Posttraumatic Stress Disorder (PTSD), Borderline Personality Disorder, Antisocial Personality Disorder (ASPD) and Paranoid Personality Disorder) that specifically include the symptom of aggressive behavior. In each of these disorders, excessive sudden anger is a possible symptom of the disorder. Sudden anger attacks have also been associated with Panic Disorder and Major Depressive Disorder and aggression is also associated with Sexual Sadism (DSM-IV-TR). Research has shown that mental health practitioners tend to show bias toward assigning personality disorder DSM-IV-TR diagnoses when diagnosing patients with impulsive anger when presented with clinical vignettes related to anger (Lachmund et al. 2005).

The false impression that dysfunctional anger always leads to impulsive type aggression is often perpetuated. Many aggressive acts, however, such as those seen in some school shootings, serial sexual assaults, or stalking cases, may not be related to impulsivity, and they may not be entirely motivated by anger. Furthermore, not all anger-generated aggression (whether impulsive or planned) is related to mental illness.

### Clinical Factors Associated with Violence

Much of the literature dealing with violence and mental health problems derives from samples involving individuals charged or convicted of a crime who for one reason or another were also assessed for psychiatric illness. This pattern makes any firm conclusions about causality difficult since the conclusions may have been biased toward finding associations between mental illness and crime and/or violence. Also, as noted above, violence and aggression are contextual. Violence in a homeless shelter by a paranoid person, in a surgical operating suite, in a barroom knife fight, in a consensual sadomasochistic relationship, or in war, all clearly derive from very different motivations.

It should be noted that the review below will highlight only a selection of diagnoses and their relationship to violence. For a review of other diagnoses, see individual related chapters in this volume.

**Violence and Mental Illness**

Though most persons with mental illness will not become violent, people with untreated mental disorder have a higher incidence of violence and aggression in their lives (Swanson et al. 1990, Coid 1996). This association may be especially significant for those who require psychiatric hospitalization in adolescence (Kjelsberg and Dahl 1998, Soyka 2000).

Of mental disorders, those most commonly associated with nonsexual violence are: substance abuse disorders (including alcohol abuse), schizophrenia, personality disorders and mood disorders. While these disorders are reviewed separately, evidence suggests that among those with serious mental illness, risk of violence increases in association with alcohol or other drug abuse combined with medication noncompliance (Swartz et al. 1998, Steadman et al. 1998).

**Schizophrenia and other Psychotic Disorders**

Of men convicted of homicide, one literature review found between 5–11% had a previous diagnosis of schizophrenia (Soyka 2000). A study (Wallace et al. 1998) found men with schizophrenia to have a risk of committing murder that is 5–18 times that of the general population. Studies have shown an association between schizophrenia and violence that cannot be fully explained by personality disorders and substance use (Brennan et al. 2000). The risk, however, of violence among people with schizophrenia has also been shown to be strongly associated with substance and alcohol use. For example, in a 26-year follow-up study involving over 11 thousand individuals in an unselected birth cohort, those who were male, and had been diagnosed with schizophrenia and alcoholism were 25.2% more likely to have committed a violent offense than men without schizophrenia or alcoholism (Räsänen et al. 1998). Targets of violence among persons with serious mental disorders such as schizophrenia were most frequently family members (Steadman et al. 1998).

In the Epidemiologic Catchment Area study (ECA) data, 13% of participants diagnosed with schizophrenia (compared to a base rate of 2% for persons with no psychiatric diagnosis) reported having engaged in some form of violent act over the preceding year, a figure much lower than those with substance use disorders (Swanson et al. 1990). Steadman et al. (1998) demonstrated that patients with serious mental illness like schizophrenia were less likely to

be violent during follow-up than those with other mental disorders, such as personality disorders.

Paradoxically, a diagnosis of schizophrenia (regardless of whether or not the individual also abuses alcohol) was found to reduce the risk of violent re-offense by the authors of one actuarial risk assessment instrument, the Violent Risk Appraisal Guide (VRAG) (Quinsey et al. 1998). This finding likely results from the fact that the standardization sample used to create the VRAG included, among others convicted of crimes, men found not criminally responsible for the crime that resulted in them being sent to a maximum secure psychiatric hospital. Within this population, those with schizophrenia would represent a subgroup for whom effective treatment was offered, particularly within the subgroup who were re-released into the community.

A second counterintuitive finding derives from a recent prospective 1-year follow-up study which found that specific paranoid delusions were not predictive of risk of violent re-offense (Monahan et al. 2001). This contradicts earlier opinions that delusions, particularly, types of paranoid delusions represented significant risk factors for subsequent violence (Taylor 1998).

Mood and Anxiety Disorders
Early ECA data showed that 12% of persons with depression, 11% of persons with a diagnosis of "manic-depression" (bipolar disorder), and 12% of persons with panic disorder reported having engaged in some type of aggressive act during the preceding year in the United States (Swanson et al. 1990). Mania has also been associated with impulsivity and aggression (Sachs 2006). Clinically significant changes in mood by definition are dysphoric. It would seem likely that disorders that influence mood could also influence predisposition to engage in violence (Davidson et al. 2000). There is an extensive literature linking abnormalities in monoamines (especially serotonin) with mood disorders, impulsivity, and aggression (see for review: Praag et al. 1990).

Though anxiety disorders are less often associated with aggression, some experts have suggested that “anger attacks” may resemble “panic attacks” and may occur in patients with depression (Fava and Rosenbaum 1999).

Violence and Intellectual Disability
Approximately, 3% of the population in North America meets DSM-IV-TR criteria for mental retardation (hereafter referred to by the preferred designation of “intellectual disability” (American Psychiatric Association 2000)). This population, however, is significantly overrepresented in the criminal justice system. A review (Endicott 1991, p. 4) concluded that the percentage of incarcerated inmates with intellectual disabilities is at least twice as high as in the general population with an estimated incidence of between 5 and 10%.

A recurring theme in the literature on aggression is that reduced intelligence is a significant risk factor. Few studies, however, distinguish between intellectual disability per se and intellectual disability in the company of other serious brain disorders. For example, a literature review (Trimble and Elst 1999) of aggression and specific brain lesions concluded that patients with aggression tended to have a combination of lower intelligence combined with increased general psychopathology. The same study’s primary reported finding was a failure to find a difference in total amygdala volume though there was an association between aggression and left-sided amygdala atrophy and a history of encephalitis.

Violence and Personality Disorders
Violence may be seen in persons with personality disorders, particularly paranoid, borderline and ASPDs. ASPD is clearly associated with violence. Impulsivity, irritability, aggressivity, and a history of childhood conduct disorder are among the criteria for this diagnosis. Psychopathy is a personality construct related to but distinct from ASPD. Most persons with psychopathy meet criteria for ASPD, though not all persons with ASPD qualify as psychopathic. Psychopathy includes the social deviant dimensions of ASPD such as antisocial behavior and impulsivity but also includes emotional aspects that include interpersonal manipulation and lack of emotionality. Psychopathy is generally assessed, by those trained in its use, via the Hare Psychopathy Checklist-Revised (PCL-R) (Hare 1991) or the Hare Psychopathy Checklist-Screening Version (PCL-SV) (Hart et al. 1995). Table 127–4 describes an overview of the Screening Version. Though clinicians will more commonly rely on DSM-IV-TR diagnoses of ASPD in clinical settings, consideration of psychopathy as a significant risk factor for violence has been well-established (Hart and Hare 1997, Hart et al. 1994). Still, it is important to remember that not all psychopaths will become violent, and not all violence is related to psychopathy (Babiak and Hare 2006).

Violence, Physiology, and Biology
The literature on the association of organic disorders and violence and aggression can be broadly subclassified under the headings of substance induced, hormonal, genetic, and brain injured/neurologically based. In addition, specific findings related to neurotransmitter function and violence as well as other neurobiological aspects of aggression have been described. As in previous sections, although these sections are described separately, this is more for heuristic reasons than for clinical accuracy since biologic causes of aggression tend to occur together.

Substance Induced
Alcohol
By far the most well documented and researched “aggression inducing” substance is alcohol. Several reviews indicate more than half of all homicides, assaults, and rape occur in the context of alcohol and/or drug consumption by at least one of the parties involved (Roberts et al. 1999). Rates of association are, however, highly variable. For example, one
meta-analysis of studies reporting alcohol use at the time of the commission of murder found rates among homicide offenders to vary from 28% to 86%. These rates were higher than those of sex offenders (13–60%) or sex offense victims (6–40%) but similar to those of homicide victims (14–87%) (Roizen 1997). These findings are not surprising given the widespread use of alcohol; the influence of alcohol on events coming to the attention of authorities; the influence of alcohol in bringing offenders and victims into proximity with each other; and the fact that alcohol and violence appear to have a dose dependent relationship. Other important factors include issues of quantity and pattern of alcohol use. For example, intermittent drinkers are more likely to be involved in violent episodes (either as perpetrators or victims) than are chronic drinkers (Kantor and Straus 1987).

Still, in spite of confounding variables, there is considerable evidence to support the hypothesis that crimes involving violence are more closely associated with alcohol than are nonviolent crimes (Cordilia 1985). Studies aimed at unraveling the direct effects of alcohol on violent behaviors from “expectancy effects” have been reviewed elsewhere with the conclusion that the direct pharmacologic effects of alcohol interact with psychological effects to increase risk of violence (Volavka 1995).

Pharmacologically, alcohol is a sedative associated with behavioral disinhibition and dose dependent decrements in consciousness. Other lines of research (Cloninger 1995, Virkkunen 1979, Virkkunen and Linnola 1993, 2002) strongly associate alcohol with decreased levels of serotonin, particularly, among a subgroup consisting of early-onset alcoholism and antisocial personality traits. Serotonin is generally viewed as an inhibitory monoamine, so the contradictory and variable effects of alcohol, presumably acting as a systemic inhibitor of an inhibitory neurotransmitter are not unexpected. This will be discussed further below.

While there is good evidence to implicate alcohol in the commission of intentionally aggressive acts, there can be little question that alcohol is even more important as a cause of significant unintended violence in the form of motor vehicle accidents and impulsive aggression.

Illegal drug use

Compared to alcohol-violence research, the association of illegal drugs with violence is even more difficult to interpret since people using illegal drugs are by definition already involved in criminal activities. For example, although violence is associated with narcotic users, this seems primarily due to the need to engage in criminal activities to pay for narcotics rather than because of a primary effect of the drug. In contrast to emergency rooms where community users of narcotics are encountered, and aside from episodes of aggression associated with delirium, the extensive legitimate use of prescribed narcotic medications in hospitals for pain relief is rarely associated with aggression.

While illegal drug use is frequently cited as a contributor to violent crime, studies directly linking a specific illegal drug with violence independent of other risk factors are rare. A study (Hanlon et al. 1990) found a direct relationship between self-reported quantities of opioids used and frequency of crime (including violent crime) at the time of use.

Pharmacologically, opioids including morphine, methadone and heroin, are sedatives that reduce pain and level of consciousness. Ex-abusers given “moderate doses” of heroin have been described as becoming “friendly and mellow” (Volavka et al. 1974). If fact, opioids at one time were considered as a possible treatment for rage and aggression (Berken et al. 1978, Verebey et al. 1978). In contrast, opioid antagonists, such as naloxone have been associated with aggression, especially in emergency room settings in which the effects of opioid drug overdoses are rapidly reversed (Gaddis and Watson 1992).

Similar comments can be made about benzodiazepines, which are generally associated with soporific effects in patients across the life-cycle (Gleser et al. 1965, Yudofsky et al. 1990). However, “paradoxical” disinhibiting effects of benzodiazepines have also been noted (Paton 2002).

While cocaine and its derivatives have been associated with violence, a direct pharmacologic effect of cocaine on aggression has been disputed (Resnick 1977). In particular, reports of violence associated with cocaine and free-based cocaine (“crack”) consist primarily of reports involving overdoses in which delirium is likely, or in which aggression appears secondary to paranoid thinking either due to the drug itself or to an accurate perception of events resulting from criminal activities involving a valuable illegal commodity (Brody 1990, Manscure et al. 1988, Inciardi and Pottier 1994). Multiple drug use, such as combining cocaine and alcohol, may lead to an increased risk of violence (Pennings et al. 2002).

Phencyclidine (PCP) is a drug with a reputed association with uncontrolled violence of almost urban myth proportions. Careful reviews of published clinical reports led a group (Brecher et al. 1988) to conclude, however, that the assumptions about PCP and a direct link to violence may not be as clear as was first thought. The finding of higher self-reported rates of assault in association with PCP use by male jail inmates who also had a history of psychiatric hospitalization led another group to conclude that while violence and PCP use is associated, self-reported behavioral effects of PCP may be (better) associated with personality traits and other background features (McCardie and Fishbein 1989).

As with cocaine and PCP, amphetamines, have also been linked to aggression. In the context of amphetamine-induced delirium, sleeplessness and paranoid thinking can reach delusional proportions (Kalant 1966). There is also evidence that chronic amphetamine use may augment aggression via serotonin depletion in brain areas linked to regulation of aggression: especially the frontal-orbital cortex, anterior cingulate gyrus and temporal cortex (Sekine et al. 2006). Nevertheless, a recent review concluded that acute intoxication may not lead to violence, but may increase the chance of aggression in the context of a provocation (McKetin et al. 2006). However, relative to other factors, methamphetamine appeared to have a small impact on assault rates.

Hormones and Violence

Virtually, every survey of violence and aggression notes a preponderance of problems in males as compared to females. The two primary hormonal differences between men and women are: (a) higher levels of testosterone in men (b) cyclical variation of estrogen and progesterone in premenopausal women. There have been numerous reports of significant association between testosterone levels and both physical
and verbal aggression (Virkkunen et al. 1994, Brooks and Reddon 1996). A study (Dolan et al. 2001) found that plasma testosterone was positively correlated with aggressive acts in male offenders with personality disorders. In a study of genetics of aggression, hostility, and anger (AHA syndrome) (Slyuter et al. 2000), found substantial heritable abilities for testosterone and moderate to fair heritable abilities for the other measures of the syndrome.

An open question is the specific relationship of testosterone to sexual aggression. A study (Dabbs et al. 1995) found that male prison inmates with higher testosterone levels were more likely to have committed sexual or violent offenses and more likely to have violated prison rules than individuals with lower testosterone levels.

Using a subsample from the 1995 study, Dabbs et al. (2001) examined characteristics of the index offense in subjects for whom a parole board investigative report was available. Testosterone levels were related to the characteristics of the offense for the “Kill (murder/manslaughter offense) group,” but not for the “robbery,” “assault rape,” or “child molestation” groups.

An independent study (Giotakos et al. 2003) reported significantly higher plasma testosterone in rapists. Luteinizing hormone (LH); the pituitary hormone associated with stimulation of testosterone production, was positively correlated with the experimenter’s measures of aggression and impulsivity.

Despite some of these findings, the relationship between testosterone and aggression is less linear than earlier reports may have suggested. In two studies involving groups of forensic patients who had been charged with violent or nonviolent crimes and nonviolent controls, no significant differences were found in terms of testosterone or testosterone metabolites (Bain et al. 1987, 1988). An investigation (Rada et al. 1976) found higher levels of testosterone in rapists who also beat their victims but failed to replicate this finding in a subsequent study (Rada et al. 1983).

**Genetic Factors and Genetic Syndromes**

It is generally accepted that genetic factors can predispose people to impulsive and aggressive behaviors. Several genetic conditions have been identified as potentially interesting with regard to their association with violence. The single genetic condition receiving the most attention is the XYY “superman” karyotype. The condition occurs in 1/1,000 males (Allanson and Graham, 2002). For years, XYY was linked to increased risk of violence and several case reports (e.g., Freyne and O’Connor 1992) of crimes committed by men with XYY karyotypes were published. Early reports suggested that men with a history of criminality, arson or sexual offenses should be screened for an XYY karyotype (Hoffman 1977). However, most experts now agree there is no definitive evidence that men with XYY are more prone to criminal violence than other men (Beltz 2005).

Men with an extra X chromosome (Klinefelter’s syndrome) have also been identified as being predisposed to aggression (Dervaux and Artiges 2002). Klinefelter’s syndrome occurs about twice as frequently as XYY syndrome, and is associated with hypogonadism (low serum testosterone but high serum follicle-stimulating hormone and serum LH levels). Due to delay in closure of the bone epiphyses, men with Klinefelter’s syndrome are of above average height. A large study that examined 4,139 men with height in the top 16 percentile of a Danish cohort, found similar crime rates (including nonviolent crimes) in men with XYY and XXY genetic conditions (Witkin et al. 1976).

Twin and adoption studies have demonstrated that aggressive behaviors are partially heritable (Cadoret et al. 1997). It has been estimated that two-thirds of the measured variations of personality traits can be accounted for by genes (Bouchard 1994). Genetic syndromes cut across numerous etiologic pathways since they not only do involve heredity but also hormones, neurotransmitters, anatomy, and physiology. In a remarkable investigation, 221 pairs of biologically unrelated adopted children were compared to 11 pairs of biologically related children who had been adopted together, as well as a control group consisting of 94 singleton children. In this study, the researchers concluded that 70% of the variance for aggression and 39% of the variance for delinquency was accounted for by genetic (as opposed to familial) factors. Larger variances were also noted for boys on factors involving “externalizing” and “aggressive” behaviors (Ooord et al. 1994). Other genetic studies have further examined the link between monoamine oxidase (MAO) inhibition and violence (see below).

### Brain Lesions/Injuries and Other Neurologically-Based Impairments and Aggression

From the time of Phineas Gage and his infamous frontal lobe injury leading to a wide range of new behaviors, the majority of the literature concerning aggression and brain lesions is derived from observations of individuals with closed head injuries since these are less likely to be lethal than open head injuries. One notable exception is a study (Grafman et al. 1996) involving 279 war veterans who had sustained penetrating head injuries. This study found increased violence and aggression associated with penetrating injuries involving ventromedial brain injuries but the association was neither affected by lesion size nor with presence or absence of seizures.

Researchers have also noted similarities between individuals with ASPD and/or psychopathy and specific brain lesions (especially left frontotemporal hypoperfusion) (Raine et al. 2003). Unfortunately, causal conclusions are problematic because people with ASPDs have a known higher tendency of being the victims of violence themselves (Paanila et al. 1999). Also, with few exceptions, studies include only men. If brain lesions cause violence independent of other mediating variables such as gender, then it would be predicted that girls and women should show the same associations of aggression with brain lesions involving especially the orbitofrontal cortex (Amen et al. 1996), left anterior temporal cortex (Hirono et al. 2000), and amygdalo–hippocampal region (Tonkonogy 1991). This theoretical problem has been noted by others who have pointed out that the majority of head injuries result from motor vehicle accidents involving males between the ages of 15 and 24 (McAllister 1992). Head injury is a problem that deserves further attention since depression has also been associated with aggression post head injury (Baguley et al. 2006).

There is an extensive literature concerning the possible relationship between seizure disorders and aggression.
Aggression associated with ictal and immediate post-ictal behavior tends to be disorganized and best understood as resulting from delirium (Treiman 1991). Reports also exist, however, concerning the possibility of an association between aggression and inter-ictal behaviors. Though controversial (Devinsky and Najjar 1999), these findings most often implicate temporal lobe epilepsy (TLE) (Elst et al. 2000). People with TLE and aggression often suffer from other neurological deficits. For example, one case controlled investigation involving Magnetic Resonance Imaging (MRI) studies of 24 patients with TLE and a history of aggression found that aggressive patients had a significant decrease in grey matter, primarily involving the left frontal lobe (Woermann et al. 2000).

**Neurotransmitters and Other Neurobiological Aspects of Dysfunctional Anger and Aggression**

Although the pathogenesis of dysfunctional anger and impulsive aggression is largely unknown, low central nervous system (CNS) serotonin (5-hydroxytryptamine, 5-HT) levels are associated with dysfunctional anger, impulsive aggression and violent behavior (Kavoussi et al. 1994). Both human and animal studies have shown an inverse relationship between cerebrospinal fluid (CSF) 5-hydroxyindoleacetic acid (5-HIAA), the major metabolite of central 5-HT, and aggression. Furthermore, administration of agents that reduce central serotonin concentration typically are associated with an increase in aggressive behavior. Conversely increased 5-HT levels are associated with decreased aggression. Psychopharmacologic studies have also found that serotonin-enhancing drugs, including selective serotonin reuptake inhibitors (SSRIs) can be effective in reducing anger and impulsive aggression (Salzman et al. 1995). Evidence also points to testosterone having a role in modulation of dysfunctional anger and impulsive aggression at least in part, by decreasing serotonin receptor sensitivity (Zhang et al. 1999). These lines of evidence implicate abnormal serotonergic function in dysfunctional anger and impulsive aggression.

Since a dysfunctional serotonergic neurotransmitter system has been implicated in the etiology of dysfunctional anger and impulsive aggression, genes regulating 5-HT synthesis, release and reuptake, metabolism, or receptor activation are good candidates for studies of genetic disposition to dysfunctional anger and impulsive aggression. Tryptophan hydroxylase (TPH) gene polymorphism may be associated with anger-related traits (Manuck et al. 1999). In a large Dutch kindred, males with a point mutation in the eighth exon of the MAO-A gene were found to show impulsive aggression and sometimes, violent behavior (Brunner et al. 1993). In addition, male MAO-A gene knockout mice were shown to display enhanced aggression (Cases et al. 1995).

Serotonin transporter (5-HTT) plays an important role in regulation of 5-HT transmission, and SSRIs are thought to exert their effect on the treatment of aggression through inhibiting the 5-HTT. The serotonin 2A (5-HT_{2A}) receptor has also been implicated in the pathogenesis of impulsive aggression and suicidal behavior. TPH is a rate-limiting enzyme for serotonin biosynthesis and MAO is a critical enzyme which degrades a variety of biogenic amine, including serotonin. Thus, they are logical candidate genes that may contribute to abnormal serotonergic functioning.

Other neurotransmitters have been associated with aggression, in part related to the neurotransmitter function itself, and in part related to the complex network of interactions between neurotransmitter systems. Norepinephrine, for example, known as the “fight or flight” mediator, has also been associated with aggression (Coccaro et al. 2003). Further, beta adrenergic blockade can be effective in decreasing aggression (see below). Other neurotransmitters and compounds implicated in mediating aggression include dopamine, Gamma-Aminobutyric Acid (GABA), glutamate, substance P, cholesterol, acetylcholine, nitrous oxide and endogenous opioids (for a further discussion, see Volavka 1999).

**Other Biological Aspects of Dysfunctional Anger and Aggression**

As an example of other biological aspects of aggression, studies have shown a positive association between chronic anger and cardiovascular diseases (CVD). These studies suggest that both extreme inhibition and expression of anger is related to higher CVD risk and associated risk factors (e.g., hypertension). Williams et al. (2000) reported that individuals most prone to anger were 2.7 times more likely to have a heart attack than those with the lowest anger ratings. The two main hypothetical models proposed to explain the mechanisms underlying this association are: (1) An emotional and cardiovascular reactivity model that emphasizes anger inhibition, slow cardiovascular recovery, and low parasympathetic tone (Larkin et al. 1998) and (2) anger inhibition and cardiovascular recovery hypotheses that emphasize anger expression, cardiovascular reactivity and high sympathetic tone (Brosschot and Thayer 1998).

**Treatment of Aggression**

As illustrated by the foregoing sections, the etiology of aggression is multi-determined, spanning across many psychiatric syndromes (Fava 1997). Therefore, treatment of the aggressive or violent patient must be multifactorial, and by current standards, should encompass consideration of environmental, psychological, cultural, and biologically-based therapies. It is important to note though that at the time of this writing, no medication has been approved by the U.S. Food and Drug Administration (FDA) for the treatment of aggression. Indeed, evidence based data related to the treatment of aggression is rather limited. Treatment decisions should be made with caution and guided primarily by clinical judgment, and where possible, informed by the results of a comprehensive psychiatric and medical assessment. This is particularly important given that aggressive acts are primarily epiphenomena of other psychiatric, neurological, or other medical disorders (Booth et al. 2006, Fava 1997) or driven by contextual social factors.

**Nonpharmacological Treatment Options**

Although pharmacologic treatments may ultimately be required, in the absence of immediate danger, a combination of one or more of the following de-escalation strategies should be initiated when managing acute aggression (Corrigan et al. 1993, Allen et al. 2001). These...
can include interventions such as verbal de-escalation by talking to the patient and avoidance of overt stimulation. If attempts to de-escalate an acutely aggressive patient fail to yield the desired outcome, displaying a show of force and ultimately the use of mechanical restraint and/or seclusion may become necessary. Cases of death associated with mechanical restraint use and questions of misuse of this technique recently spurred a movement in seclusion and restraint reduction in behavioral healthcare (see e.g., Pinals and Appelbaum 2003). Current United States legislation and US national standards require that behavioral restraint use be an option of last resort after less restrictive alternatives have been tried. Some medications used in an emergency situation to quell aggression, if not part of an existing behavioral treatment plan, can be considered chemical restraints and follow similar restrictions regarding their use.

Chronic management of the violent or aggressive patient can also include a number of nonpharmacological strategies either alone or in combination with psychopharmacological approaches. The specific psychopathology and treatment needs of patients with chronic violence will dictate appropriate interventions. For example, treatment of aggression related to psychosis may require supportive therapy and social skills training as well as psychotropic medications. Potential nonpharmacological interventions are summarized in Table 127–5.

### Pharmacological Treatment

Several medications have been shown to improve aggressive behaviors associated with a number of, and frequently unrelated, disorders. Below is a review of data on the following medication classes and the treatment of aggression: (1) Antipsychotics and benzodiazepines (2) anticonvulsants and lithium, and (3) beta-blockers. In some situations, (1) Antipsychotics and benzodiazepines (2) anticonvulsants (3) lithium, and (3) beta-blockers. In some situations, antipsychotics, given alone or in combination with other medications, have been safely used for decades in the treatment of aggressive behavior (Ladavac et al. 2007). Notwithstanding their seemingly beneficial therapeutic effects, their use is limited by their side effect profiles (Leucht et al. 1999). Extrapyramidal symptoms (e.g., acute dystonic reactions), orthostatic hypotension, akathisia, and anticholinergic effects are concerning and not uncommon occurrences (Yudofsky et al. 1987). Typical antipsychotics have been associated with cardiac conduction abnormalities and a prolongation of the rate-corrected QT interval, resulting in potentially fatal cardiac arrhythmias (McAllister-Williams and Ferrier 2002). The latter side effect has been seen in patients receiving, for example, high dosages of intravenous haloperidol (Salzman and Hoffman 1982). Similarly, droperidol (Inapsine®), a butyrophenone antipsychotic at times used in crisis emergency room circumstances, prescribed both intramuscularly and intravenously, has been associated with a number of cardiac-related side effects, resulting in a “black box” warning by the Federal Drug Administration (FDA) (Federal Drug Administration 2001). In addition, typical antipsychotics have been associated with worsening aggression in some studies (Crowner et al. 1990).

Because of the foregoing concerns, and in light of their seemingly more benign side effect profile, atypical antipsychotics (second generation), such as risperidone, quetiapine, clozapine, aripiprazole, ziprasidone, and olanzapine, have increasingly been prescribed to treat aggressive patients (Hovens et al. 2005). Of note, several atypicals can be given intramuscularly, such as olanzapine, aripiprazole, ziprasidone, and risperidone. Others come in rapidly disintegrating tablets (e.g., risperidone and olanzapine). These alternative forms of medications are useful in the management of acute aggression and with patients presenting with swallowing difficulties or histories of inconsistent medication compliance.

Risperidone, an antipsychotic with both high D2 and 5-HT blocking properties, in combination with a benzodiazepine, has been found to be as effective as haloperidol in the treatment of aggressive patients (Currier et al. 2004). For example, in a prospective, nonrandomized, rater-blinded, double-arm study, Currier and Simpson (2001) reported on a cohort of 60 acutely psychotic and agitated patients who were given either oral risperidone (2 mg) plus oral lorazepam (2 mg) or intramuscular haloperidol (5 mg) plus intramuscular lorazepam (2 mg). Treatment outcome was measured at different time points using the five agitation subscales of the Positive and Negative Syndrome Scale (PANSS) and the Clinical Global Impressions (CGI) scale. Both patient groups (30 patients per treatment arm) showed a similar decrease in their level of agitation.

Olanzapine seems effective in the treatment of aggressive behavior (San et al. 2006). In a retrospective, open-label,
naturalistic trial. Janowsky et al. (2003) treated a small cohort of 20 patients, presenting with a history of self-injurious, destructive, and/or assaultive behavior and various degrees of mental retardation, with olanzapine (mean dose: 9.1 mg/day). Most patients received concurrent medications prior to and during the olanzapine trial (e.g., anticonvulsants and lithium, adrenergic agents, serotonergic antidepressants, typical antipsychotics, and benzodiazepines). Psychiatric comorbidity was prevalent among the cohort and consisted of mood, psychotic, and pervasive developmental disorders. Statistically significant improvements in target behaviors were noted. The most common side effect was weight gain (mean weight gain of 3.4 kg) followed by sedation and constipation, in that order. Though this study did not prove that olanzapine by itself is useful in the treatment of aggression, future studies certainly seem warranted.

Among the atypical antipsychotics, clozapine, an antipsychotic with relatively weak dopaminergic activity, has been extensively studied in psychotic and personality disordered patients presenting with various forms of aggression (Chengappa et al. 1999). Of particular interest is a study conducted by Buckley et al. (1995, p. 13) that reported on 30 institutionalized schizophrenic patients treated with clozapine. Eleven patients presented with a history of chronic violent behavior. Treatment response was correlated to the scores derived from the Brief Psychiatric Rating Scale (Chengappa et al. 1999). Of particular interest is a study conducted by Buckley et al. (1995, p. 13) that reported on 30 institutionalized schizophrenic patients treated with clozapine. Eleven patients presented with a history of chronic violent behavior. Treatment response was correlated to both the scores derived from the Brief Psychiatric Rating Scale (BPRS) and the number of hours spent in seclusion/restraint. Psychotic symptoms improved for both study groups after 6 months of treatment with clozapine. In addition, and, according to the authors, seemingly independent of clozapine’s effects on psychotic symptoms, the violent cohort showed a significant decrease in the frequency of violent episodes (decreased by approximately 60% at 6 months of treatment), suggesting thus a “distinct anti-aggressive effect…” of clozapine.

Aripiprazole, has also been used in the treatment of aggressive patients. Of interest are results of a double-blind, placebo-controlled study of aripiprazole in the treatment of 52 subjects with DSM-III-R borderline personality disorder (Nickel et al. 2006). Subjects were randomized to receive either 15 mg aripiprazole (n = 26) or placebo (n = 26) for 8 weeks. Treatment outcome was measured using several scales, including the State-Trait Anger Expression Inventory. Subjects receiving active drug treatment showed a significantly greater rate of improvement on all outcome measures than subjects receiving placebo. No significant side effects were observed.

The data in support of atypical anti-psychotics has been growing. Nevertheless, some studies have found their side effects can lead to problems in medication adherence. For example, one multicenter, double-blind, placebo-controlled trial, Hsiao et al. (2006) treated a cohort of 421 patients suffering from Alzheimer’s disease and psychosis, aggression, or agitation with either olanzapine (mean dose: 5.5 mg/day), quetiapine (mean dose: 56.5 mg/day), risperidone (mean dose: 1.0 mg/day), or placebo, using a flexible dosing schedule. Outcome was measured using the Clinical Global Impression of Change (CGIC) scale at 12 weeks. A substantial number of patients discontinued active treatment as a result of side effects. Improvements on the CGIC scale did not reach statistical significance.

Benzodiazepines

Benzodiazepines, such as lorazepam, have been used alone or in combination with high-potency antipsychotic medications in the treatment of acute aggression. Although several benzodiazepines have been shown to be effective in the amelioration of aggression (Rund et al. 2006), lorazepam is typically considered the benzodiazepine of first choice in acute settings (Wermeling et al. 2001). For example, in a double-blind, prospective study, Salzman et al. (1991) examined the effects of 2 mg intramuscular lorazepam compared with 5 mg intramuscular haloperidol on aggression in a cohort 60 psychotic patients. Both medications were added, using a fixed-dose schedule, to ongoing neuroleptic therapy. Diagnoses consisted of psychotic spectrum disorders (n = 30), bipolar disorder (n = 11), organic mental disorders (n = 6), and other psychiatric disorders (n = 14). Subjects treated with either medication over a 24-hour period showed a significant decrease in aggressive behaviors, as measured by the Overt Aggression Scale (OAS). The OAS, a frequently used observation-based instrument in aggression-related studies, measures the severity of (1) verbal aggression, (2) aggression directed against objects, (3) self-directed physical aggression, and (4) physical aggression directed towards others (Silver and Yudofsky 1991).

In a second double-blind, prospective, short-term study (Dorevitch et al. 1999), a cohort of 27 acutely aggressive subjects were treated with parenteral haloperidol (5 mg) or the parenteral benzodiazepine flunitrazepam (1 mg) (flunitrazepam is a benzodiazepine that has not been approved by the FDA). In contrast to the aforementioned studies where a benzodiazepine was given as an adjunct to an antipsychotic medication, this study showed that flunitrazepam when given alone was as effective as haloperidol in ameliorating aggressive symptoms. In fact, the use of either medication resulted in a decrease in OAS score. Although the “anti-aggressive” effects lasted for more than 2 hours for both medications, flunitrazepam had an earlier onset of action, achieving maximum “antiaggressive” effects within 30 minutes following its administration. Clinically significant side effects were not reported.

Veser et al. (2006) compared the effects of oral risperidone (2 mg) and haloperidol (5 mg) to oral placebo in patients, presenting in an acute treatment setting, with signs of agitation and/or psychosis. Patients were also given intramuscular lorazepam (2 mg). Interestingly, lorazepam monotherapy was as effective in ameliorating the target symptoms as combination treatment with either risperidone or haloperidol.

Benzodiazepines are usually not used in the treatment of persistent or chronic aggression. In fact, long-term benzodiazepine therapy can result in tolerance, withdrawal, and substance dependence. Similarly, benzodiazepines have been associated with idiosyncratic behavioral disinhibition, especially if used in brain injured patients.

Lithium and Anticonvulsants

Anticonvulsants, lithium, and several β-blockers (see below) have been shown to be effective in treating persistently aggressive and irritable patients (Kavoussi and Coccaro 1998). Among the anticonvulsants, carbamazepine has been reported to be effective at therapeutic serum levels (4–12 μg/ml) in aggressive patients presenting with and without
Lithium has also been shown to be effective in the treatment of manic episodes and impulsive aggression not associated with mania (Grof and Grof 1990). It is less effective, if not ineffective, in patients suffering from mixed episodes (Swann et al. 1986, Grof and Grof 1990). In these latter cases, anticonvulsants, such as divalproex sodium, seem to be more effective. For example, Ruedrich et al. (1999) studied the effects of divalproex sodium (mean dose: 920 mg/day with mean valproic acid levels of 87.8 μg/ml) on aggressive behavior in 28 developmentally disabled adults, ranging in age between 20 to 63 years, and presenting with various forms of aggressive behaviors, including general aggressiveness (93%) and self-injurious behavior (64%). Other problematic behaviors included sexually inappropriate behavior (36%), rituals (43%), and temper tantrums (43%). Patients were assessed for up to 73 months. Overall, treatment with valproate decreased aggressive episodes in almost all patients. Side effects, including hematological and gastrointestinal, led to discontinued use in some cases.

Other anticonvulsants have been used with various degrees of efficacy in the treatment of aggressive patients. In a placebo-controlled, double-blind, crossover study, Bar- ratt et al. (1997) studied the effects of phenytoin on aggressive acts in 60 prison inmates. Impulsive aggressive acts decreased with active drug treatment by 71% in frequency (35% among nonimpulsive subjects) and by 60% in intensity (29% among nonimpulsive subjects), respectively. Placebo effect on frequency and intensity of aggressive acts was in the lower to mid-20% range for both groups. No significant side effects were reported in either group. In another double-blind, placebo-controlled, parallel group study, Stanford et al. (2005) compared the efficacy of phenytoin (300 mg/day), carbamazepine (450 mg/day), and valproate (750 mg/day) in a cohort of 29 male patients presenting with a history of impulsive aggression. DSM-IV-TR diagnostic criteria for major depression were met by 5 subjects whereas 11 subjects met diagnostic criteria for either alcohol or substance abuse (n = 11). Interestingly, twenty-four subjects met diagnostic criteria for a personality disorder, specifically ASPD (n = 17). Treatment outcome was measured over the course of 6 weeks using the OAS. Consistent with the findings of previous data, patients in this study receiving active treatment, especially phenytoin and valproate, showed a significant improvement in their average aggression scores compared to placebo.

Published data have also appeared for the use of newer anticonvulsants in the treatment of aggression. Topiramate, a sulfamate-substituted derivative of the monosaccharide 1,fructose, is an anticonvulsant used to treat seizures in patients with epilepsy or Lennox-Gastaut syndrome, mood disorders, and pain disorders. In a recent retrospective, case-controlled, “mirror image” study, Gobbi et al. (2006) studied the effects of topiramate and/or valproic acid on the intensity and frequency of aggressive behavior, using a sample of 45 adult patients afflicted with either schizophrenia, schizoaffective, delusional or bipolar disorder. Patients were treated over a 12-week trial period with either topiramate (mean dose: 250 mg/day), valproate (VPA dose had to be in the therapeutic range), or combination treatment (topiramate and VPA). In addition to the above medications, 98% of patients received concurrent treatment with either a typical or an atypical antipsychotic medication. Episodes of agitation and Overt Aggression scores decreased in the topiramate only cohort. In contrast to patients receiving valproate, patients on topiramate did not show a decrease in their Agitation-Calmness Evaluation scores.

β-Blockers

Several β-Blockers have been found to be useful in treating aggression and/or uncontrollable outbursts of violence associated with brain-injuries, mental retardation, dementia, and chronic schizophrenia (Mansheim 1981, Greendyke et al. 1984, Sorgi et al. 1986, Bond et al. 1989, Brooke et al. 1992). Among the β-blockers, propranolol (nonselective and lipid soluble) is the most widely studied (Greendyke et al. 1984). In a recent double-blind, placebo-controlled study, Peskind et al. (2005, p. 24), randomized a group of 31 subjects with probable (n = 22) or possible (n = 9) diagnosis of Alzheimer disease to receive propranolol (n = 17) or placebo (n = 14), using a “augmentation design.” Treatment outcome was correlated with a change in scores on the “agitation/aggression,” irritability/lability,” and/or “aberrant motor activity,” items of the Neuropsychiatric Inventory (NPI) and the CGIC. Propranolol was increased, using a flexible dosing schedule, over the course of 9 days to 120 mg/day and maintained at that dose for 6 weeks. Recipients of propranolol showed significant improvements on the “agitation/aggression” and “anxiety” items of the NPI and moderate to marked improvement on the CGIC (1:7). Only one subject receiving placebo was marked as moderately improved. Side effects were primarily cardiovascular in nature. Behavioral improvements though were not maintained over time.

In a double-blind, placebo-controlled study, Ratey et al. (1992) treated 41 chronic psychiatric patients, presenting with at least one aggressive episode per week, with nadolol (more hydrophilic compared to propranolol). Patients were followed for a total of 17 weeks. Treatment outcome was measured using the OAS, BPRS, and the Clinical Global Impressions scale. Subjects given the active drug showed a decrease in target symptoms and an overall improvement in their clinical status.
Although usually used in chronically aggressive patients, Allan et al. (1996) studied the effects of adjunctive nadolol, using a double-blind, placebo-controlled design, on 34 schizophrenic patients presenting with current histories of aggression. Patients were randomized to receive either nadolol (total daily dose of 120 mg) or placebo. Subjects randomized to active treatment showed a statistically significant decrease in their BPRS and Simpson Angus Neurologic Rating Scale scores.

Summary of Findings Related to Pharmacological Treatment of Aggression

As illustrated in the foregoing paragraphs, much has been written about the use of medications in acutely and chronically aggressive patients. For acute aggression, antipsychotic and/or benzodiazepine use has been a mainstay of treatment. For the treatment of chronic aggression, in clinical settings various classes of medication have been used with good effects. However, it is critical to bear in mind that methodological problems (e.g., heterogeneous study population, concurrent use of different medications, etc.) make it difficult to draw definite conclusions with regard to the “anti-aggressive” efficacy of medications. In order to resolve these issues, well-controlled studies with sophisticated methodologies are needed.

Conclusions

The assessment and management of violence among psychiatric patients is arguably as important as the assessment and management of suicide. When a patient presents with acute or chronic aggression, it is important to examine the factors that have coalesced to lead to aggressive behaviors. While not all aggression stems from anger, some understanding of the pathophysiology related to aggression. Nonpharmacological and pharmacological treatment interventions can provide a useful armamentarium available for prevention, which is the ultimate goal of the treatment of the aggressive and violent patient.

Introduction
The accumulated enduring knowledge in clinical psychiatry has emerged from research studies employing empirical observation in the context of proper study design, reliable and valid measurement, and approaches to data analysis that respect both the assumptions for the use of the techniques and the limits of statistical significance. The centrality of these fundamental and enduring precepts holds even though methods and statistics in psychiatry are like all other arenas of inquiry in that new techniques and approaches are regularly being introduced. Nonetheless, there are a variety of practices in the research literature that have become standard customs in the design and conduct of psychosocial research, of which clinical psychiatry is a subset. These are important to learn about because much information about psychological processes still finds its way into the literature in the form of books and chapters that are not subject to peer review, and because even when material is subject to peer review, the process is not foolproof. Thus, even though studies are published in reputable peer-reviewed journals, this is not an ironclad guarantee that the conclusions are appropriate or that the methods used were sound. Although one may not envision being a practitioner of research, being an informed consumer of research findings is vitally important to the continuing education of psychiatrists. An argument can be made, therefore, that research design and methodology and the statistical techniques that accompany such designs are central to the knowledge of clinicians, since the clinical decisions that will be made should be made on the basis of hard evidence, rather than on the basis of clinical lore or anecdotal case reports. The increasing emphasis on evidence-based treatments is the most recent manifestation of this view.

Even though psychiatry is merely a single specialty in the domain of medical science, it is nonetheless true that the areas of study and the techniques used in research in psychiatry are very broad. These range from basic molecular biology (Malenka 1994) to clinical phenomenology (Ursano et al. 1999) to nationally representative epidemiology of mental disorders (Weiss et al. 1992). Even in the nonbench laboratory areas, a complete account of research methods, measurement issues, and, most of all, statistical techniques would require a whole text. The focus of this chapter will be on basic matters pertaining to the biopsychosocial underpinnings of psychiatry outside the wet laboratory. This covers the kinds of research reports that will have a direct impact on clinical practice (e.g., effectiveness trials such as STAR*D (Rush et al. 2006)) and are more clinical or psychological in nature.

The presentation will begin with a discussion of issues of the design of studies in terms of integrity and statistical power. The next section will examine issues of measurement, explicating the concepts of reliability, validity, interobserver agreement, and the measurement or assessment of change. The chapter continues with a presentation of statistical techniques, starting with some basic parameters, and moves through univariate techniques to multivariate approaches. It also deals with the measurement of change and the proper approach to statistical significance. The final section includes tips on reading research and some practical suggestions for conducting psychiatric research.

Issues of Design
Psychiatric research spans two broad domains with different implications for design and analysis: (1) experimental investigations (e.g., randomized clinical trials) where the question of interest is controlled or manipulated in some fashion, and (2) field or observational research where questions of explanation and causal inference are drawn from systematic observation and recording of behavior or phenomena but are not subject to experimental intervention. The impact of trauma on subsequent adjustment, the influence of number of prior hospitalizations on risk of relapse, and the effect of early childhood loss on later adult depression are examples of the latter.
A very thorough, detailed, and thoughtful exposition of these issues is presented by Cook and Campbell (1979). They identify several designs used in research studies, some valid and others not, and the threats to the integrity of the conclusions drawn from data collected with such designs. Although an exhaustive listing of the various designs is beyond the scope of this presentation, many of the basic principles of design are essential to informed conduct or consumption of psychiatric research. These are designs that do not include random assignment of subjects to conditions; as a consequence, they are termed quasiexperimental designs and comprise a surprisingly large number of the psychiatric research studies published in peer-reviewed journals every year.

**Designs and Threats to Validity**

Cook and Campbell, and before them Campbell and Stanley (1966), identified common flawed quasiexperimental designs and a variety of threats to the validity of the conclusions drawn from such studies. Although nearly 40 years old, the problems discussed in their presentations still are relevant, since often the psychiatric researcher cannot design the ideal study due to ethical, logistic, or fiscal constraints. The designs appear in Figure 128–1.

The first quasiexperimental design denoted is the one-group posttest-only design. This design gathers observations on only one group after treatment has occurred; consequently, virtually nothing can be concluded because no controls exist. Nonetheless, some observational research begins with this activity. The posttest-only with nonequivalent groups is a second design that is not likely to yield useful information and has serious threats to internal validity as well. In this design more than one group is observed, but because the groups are not formed randomly, those not receiving treatment may be different in any number of ways having nothing to do with the treatment from those who did receive the treatment. Often there will be an attempt to “statistically equate the groups” or “control for the differences” by using analysis of covariance. This is an inappropriate and invalid use of analysis of covariance (see Miller and Chapman 2001).

A third design is termed the one-group pretest–posttest. An obvious improvement on the two prior designs in that subjects are observed prior to treatment so that some baseline can be established; this design, as the others, is nonetheless vulnerable to a variety of alternative interpretations of a change in status at posttest other than the treatment administered. A discussion of the various threats to internal validity will clarify why this is so.

The concept of a threat to the internal validity of a design can be explained as follows. When an experiment is conducted, the goal is to show that manipulation of one variable (e.g., whether the pill is a placebo or is an active pharmacologic compound) has an impact on, has an effect on, or causes a change in another variable (e.g., hyperarousal symptoms of PTSD). A particular study or design possesses good internal validity if there is a strong chance that the conclusion we draw (the medication is or is not effective) is actually due to the variable being manipulated and the output variable being measured. If there are many other plausible or even possible reasons that the output variable might

have changed other than the impact of the experimental or treatment variable, then such a study does not have good internal validity.

The final threat to internal validity is termed “statistical regression” or “regression to the mean.” This is a somewhat complex concept to describe, but may operate very powerfully, especially in concert with other threats such as selection. Statistical regression refers to the phenomenon of those who obtain extreme scores at pretest tending to obtain less extreme scores at posttest, at both the high and low ends of the measure. The phenomenon is due in part to the reality that virtually all variables are measured with some quantity of error. Because these errors are generally randomly distributed, an individual whose score was unrealistically lowered at pretest by error will show a higher score at posttest, and vice versa, due simply to the error of measurement being distributed differently the next time around. At time 2, other subjects will have unrealistically lower or higher scores due to greater error at that occasion. In circumstances in which the measure being used to index the variable of interest is measured with a great deal of error (is not reliable—see below), statistical regression can potentially exert a greater influence.

Because regression to the mean operates more powerfully at the extremes of distributions of scores, it is easy to see why it is such a potent confounding influence. Many times only a small portion of potential subjects can receive treatment. If the subjects to be studied are selected on the basis of their having obtained the lowest scores, then simply on the basis of regression toward the mean, these same subjects will be likely to obtain higher scores on the posttest assessment. Thus, many treatments that have been claimed to help those who have the worst pretest status are merely demonstrating the influence of unreliability of measurement and statistical regression. It is precisely because of this threat that the three designs described above are so problematic. Even though researchers concerned with carefully delineating the threats to internal validity have shown that regression toward the mean will not inevitably occur (Rogosa 1988), it is a powerful threat when it does. This makes the interpretation of change or improvement a more difficult enterprise than it might at first seem. A more detailed discussion of the measurement of change is presented below.

There are a number of quasiexperimental designs that do not share the same threats to validity of the conclusions. Many are complex and useful only in specialized circumstances for highly precise questions. Of these designs, the most commonly used and relevant is the untreated contrast group design with pretest and posttest measures. In this design, two groups of subjects are studied, with observation and assessment occurring at least twice for both groups. The first assessment is prior to the intervention for the group receiving it; the second and any subsequent observations occur after the intervention. In this design, the major threats to the validity of the conclusion that any differences at posttest between the groups not understandable from existing differences at pretest are the threats of selection and maturation. The American Psychological Association’s Wilkinson and Task Force on Scientific Inference (1999), in a recent publication, called attention to the need to describe the untreated group in this design a contrast group rather than a control group—the term that has been typically used. The rationale for this change was the recognition that in such designs it is rarely possible to control, either by selection or by statistical analysis, all the potential variables that could
affect the outcome other than the intervention. This modification in nomenclature emphasizes that our certainty about conclusions in much psychiatric research conducted without the benefit of random assignment is often less than that has previously been thought.

It is one easy step from the untreated contrast group design to a design in which the untreated contrast group receives an alternate treatment with measures at pretest and posttest. This is obviously a better design because it includes an alternate intervention. Nonetheless, even an inert treatment frequently produces effects, sometimes from the mere attention of having been provided a treatment, even if it is a placebo. In fact, in psychopharmacologic trials, placebo response of 20% or even higher may be found. It should be clear, however, that this quasi-experimental design does not rule out alternative interpretations of differences between the groups at posttest other than that the interventions showed an effect.

The fact that there is simply no substitute for the random assignment of subjects to conditions in any study where this is at all feasible cannot be overemphasized. The vast majority of threats to internal validity vanish when subjects are randomly assigned to conditions. Although not all threats are nullified, by far the strongest designs are those that employ random assignment. If a study has assigned subjects to conditions at random, then the robustness of the conclusions are considerably strengthened compared to any other type of design. As a consequence, this should be the goal in study design whenever it is logistically or economically feasible, and this is why evidence-based medicine rests largely on randomized clinical trials (Friedland et al. 1998).

There is another class of threats to validity that the Campbell and Stanley (1966) and Cook and Campbell (1979) approaches enumerate. These are threats to the external validity of the conclusions of the study. Whether the sample of subjects studied in a particular study and the results derived from them can be generalized to other similar and dissimilar groups is a key threat to external validity. This problem can be conceptualized as an answer to the following question: How representative of the population as a whole was the sample that yielded the results of a particular study? Epidemiology and survey research are highly developed disciplines, one of whose key foci is the representativeness of the sample relative to the population from which it was drawn and to which the study’s conclusions are to be referred back. Although it may not always be easy to ascertain how representative a sample of subjects is for generalizing the conclusions from that study to other groups, the issue is nonetheless a key one. For example, it might make a great deal of difference if the efficacy of a new antidepressant was initially established on a relatively young sample when a clinician is intending to use it in geriatric settings. Similarly, the mandate by the National Institutes of Health to include research subjects representing both genders and representative ethnicities in federally sponsored research or to provide a rationale why this cannot be done is a dollars and cents statement about the centrality of this concern. Most clinical studies in psychiatry use samples of convenience. Doing so makes the determination of generalizability a more difficult task. Despite the difficulty in ascertaining whether the sample well represents the population of interest, it is an important and frequently overlooked aspect of research and a partial answer for the lack of cumulative findings in clinical psychiatry.

The other threats to external validity are more complex and have to do with the possibility that there will be an interaction between treatment and other factors such as selection or history. The concept of interaction has both a statistical and a conceptual meaning. Leaving aside the former (see below), the latter can be understood as meaning that the impact of the treatment may be different for different subjects depending on their history or selection. For example, if a treatment protocol is time consuming, grueling, and difficult to adhere to, those who are able to complete it may not be representative of those who began it, let alone those to whom it was intended to apply. These threats to external validity are abstruse, but they may operate nonetheless and it is well to attempt to minimize their influence.

A summary of issues of design and threats to validity suggests that many quasi-experimental designs are not worth pursuing, that random assignment and control groups are fundamental requirements for sound designs intended to study the effects of treatments or interventions, and that the representativeness of the sample studied to the population the researcher defines can have important implications for the viability of the findings in other groups of people who are of a different age, gender, ethnicity, or health status. Good research design attempts to minimize both internal and external threats to the validity of the conclusions of the study.

**Power and Statistical Inference**

The concept of statistical power in the social and behavioral sciences is now synonymous with the late Jacob Cohen (1962), who alerted the field to the issue of power and whose persistence and high-quality work has produced the standard reference for the field (Cohen 1988), despite other well-done efforts (Kraemer and Thiemann 1987). The revolutionary influence and importance of power analysis on the design and conduct of psychiatric research cannot be understated. Not only have matters of the power of statistical tests become routine considerations in the decision making and funding of extramural grants, but also considerations of power have come to be incorporated in the appraisal of whole bodies of research as well. This is a distinct advance in the conduct of psychiatric research; prior to its recognition much research was conducted, which was, from the perspective of shedding light on theories, a waste of time, resources, and journal space due to the inattention to issues of power.

The power of a statistical test refers to the probability that a given effect (e.g., mean difference in average level of depression between treatment and control group) will be detected using a sample of a specified size, with the probability level of the statistical test being set at a predetermined level. Said more colloquially, power is the chance you have of actually finding what you are looking for in your study, statistically speaking.

Power analysis, or the determination of how many subjects are needed for the study as designed, or the calculation of how likely it was that an effect would be
found (after the research is completed), is a part of null hypothesis significance testing—the currently dominant approach to data analysis in psychiatric research and behavioral sciences in general. This approach is typically credited to the statistician R. A. Fisher (1925) and was used in its early phases for research questions in agronomy—whether there was a difference in yield from corn planted with one versus another fertilizer. The well-known \( p < 0.05 \) of statistical significance testing (Cohen 1994) is a part of the picture in power analysis. It refers to the probability that the null hypothesis was rejected in error, also referred to as a Type I error. That is, Fisher’s system was designed to evaluate whether the mean value obtained on the dependent variable for the sample of observations studied could plausibly have come from the population, as defined by the researcher. Thus, the null hypothesis is generally conceptualized as a difference of exactly zero between an obtained value and a hypothesized one. In this context, the \( p < 0.05 \) of statistical testing states that a difference as large as the one obtained from the sample studied would occur only five times out of a hundred, if in reality there was no difference in the variable in the population. The 0.05 is referred to as the alpha level.

Power is one of four parameters that are interrelated in such a way so that when three of them are chosen, the fourth is determined from the choices. The four parameters are these: (1) the alpha or probability level of the significance test (typically 0.05 or 0.01); (2) the size of the effect hypothesized or to be detected; (3) the size of the sample being studied; (4) the power of the statistical test. In some ways, it is helpful to think about power as being related to another type of error that is the converse of the Type I error. The power of a statistical test is the quantity 1 minus the probability of making a Type II error, where a Type II error is failing to reject the null hypothesis when in reality in the population the difference is not zero. For completeness, the probability of making a Type II error in any statistical test is termed beta. Power is simply 1 – beta.

If it is not intuitively obvious at this point, and it very well may not be, it should be observed that the design of research studies needs to balance the two types of errors. The first is falsely rejecting the null hypothesis—saying that a new antipsychotic reduces negative symptoms when in reality it does not. The second is failing to reject the null hypothesis—concluding that the new antipsychotic does not reduce negative symptoms when in fact it does. It turns out that the size of the sample has an impact on the probability of making both Type I and Type II errors, for any given effect size (the larger the sample, the better for the hypothesis). It also turns out that much research has failed to reject the null hypothesis and has been taken as evidence against a theory when in fact the study as designed and conducted had such poor power to detect the hypothesized effect that failing to find it should have surprised no one, since the power was well below even as poor a level as only 0.50. Most studies will attempt to have power of at least 0.65, although power of 0.80 is more standard.

Power analysis is so important because it gives the researcher a means to determine how many subjects she or he must include in any particular study to have a fighting chance to show the hypothesized effect. It also gives journal reviewers and grant reviewers a means to determine whether a particular study has been or will be conducted with a sufficient number of subjects \((N)\) to make the result and whether it is a rejection of the null hypothesis or a failure to reject it, substantial, meaningful, and worth the expenditure of resources.

One clear byproduct of the increased attention to power in the design of psychiatric research is a concomitant attention to measures of the size of the effect of the study. For example, many thousands of research studies present means and standard deviations for some number of groups being compared, and then an \( F \) ratio with either the probability of obtaining that \( F \) statistic or the probability of obtaining a number of asterisks indicating the alpha significance level. This type of presentation is not helpful in learning how much of a difference there was, or how many patients improved, or the like. The fact that an effect was statistically significant does not say how big a difference it makes; effect sizes do.

There are a variety of different effect sizes depending on the statistic that is being tested. For example, in a design termed a one-way analysis of variance (ANOVA) (see section on Statistical Techniques), a useful effect size is the percentage of variability in scores on the dependent variable accounted for by knowledge of subjects’ group membership. For a two-group comparison, a standardized measure of effect size is the difference between the two means, divided by the average of the standard deviations. This latter effect size, termed \( d \), gives a number that is free of the metric of the dependent variable. Cohen (1988) has offered values for this effect size metric of 0.2 for small, 0.5 for medium, and 0.8 for large. For the latter value, this translates into the two groups being separated so that almost half of their distributions do not overlap. Another measure of effect size is simply the square of the Pearson correlation coefficient \((r^2)\). This yields the percentage of variability in scores on one variable predictable or knowable from subjects’ scores on the other variable.

There is more that can be presented about power analysis, and the interested reader is referred to Cohen (1988) or Kraemer and Thiemann (1987). High-quality research should present measures of effect size in the reports of the results of interventions or other designs to allow meta-analytic research (studies where the raw data are the results of published studies, see Cooper 1998) to be easily conducted. These are far more important than the mere statistical significance of that effect because with enough subjects in a sample, virtually any effect, however minuscule, will obtain statistical significance. The balance that should be sought is to have enough power to detect the size of the effect hypothesized or deemed important clinically. Thus, thinking about research should be in terms of how many subjects will be needed in a study, in order to detect a difference of some specified magnitude (hopefully that will be clinically meaningful) with a reasonable degree of power. When research design is approached this way, it is then possible to be clear about the trade-offs between power and precision of estimates, costs and logistics, ease, and relevance. Without such an approach, research in any area does not truly become cumulative (Meehl 1978). Recently, Kramer and Kupfer (2006) suggested newer effect sizes, including success rate difference, to highlight clinical significance.
Issues of Measurement

Reliability
An essential characteristic of any form of measurement used in psychiatric research is that it be reliable. Reliability is simply the characteristic that measurements of the same phenomenon produce the same result each time the measurement is done, assuming that the characteristic being measured has not changed. For example, if a researcher was interested in measuring the degree of demoralization of a group of patients, his/her measure of demoralization would be reliable if the results for the group of patients were essentially the same every time the measure was administered, given that the actual level of demoralization of each of the patients in the group had not changed. This type of reliability is typically termed test–retest reliability and is usually associated with questionnaires or scales such as the Beck Depression Inventory–II or the Hamilton Anxiety Scale. It is most often indexed with a Pearson correlation coefficient between scores at times 1 and 2. Obviously, reliability of measurement also applies to much “harder” variables in psychiatric research such as serum lithium levels, or hippocampal volume. Reliability is not usually an issue with harder measures, because potential sources of error, such as contaminated laboratory equipment, are so obvious a basis for errors in the result of the measurement that they are controlled and rarely conceptualized as a potential source of unreliability. With imaging data, however, such as from MRI or fMRI, raters are needed to segment images and make other decisions. Consequently, indices of reliability should be part of the research output (e.g., Frisoni et al. 2002).

In the research literature, there is reference to another form of reliability of measures, usually based on questionnaires of some sort. This reliability is termed internal consistency or internal homogeneity reliability. This form of reliability of measurement can be considerably different from the stability of measurement and probably should not be taken as a substitute. Internal consistency refers to the way the set of items or questions that comprise a scale or measure cohere or are interchangeable with each other at that single measurement occasion. That is, a measure is highly internally consistent (and therefore reliable), if the way subjects answer one item tends to predict or correlate with the way they answer the remaining items. The standard indicator of internal homogeneity for scales with a dichotomous response format is an ANOVA-based coefficient termed alpha (α) introduced by Cronbach (1951). Other things being equal, if a measure is presumed to measure a single construct such as neuroticism, a coefficient alpha above 0.75 or 0.80 is desirable. Nonetheless, there are a wide variety of measures that do not have high levels of internal consistency because the construct being measured is broad or complex. Also, the sample used to calculate coefficient alpha can have an impact on the consistency of the set of items. A sample with both depressed and nondepressed subjects may well yield a lower coefficient alpha than a sample with either one or the other group. A little-known but important fact about coefficient alpha is that its magnitude can be increased, and hence the internal consistency reliability of a measure, merely by increasing the number of items in the measure, without changing at all how much on average they go together.

Validity
Validity has been discussed in the section on research designs. Validity also has a meaning in measurement. Although writers on psychological assessment and psychometrics have delineated a variety of types of validity such as content validity, content validity, predictive validity, convergent validity, and divergent validity, they are all forms or varieties of a more basic type of validity—construct validity (Cronbach and Meehl 1955). Evidence of construct validity answers a deceptively simple question: Does this instrument, test, or scale actually measure what it is claimed to measure? For example, if a new scale for measuring anxiety is offered to the field, the measure will have construct validity if it actually yields higher scores for those who are anxious, if scores on the scale are related to scores on other measures related to anxiety such as neuroticism, and if the theoretical concepts regarding anxiety are born out in what Cronbach and Meehl described as the nomological network of the construct. By this they meant the theory-based predictions that the construct of interest was related (both positively and negatively) to some but not to other constructs. If a theory of anxiety makes no prediction or statement about the relationship between intelligence and anxiety, for example, then the correlation between a well-validated measure of IQ such as the WAIS-III (Wechsler 1997) and this new measure of anxiety should be approximately zero.

The process of accumulating evidence of the construct validity of a measure is actually a daunting task if it is to be done carefully and well. An often overlooked aspect of the validation of tests, scales, or measures is to show that the measure is not related to constructs or variables that it should not be related to. That is, variables that are sometimes regarded as nuisance variables such as age, gender, ethnicity, education, or occupation frequently show some degree of relationship with psychological constructs despite the absence of any predicted or theoretically expected relationship. Much more research is conducted to show that a measure does relate to other measures it is theoretically predicted to be related to, than is conducted to show that a measure is not related to other measures of which it is theoretically predicted to be independent. Both forms of evidence are necessary to establish construct validity. Campbell and Fiske (1959) offered an elegant methodology for accruing evidence that a scale or test measures what it claims to measure—the multitrait–multimethod matrix. The fundamental recognition of this work was that this latter divergent validity aspect of the set of relationships among scales or tests was as important as the former convergent evidence. A measure of anxiety should be more strongly related to other measures of anxiety than to measures of depression. It is fair to say that if a measure demonstrates both convergent validity and discriminant or divergent validity in a variety of settings, with a variety of samples under a variety of conditions against criteria that are reliable and valid, then that measure very likely possesses construct validity—it measures what it is claimed to measure.

It should be noted that even though it is relatively simple to describe the concept of validity of instruments or measures, the process of empirically establishing this vital property is quite difficult. Although it might seem intuitively
obvious that patients with a particular disorder, e.g., bipolar disorder, would answer a set of true–false questions in a certain way, empirical studies have repeatedly demonstrated that the only surefire method to construct and determine the scoring of scales is to do so empirically. This is why scale construction is a specialized activity requiring advanced knowledge, training, and experience. Measures such as the Minnesota Multiphasic Personality Inventory-2 (Butcher et al. 1989) demonstrate this truism.

Interobserver Agreement

There are a number of circumstances in psychiatric research in which the agreement of independent observers is or should be a basic requirement of empirical studies. Among the most basic issues is that of agreement between clinicians about the diagnosis of patients included in studies (Kraemer 1992). As part of the effort to increase interrater reliability in the diagnosis of psychiatric patients, over the last several decades there has been an attempt to construct, validate, and employ structured diagnostic interview protocols such as the Structured Clinical Interview for DSM-IV (SCID-I/P; First et al. 2001) to assist in making the process of arriving at an axis I and axis II diagnosis more homogeneous and uniform. Nonetheless, careful research has shown that diagnosis and diagnostic formulations are difficult decisions about which agreement among seasoned and well-trained clinicians cannot be assumed (DeWitt et al. 1983).

Another important arena in which clinical judgment is necessary, but agreement between or among judges is not always easy to obtain, is in the domain of assessment of outcomes from treatment. Rarely is the outcome or change in clinical status conceptualized simply or in just one dimension. Often the outcome of interest is a complex mix of symptoms, social functioning, and other features such as the Global Assessment of Function, Axis V of the DSM. Similar concerns about whether judgments made by different interviewers or raters of the outcome of psychiatric treatment are interchangeable frequently exist. As a consequence, considerable attention has been paid to methods for assessing the degree of agreement among or between raters.

There are two key statistics for indexing the degree of interchangeability of ratings. The first, kappa (Cohen 1960 (yes, same guy)), is used when the judgments are categorical or measured on a nominal scale of measurement. Here interchangeability between raters is technically described as interrater agreement. Kappa is a statistic that presents the percent agreement between raters on their ratings corrected for the amount of agreement that would be expected by chance, given each judge’s distribution of ratings. To illustrate what kappa does, suppose two judges were categorizing nine patients into one of three categories, A, B, or C, and produced the following ratings. Judge 1: A, C, B, A, C, B, A, C, B; Judge 2: A, B, B, B, B, B, B, B, B. An ordinary percent agreement would be four out of nine or 44.4%. But the kappa coefficient for these same data is only 0.167 because chance agreement between the judges based on the marginal distributions is 33%. Even though the ordinary percent agreement is close to 50%, the kappa of 0.167 would be categorized as revealing unacceptably poor agreement. Kappa is the currently accepted standard for any situation where agreement about categorical ratings is at issue. It is remarkable, however, how often only raw % agreement is presented in the literature (Figure 128–2).

The second statistic is used in circumstances where the ratings are on an interval scale; the Global Assessment of Functioning is a good example. The decision the rater makes here is not what category into which to place a patient, but rather is to assign a numerical score describing how much or little of the attribute the patient demonstrates or has attained. The appropriate statistic to use in these circumstances is the intraclass correlation coefficient (ICC), the preferred index of interrater reliability. Shrout and Fleiss (1979) provide the best description of the six versions this statistic can take. The ICC is different from the Pearson correlation coefficient in that it takes account of unreliability between judges from two sources. The first is differences between the judges in the relative ordering of subjects; the second is differences between judges in the absolute level of ratings. For example, if two judges rated the same five patients on the GAF, the following scores might be produced: Judge A: 30, 40, 50, 40, 40; Judge B: 40, 50, 60, 50, 50. In these circumstances, the relative ordering is identical, and therefore the Pearson correlation would be +1.00, a coefficient that might, at first glance, indicate perfect interrater reliability. Yet, the two judges agree not at all about the actual rating given. (In fact, kappa is = 0.316, showing less than chance agreement if the ratings were analyzed as if they were categorical.) The ICC for these data would be 0.50 for the reliability of a single judge and 0.667 for the reliability of the rating derived from the average of both judges. The vital issue in this example is that the ICC does not indicate perfect reliability even though the Pearson correlation does. This is because the ICC also takes into account the absolute level of ratings assigned, as well as their relative ordering. Using the Pearson correlation instead of the ICC to index interrater reliability is a common error committed in psychiatric research employing ratings made by judges and may well be overlooked in the review process of some journals. ICCs of above 0.65 for single rater estimates and of 0.70 for multiple rater estimates of interrater reliability define the bottom of the range of acceptable coefficients.

Change

Another key issue in measurement for psychiatric research is how to deal with change in status, functioning, or symptoms, as the result of treatment interventions or otherwise. Since the vast majority of outcome measures in psychiatric research are “soft” (Kraemer and Thiemann 1989) like a rating scale, rather than “hard” like a blood level or weight, the degree of change in rating scales or behavioral

![Figure 128–2 Illustrative data for calculating kappa.](image-url)
characteristics is often the answer to the question the psychiatric researcher would like to know most. Even the percent of those no longer meeting diagnostic criteria is “soft” and if used should probably have a sense of interrater agreement for the diagnostic decision.

For a variety of different reasons, many of them mathematically complex, there are potential problems with simple change or difference scores (Cronbach and Furby 1970), including potential regression to the mean and unreliability. Another issue is that many times the relationship between the initial score and the change score is much stronger than is desirable. As an alternative, some have proposed the use of residualized gain scores (Bond 1979). These change scores are adjusted for the relationship between pretest and posttest scores. Neither of these solutions, however, has been totally satisfactory. An understandable response to this conundrum has been to examine change from the perspective of percent improvement by designating some arbitrary magnitude (e.g., 50%) as indicating the patient has changed, or the percent no longer meeting the diagnostic criteria of the disorder being studied.

Kraemer (1981) has proposed an alternative strategy to both change scores and statistical techniques that used repeated measures. She has proposed using an intensive design with the slope of the response plotted against time as the outcome measure of change. This technique maximizes sample retention, decreases within-group variation, and maximizes the power of statistical tests using this outcome measure. Added benefits of this technique over residualized gain scores is that the measure is totally individualized and not based on the relationship in the sample between the pretest and final posttest. The principal drawback of this approach is the requirement for intensive measurement. But when this is weighed against the increase in power and the cost efficiency of multiple measurements as against the higher costs of enrolling more subjects, the approach has much to recommend it.

A recently introduced sophisticated set of statistical techniques also targeted at change, but from the perspective of longitudinal data sets (Diggle et al. 1994), is a family of models that have been referred to by a number of different designations. In psychiatric research, the most common terms are random regression models or mixed models. These models provide solutions to the problems of missing data, serial correlation (pre and post scores being correlated), changes in potential confounding variables over time (time-dependent covariates), acquisition of repeated measures at differing time points, and, most recently, nonlinear approaches that do not assume the normality of distributions of the variables, as well as several other highly technical issues. A very instructive presentation of this approach as applied to the data from the National Institute of Mental Health Treatment of Depression Collaborative Research Program served to introduce this approach to many in psychiatric research community (Gibbons et al. 1993).

The measurement of change and improvement is a very important issue, and the use of both the slope method and a categorical approach in combination is likely to yield a better sense of outcome than either method alone. In combination with a differentiated approach to the selection of outcome variables that are reliable, are valid, and measure the facets of clinical phenomena that are central to the research question at hand (Kraemer and Telch 1992), the techniques described here represent a sophisticated and state-of-the-art approach that, repeated measures ANOVA, the previous standard in the field, does not possess. Random regression models and intent to treat techniques add depth and breadth to the capacity to analyze data from psychiatric research projects.

### Standard Statistical Techniques

The sheer number of statistical techniques available for the psychiatric researcher can be overwhelming, and when the complexity of some (e.g., random regression models) is added, it might seem that the psychiatrist as a researcher should also have a Ph.D. in Biostatistics. Part of this predicament comes from the wide availability of software capable of carrying out not only the simple and standard statistical analyses but also the complex and sophisticated analyses. The advent of desktop computers and concomitant availability of software packages were initially seen as only positive because it made access easier. Currently, however, there is a fundamental reappraisal regarding the very wide availability and use of desktop-based statistical packages and techniques (Cohen 1990). Simply put, there has come to be an overreliance on statistics, frequently complex statistics with many hard-to-meet assumptions about the data on which they operate, which are completely ignored, with a concomitant decrease in attention to issues of design, fidelity of measurement, and simplicity. Consequently, this section will serve two purposes. First, basic issues in statistics will be addressed; second, comments about the use of various statistical techniques and their liabilities will be presented. Although the personal computer and statistical software packages have brought to the desktop the computing power that just 15 years ago required mainframe computers, it is not evident that the quality of psychiatric research has greatly benefited. This is because there is a growing trend of using statistical techniques without regard for whether the data violate the fundamental assumptions necessary for accurate and valid statistical inference of those techniques. Consequently, many would argue that the easy availability has been more bane than boon (Wilkinson and Task Force on Scientific Interference 1999).

### Basic Statistical Parameters

This section introduces some basic statistical parameters and distributions that are routinely used and frequently comprise most of what is required to get a clear grasp on a set of data in psychiatric research.

#### Mean

The mean is defined as the sum of the values of a variable for a set of observations, divided by the number of the observations in the set. It is the average score on the variable and is the most informative measure of central tendency of a distribution when the shape of the distribution is moderately close to the normal distribution or bell-shaped curve.

#### Standard Deviation and Variance

The standard deviation is a statistic associated with the mean of a distribution or set of observations on a variable that describes how much variability the set of observations contains. The formula for the standard deviation of the population is based on the deviation of each observation
Another basic statistic is the correlation between two variables for a sample of observations, each observation with a score on both variables. There are a number of forms of correlation, but the most common is called the Pearson product moment correlation coefficient. This statistic, designated as \( r \), can attain values from +1.0 through 0 to −1.0. The strength of the relationship between the variables is indexed by the correlation, the direction by the sign of the coefficient. A perfect positive relationship yields an \( r \) of +1.0 (see the example data set presented in the interrater reliability section). A perfect negative relationship would yield a coefficient of −1.0. In this case, as scores or values on one variable increase, scores on the other variable decrease. In practice, the strength of the relationship between two variables rarely exceeds ±0.60 or 0.65, if the variables are not intended to measure the same construct. Much more common are correlations in the range of ±0.20–0.45 in terms of substantive relationships such as the number of prior hospitalizations on the one hand and the amount of social support on the other.

Contingency Tables
Another statistical approach used to show the relationship between a pair of variables is the chi-square test (see below) applied to contingency tables. This method is typically used when both variables are categorical or nominal—that is, they are not ordered or on a metric. A simple example of such a contingency table is the 2 × 2 table produced by crossing a medical test result that yields a prediction of positive or negative for a disease with an actual independent diagnostic gold standard verdict of positive or negative with respect to disease status. The resulting four cells of this table are true positives, true negatives, false positives, and false negatives. There are a variety of statistics available to test the strength of the relationship between the two variables, but the central idea is that this way of arranging the data of two variables for a set of observations describes whether or not the categorization for one variable is contingent on the categorization of the other variable.

Univariate Approaches
Some of the central concepts in statistical inference were presented in conjunction with power analysis. This included the concept of rejecting the null hypothesis as the major decision coming from subjecting a set of data gathered from a sample of subjects to statistical analysis. As presented in that section, there is a continuing literature about the inadequacy of null hypothesis testing as a method of supporting theories about human behavior and psychopathology. Nonetheless, this form of statistical analysis continues to be the dominant approach in psychiatric research and will likely be so for many years to come (Wainer 1999). Hence, description of univariate and multivariate techniques using this form of statistical analysis is still a basic tool for the psychiatric researcher. The term univariate analysis refers to situations in which the research study has a single dependent variable to be subjected to statistical analysis. The dependent variable is usually the outcome variable or the variable whose status is thought to depend on the experimental manipulation or treatment intervention. The independent variable is the variable that is free to vary independently across subjects or is the variable whose levels are selected independently by the researcher. The dosage level of a new psychotropic medication would be the independent variable in a study in which carefully diagnosed patients were randomly assigned to one of three conditions of the independent variable—one of three dosage levels of this investigational medication.

t-Tests
When the researcher has two groups to compare—that is, the independent variable has two levels—on a dependent variable using a noncategorical (continuous) metric, the \( t \)-test comparing the two means is typically employed. A significant result (\( p < 0.05 \)) of a \( t \)-test indicates that the samples that produced the two means being compared were likely drawn from different populations. Put differently, the average score on the dependent variable for the population from which one sample was drawn is likely a different one from which the other was drawn. The effect size for the \( t \)-test, \( d \), is simply the raw difference between the two means, divided by the weighted average of the two standard deviations from each sample. So, in addition to the significance of the result of the \( t \)-test, the actual size of the difference in standardized terms is relevant and important. Cohen (1988) has defined an effect size of 0.2 as small, 0.5 as medium, and 0.80 and greater as large for \( d \).

The \( t \)-test has associated with it a term called the degrees of freedom, a concept that is too complex to present here. Suffice it to say that the degrees of freedom are related to the total number of data points in an analysis minus one, minus a function of the number of parameters being estimated or
tested. For the typical t-test, the degrees of freedom is \( n_1 + n_2 - 2 \), where \( n_1 \) and \( n_2 \) are the sample size of each group.

**Analysis of Variance**

The ANOVA is used in situations where the independent variable has more than two levels (there are more than two groups), or there is more than one independent variable of interest being examined simultaneously. An example of the first situation is the three levels of dosage described above. This design would employ what is termed a one-way ANOVA because there is only one independent variable. There are designs, however, where there is interest in the potential joint effect of more than one independent variable on the dependent variable. If there are two independent variables, the analysis would be a two-way ANOVA, for three independent variables a three-way ANOVA, etc. In practice, designs beyond three independent variables are unusual because they are difficult to interpret.

Statistical analysis using ANOVA compares the means of the several groups being studied, like the t-test does for two groups. In fact, it can be shown mathematically that the result of a t-test is identical to the result of a two-group one-way ANOVA. Thus, in this special case, the ANOVA F test and t-test are interchangeable (\( F = t^2 \)).

An example of a two-way ANOVA will clarify this method and why it is still a somewhat popular analysis for the underlying design. Suppose that the psychiatric researcher is testing a new medication, but that there is some indication that the dosage might be different for men and women. The researcher might select a design that included gender as one independent variable and dosage level as the other. If there were the same three dosage levels we have been using in our example, then this would yield a two-way ANOVA layout of \( 2 \times 3 \)—two levels of the independent variable gender and three levels of the independent variable dosage. If subjects were randomly assigned to the dosage level within each gender, then the researcher could determine whether gender mattered ignoring dosage level, whether dosage level mattered ignoring gender, or whether the combination of dosage and gender made a unique difference in the dependent variable.

The impacts of gender ignoring dose and dose ignoring gender are termed main effects in an ANOVA. The combination of gender and dosage is termed an interaction effect. How is an interaction effect understood? In this example, an interaction effect would occur if the relationship between dosage and outcome was different for men and women. Concretely, it might be that symptoms were reduced at all dosages for women with the higher doses producing more symptom reduction, but for men symptom reduction occurred only at the highest dose. In general, however, a significant interaction effect means that the relationship between one independent variable and the dependent variable is contingent on or interacts with the subject’s status on another independent variable.

Each main effect and interaction effect in an ANOVA design analysis is tested by the F statistic, which is a ratio of two variance estimates. Each F ratio has a numerator and a denominator term for degrees of freedom. The total degrees of freedom in an ANOVA are the total sample size minus one (\( N - 1 \)). Typically, each main effect has \( k - 1 \) degrees of freedom, where \( k \) is the number of levels; the degrees of freedom for the interaction term is the product of the degrees of freedom of its constituent effects, and the error term has degrees of freedom equal to the remainder. The F ratio is formed by the ratio of an estimate of variability for the effect (main or interaction) divided by an estimate of the variability of the error term, and the test of the F statistic requires both numerator and denominator degrees of freedom associated with the terms of the ratio. The ANOVA and F have certain assumptions about the data analyzed—these should be verified prior to accepting the results of an ANOVA analysis.

There are a number of measures of effect size for the ANOVA, but probably the most useful one is the percentage of total variability in scores on the dependent variable due to each effect. This can range of course from 0% to 100%; using Cohen’s (1988) rules of thumb, a small effect is 1%, a medium effect is approximately 6%, and a large effect is close to 14%.

Although there is a great deal more about ANOVA that is necessary to fully understand research studies that use this data analytic procedure, the basic elements just presented are the core issues needed to start with an understanding of ANOVA approaches.

**Chi-Square**

Chi-square (pronounced like “high” with a k, and symbolized \( \chi^2 \)) is a distribution that has many uses in psychiatric research, from the testing of contingency tables (see above) to the testing of complex multivariate hypotheses using advanced multivariate methods. For our purposes here, Pearson’s (yes, same guy as correlation) chi-square is used with contingency tables and tests whether there is an association of the dependent and independent variables. The use of chi-square with contingency tables would occur when both the independent and the dependent variables were categorical. If the independent variable were three varieties of SSRI medication and the dependent variable were an outcome designation of worse, no change, or improved, the use of \( \chi^2 \) would be appropriate.

The degrees of freedom for the chi-square test is defined as the product of one minus the number of categories of the row variable by one minus the number of categories of the column variable, that is \((R - 1)(C - 1)\).

**Multivariate Approaches**

In many cases, multivariate statistical approaches are extensions of their univariate forms. When a multivariate analytic technique is referred to, the multivariate characterization refers to the number of either independent or dependent variables, or both, depending on the particular technique.

There are a number of reasons why multivariate analysis might be useful and preferable. Primary among them is the recognition that the statistical hypothesis for univariate analysis is predicated on conducting a single analysis (like a t-test) one time. With many dependent variables that may share variability or be correlated with one another, the researcher typically wants to conduct more than a single analysis. Doing so, however, creates a situation in which experimentwise alpha inflation can occur (Cohen 1990). In these analytic situations, the nominal Type I error rate (see section on power) is not 0.05 or 0.01 but can escalate under certain circumstances to near 0.50—meaning that the null
hypothesis could be wrongly rejected not just five times or one time out of 100, but one time out of two. This leads to a distorted interpretation of the actual empirical state of affairs. Another reason that multivariate analysis may be desirable is that theoretical parsimony may be achieved by understanding multiple relationships simultaneously rather than sequentially. Finally, multivariate analysis provides techniques to answer some questions that cannot be answered using univariate approaches.

In the sections that follow, four multivariate approaches will be presented. These are by no means all the multivariate techniques available to the psychiatric researcher or used by those now working in the field. Nonetheless, they are common approaches and ones that address more typical questions in psychiatric research. Among the statistical or data analytic techniques available but not described here are analysis of covariance (ANCOVA), propensity score analysis, discriminant analysis, logistic regression, loglinear models, cluster analysis, random regression models, and life table or survival analysis.

For those desiring more information about the four techniques described below, or several others, an excellent source is the October 1987 special issue of the Journal of Counseling Psychology. This whole issue was devoted to review and summary papers describing the quantitative foundations of counseling psychology research. Without exception, each article is relevant for an aspect of psychiatric research, especially the psychosocial and clinical domains. Although somewhat older, the techniques and issues have not changed.

**Multiple Correlation/Regression**

Multiple correlation/regression is an extension of bivariate correlation/regression. Simple bivariate regression is just bivariate correlation described above with a couple of differences. In regression, the relationship between the two variables is expressed in terms of the best-fitting straight line that can be plotted through a scatterplot of the two variables, and there is a specific designation of which variable is the independent variable and which is the dependent variable. Regression is employed in developing regression equations that can be used to predict values of \( Y \) for new subjects from their scores on \( X \) when an equation predicting \( Y \) from \( X \) has been developed using a previous sample. For the initial or derivation sample, the higher the correlation, the better the prediction, and the closer all the points on the scatterplot fall to the best-fitting line. In the limiting case, a case of perfect correlation, all the points fall on the line, there is no error in prediction, and the scatterplot reduces to a straight line. This description applies to the case of a single independent variable (\( X \)), for example scores on the Hamilton Rating Scale for Depression completed by the clinician, and the dependent variable (\( Y \)), for example scores on the Beck Depression Inventory completed by the patient.

In multiple regression, there is still a single dependent variable \( Y \), but there are at least two independent or predictor variables, \( X_1, X_2, X_3 \), etc. Multiple regression finds the best weighted combination of predictor variables to minimize the errors in predicting the real \( Y \) values from those generated from the regression equation. A weighted combination refers to a sign (positive or negative) and a multiplier for each independent variable in the analysis. For example, if the question being addressed by a researcher was to predict the severity of current PTSD symptoms using as the dependent variable the impact of event scale-revised (IES-R) (Weiss 2004), and the predictor variables were a measure of combat exposure (EXP), a measure of current social support (SUP), a measure of peritraumatic dissociation (PTD), and a measure of the severity of substance abuse problems (SAB), the resulting equation might look like this: \( IES-R = Constant + 1.2*EXP - 0.68*SUP + 2.25*PTD + 0.44*SAB \). When each subject’s scores for the independent variables were plugged into the equation, a predicted \( Y \) would be calculated. The weights of the equation are calculated so as to minimize the deviations between the predicted and actual values of the dependent variable in the derivation sample.

The results of a multiple regression are tested using the \( F \) statistic, because the procedure is conceptualized as accounting for variability in the dependent variable. Hence, the measure of effect size is the proportion of variability accounted for, the multiple \( R^2 \).

There is one additional important aspect of multiple regression, and that is the manner in which independent variables are entered into the equation. This is a problematic issue because quite commonly there is a large set of predictor variables being examined of which only a subset is typically finally included. One method of variable entry is termed the simultaneous solution and includes all variables. A second method is termed stepwise. In this approach, variables are selected for entry into the equation in order of how much variance they account for in the dependent variable. The first variable entered into the equation is always the variable with the largest bivariate correlation with \( Y \). The second variable is that one which has the highest adjusted (technically partial correlation) correlation with the dependent variable after the adjustment for the first step. This process is then repeated with each new variable being evaluated; at each step, the effects of the previously entered variables are partialled out. The stepwise procedure terminates when the additional variance accounted for by the next candidate variable is not significantly different from zero.

The third method is termed hierarchical multiple regression. This preferred approach enters variables based not on the sample-specific empirical relationships among the variables being studied, but rather on the basis of theoretical or conceptual considerations. One example of this approach can be found in work examining the prediction of symptomatic distress among emergency services personnel who worked the 1989 Loma Prieta earthquake freeway collapse (Weiss et al. 1995). In this study, the question was this: after accounting for variability in symptomatic distress from variables such as social support, exposure to trauma, work experience, and the like (all entered as a set at step 1), how much additional variance was accounted for by general dissociative tendencies (entered at step 2) and, over and above general dissociation, peritraumatic dissociative experiences during or right after the rescue effort (entered at step 3)? The results showed that peritraumatic dissociation was a significant predictor over and above the variables from the event, and general dissociation. The hierarchical procedure can be used quite effectively to examine very specific hypotheses.

Another use of the hierarchical approach is in examining interactions among predictor variables just as was described for two-way ANOVA. (In fact, although it is too
detailed to describe here, it turns out that ANOVA is just a special case of multiple regression where the predictor variables are categorical—see (Cohen and Cohen 1983.)

This is done by entering the main effect variables first and then entering a new variable that is the simply the cross product of the main effect variables in the subsequent step. The partialling in multiple regression makes the cross-product variable contain only that variability not due to the main effects. But if it were entered first, this would not be the case. Most statistical packages use stepwise as the default method to enter independent variables, but this should be verified and the differences in methods should be understood prior to using multiple regression.

The overall multiple regression yields an analogue to the simple Pearson correlation r and the multiple correlation R. To derive the effect size for the overall prediction, one simply squares the overall multiple R, yielding $R^2$, or the proportion of total variation in the dependent variable accounted for by the set of predictor or independent variables. Multiple regression is frequently used in nonexperimental studies, that is those of psychopathology or clinical phenomena when quasiexplanations or causes are sought. Although it is tempting to infer causality from correlation, this cannot be logically defended. The nonequivalence of correlation and causation applies equally strongly to bivariate correlation as it does to multiple correlation.

**Factor Analysis**

Another very common multivariate technique is termed factor analysis. Factor analysis is actually a related family of statistical techniques that have a common goal but approach the solution somewhat differently, depending on underlying assumptions and other technical issues. What factor analysis does is to attempt to identify a much smaller set of underlying or more basic variables from the interrelationships or intercorrelations of a larger set of variables. An example of how factor analysis has been utilized in psychiatric research is for creating only a few variables to measure psychotherapy outcome when many facets of outcome have been measured.

When factor analysis is used, the distinction between independent and dependent variables is not particularly relevant. The starting point of a factor analysis is what is termed a correlation matrix. The elements in the correlation matrix are the simple bivariate correlations of each pair of variables of the set being factor analyzed.

Suppose a psychiatric researcher had nine different variables for each theoretically expected factor should be included, since variables that are not highly related to any of the others will be swamped in the analysis. This criterion makes it clear that, as in most other areas of psychiatric research employing empirical techniques, brute application of a factor analysis without prior conceptual or theoretical specification does not make optimum use of the power of the quantitative method.

There are four basic decisions to be made about the mode of factor analysis to be used, once it has been determined that the data set is appropriate to factor analyze. First, the researcher must decide what estimate of the common variance to use. There are two common choices: 100% or the squared multiple correlation ($R^2$; SMC) of the variable using as predictors the remaining variables in a simultaneous multiple regression identical to the type discussed in the previous section. If 100% is used, the 1.0 in the main diagonals are retained and the method of factor extraction (the second decision) is automatically selected to be principal components. This technique is not technically a factor analysis because it has an exact mathematical solution and analyzes the total variability of all variables including error variance. Using SMCs as the communality estimate includes only common variance and unique reliable variance in the analysis. Using SMCs is the prevalent practice.

The second decision is the method of factor extraction. There are a variety of methods, each having a slightly different goal and based on slightly different assumptions. The two most prevalent are exploratory descriptive approaches: principal components analysis (using communality estimates of 100%) and principal factors, with the latter being the more appropriate method in most situations where a psychiatric researcher would be conducting a factor analysis in the first place.

The third decision is a fundamental decision and difficult to make: how many factors should be extracted and retained? There have been a number of criteria proposed to make this decision. Sometimes the decision can be made on theoretical grounds because a theory or hypothesis specifies that there should be a certain number of underlying

The mathematics of the extraction of factors involves matrix algebra and is quite complex. Suffice it to say that the family of techniques analyzes the variance in each variable that it shares in common with one or more of the remaining variables in the matrix. It would be convenient if the technique automatically provided an unequivocal solution to the number of underlying factors—hence the name factor analysis—for a set of correlated variables. Unfortunately, there are a number of interpretive decisions that the researcher must make to select the particular approach in the family of factor analytic techniques, including deciding ultimately how many underlying factors to retain.

Tinsley and Tinsley (1987) present several criteria that need to be met in order for a factor analysis to be appropriately conducted for a set of data. First, all subjects must have scores on all variables. Second, the sample size must be sufficiently large. Rules of thumb have been offered that the sample should comprise 10 subjects for every variable, but certainly no fewer than four or five per variable. This rule is applicable up to about 300 subjects. Once more than 300 subjects have been collected, the subjects to variables ratio is less important. Third, a sufficient number of variables for each theoretically expected factor should be included, since variables that are not highly related to any of the others will be swamped in the analysis. This criterion makes it clear that, as in most other areas of psychiatric research employing empirical techniques, brute application of a factor analysis without prior conceptual or theoretical specification does not make optimum use of the power of the quantitative method.
dimensions. More typically, however, one or several empirical gauges are employed. One such criterion is that the factor has an eigenvalue \( \geq 1.0 \). Each factor has an eigenvalue, but the technical description of this is beyond the scope of this presentation. Although popular, the eigenvalue \( \geq 1.0 \) rule has recently been questioned (Cliff 1988). Another empirical criterion is to retain a certain number of factors based on how much of the total common variance they account for. It should be clear from this discussion, however, that the determination of the number of factors underlying a set of variables is not an exact and automatic process and is open to interpretation in any particular analysis. Thus, when used to validate the criteria for a psychiatric diagnosis, a factor analysis result is not self-evident.

The final major decision in factor analysis is the type of rotation method to use with the retained factors. Because there are many factor solutions to any correlation matrix, the choice of rotation method influences the final interpretability of the solution. Factors are interpreted based on the loadings of each variable on the factor. The loading is simply the correlation between that factor and the variable it is associated with. The purpose of the rotation methods is to partition the variability within and across factors to make the final solution clearer. Usually this means trying to achieve a solution, where for all retained factors, only a few variables have high loadings on the factor and the rest have negligible loadings. There are two classes of rotation methods: oblique and orthogonal. The former allows the factors to be correlated; the latter requires that the factors be uncorrelated, also termed orthogonal. An orthogonal rotation method is selected in practice virtually exclusively. The method typically selected is termed varimax. This usually produces the most interpretable structure of loadings.

An increasingly popular factor analytic technique is termed a confirmatory factor analysis. Derived from structural equation modeling (see below), a confirmatory factor analysis begins with more specifications and limitations and is more suitable for actually testing hypotheses about the structure of a set of variables.

The procedures for performing a factor analysis are complex and the decisions involved in an ultimate solution are many. Hence, reporting or reading the results of a factor analysis requires providing complete details and accompanying rationale for all of the decisions made throughout the process. The caveat is that many software packages will make all the decisions with no input from the user at all.

**Multivariate Analysis of Variance**

Multivariate analysis of variance (MANOVA) is indeed ANOVA with multiple dependent variables. It has been a procedure that has been gaining in application with advent of statistical packages. The main advantage of MANOVA is that it solves the problem of experimentwise alpha or Type I error inflation (see above), as well as the related Type II error rate when multiple statistical tests are conducted on the same set of data. Also, the approach is able to handle the intercorrelations that typically exist among a set of dependent variables.

MANOVA layouts follow the same structure as ANOVA layouts—one-way, two-way, or multifactorial designs. As in ANOVA, the total variability is partitioned into sources of main effects, interactions, and error, but this time it is the variability in the set of dependent variables. MANOVA employs matrix algebra in its mathematical operations.

Interpreting the results of a MANOVA is more complex than for an ANOVA. ANOVA produces just one test statistic, \( F \), MANOVA analyses, however, produce four test statistics, which usually yield slightly different verdicts about the analysis. Some are more commonly used, including Wilks’ lambda and Pillai’s trace; each is based on the eigenvalues derived and certain degrees of freedom. Nevertheless, all are tests of the null hypothesis.

Once it is shown that the overall multivariate null hypothesis can be rejected, the customary procedure is to examine the univariate \( F \) tests to determine in which of the dependent variables are the independent variables having their strongest impact.

MANOVA can be an efficient and statistically powerful tool when a research study has multiple dependent variables. On the other hand, it is a complex technique, it has certain distribution assumptions that are rarely examined or verified, and understanding the results cannot be accomplished merely by transcribing the results from the computer printout into a journal article.

**Structural Equation Modeling**

The final multivariate approach is termed structural equation modeling and is really a family of statistical approaches. Structural equation modeling, also known as causal modeling or covariance structure analysis, is the newest of the multivariate techniques, gaining real currency in the behavioral sciences only in the late 1970s and early 1980s. It has grown to such a degree that there is now a journal devoted to the technique (Structural Equation Modeling). To some (Cliff 1983, Freedman 1987) it is a controversial if not fundamentally flawed approach. Most, however, consider it to be a useful strategy if approached carefully, modestly, and with full awareness that even though it purports to be a method to test causal models, it cannot actually establish causal relationships and that unless competing models are also tested, both more and less plausible, the results carry far less weight (Figure 128–3).

![Simplified structural equation model for outcome](image-url)
Structural equation modeling makes use of what are termed latent variables. These are hypothesized to be truly causal variables that are estimated by or measured by actual empirical measures. An example of this would be a structural equation model with a latent variable of intelligence. The data set collected would need to include several actual measures of intelligence, including perhaps the WAIS-III verbal IQ score, performance IQ score, verbal comprehension, perceptual organization, working memory, processing speed, a score on the Raven progressive matrices, the Miller analogies test, and perhaps the medical college admission test. The approach requires the researcher to specify, in advance of conducting any analyses, the specific causal model of which latent variables explain scores on other latent variables. In our intelligence example, latent explanatory variables might be family income, average intelligence of first-degree relatives, a measure of environmental complexity during the formative years, or a variety of other hypothetical constructs theorized to explain individual differences in intellectual functioning.

A complete structural equation model comprises two parts. The first is the actual structural model that details the hypothesized or theorized causal model including paths and directions of cause or influence among the hypothesized latent variables. The second component is a measurement model that specifies the relationship between the actual empirical variables (sometimes referred to as indicators) and the latent variables that are being used to estimate. The application of structural equation modeling includes an actual path diagram showing arrows of influence, the directionality of the presumed causal effects, and any multiple causal paths that may be postulated.

The analysis employs the covariance matrix among the observed variables. The covariance matrix is of the same form as the correlation matrix except that the existing metric or scale of each variable is used instead of a standardized metric as is used in correlations. The yield from the analysis is an estimate of the relationships among latent variables in a hypothesized population from the actual relationships among variables in a particular sample. Consequently, the statistical question to be tested is: How well do the actual sample data fit the hypothesized structure? This question is assessed with several measures of goodness of fit. The goodness-of-fit indices are derived from one of a number of iterative (repeated many times with small adjustments from the results of the last pass through) procedures. Typical approaches are maximum likelihood estimates or least squares procedures. The typical goodness-of-fit statistic is chi-square, but the derivation of chi-square here is quite different from that discussed for the contingency table.

Structural equation modeling is like factor analysis in that for stable and meaningful results relatively large samples are required. For a model of four to five variables, Bentler (1985) suggests at least a ratio of 10 subjects per variable; others suggest as many as 30 subjects per variable. Clearly, structural equation modeling requires a large sample and many measures taken with that sample and is probably not appropriate for much of clinical psychiatric research.

There are two major difficulties with structural equation modeling. The first is that even if the statistical results suggest that the collected empirical data from the sample are a good fit to the hypothesized latent model, researchers rarely, if ever, construct implausible or impossible causal models and attempt to fit the data to that model. If this were done and presented along with the results of the hypothesized model, then considerably more confidence would accrue to the hypothesized model. Second, the assessment of fit proceeds in the opposite manner from the usual statistical test and can have unforeseen problems (Tomarken and Waller 2003). That is, if the null hypothesis is rejected then the model is rejected; if the null hypothesis is not rejected, then the model is deemed accurate, valid, or supported. But as described in the section on power and Type II errors, failure to reject the null hypothesis may be merely an issue of low power to do so, not strong evidence that the null hypothesis is indeed false. In structural equation modeling, the power of the statistical test is not usually known or even estimable with any accuracy or confidence. Hence, a model may be said to fit the data when it is really not a valid model. On the other hand, if power is very high, which may occur with very large samples, the null hypothesis of the chi-square goodness-of-fit test may be rejected even when the difference between the sample data and the hypothesized population model is quite trivial. All these suggest considerable caution in the use, interpretation, and consumption of research involving causal or structural equation modeling.

The logistics of performing such an analysis are also somewhat intimidating. Specialized computer programs are required, and the specification of the model, its parameters, and a variety of other decisions require considerable investment. There are now a number of widely used statistical programs.

**How to Read Published Research**

Even if one is a novice regarding the conduct of psychiatric research, one can be an informed, thoughtful, and careful consumer of the psychiatric literature. As difficult as it might seem to believe, the mere fact of its appearance in a peer-reviewed journal does not automatically and invariably convey upon it integrity of methods, results, or conclusions. The reader should approach empirical psychiatric research with a critical and skeptical stance. The author's job is to present a convincing rationale and method. The reader should be asked to take nothing for granted nor to have to assume certain basics if they are not explicitly presented. With these caveats in mind, the reader can evaluate the adequacy of each major component. Below are a series of questions the reader can ask about each major section of a research study. The paper published by the American Psychological Association Taskforce on Statistical Inference (Wilkinson et al. 1999) can also be a very valuable guide.

**Design**

Important questions to ask about the design of a study have to do with the internal and external validity of the study. Are there potential alternate explanations for the results from causal factors that the study is not controlling that the authors address? Are subjects randomly assigned to conditions? How representative of the population of interest is the sample that was studied? Do the methods by which the subjects were recruited promise to avoid introducing bias into the study? Is the design a real
experimental design or is it quasiexperimental? If the latter, are the potential problems with the study made explicit by the author and taken into account when the findings are presented and discussed?

Sample
Important questions to ask about the sample presented in a research paper are these. How was the sample accumulated or drawn, by convenience or using an explicit sampling strategy from a known population? Was assignment to intervention groups random or was some less desirable method used? Of what population is the sample said to represent? Is the sample adequately characterized in terms of gender, ethnicity, age, or other characteristics that could have an impact on the results of the study? If the final sample studied is a subset of some initially larger group, is it clear why and how those remaining were retained and how and why those who were not retained were excluded? Is there discussion of an analysis of the data showing that the remaining subjects are not different in some important way that could have influenced the final results form those who were excluded? Is enough detail about how subjects were recruited present so that another researcher could replicate the recruitment if he or she wanted to perform the same study? Finally, is there an explicit statement regarding informed consent?

Measures
Are the measures used clearly identified and are appropriate citations for their origin given in the references? Do the measures possess reliability and validity? If the measures are newly constructed for the study at hand, is there careful attention to the psychometric properties of the measures in the methods section? Is there any mention of missing data for subjects, and, if mentioned, is there a description of how this was dealt with or why it occurred? If missing data are not mentioned, is it plausible that all measures for all subjects for all measurement occasions were actually collected? If ratings have been made, are there indices of interrater reliability or interrater agreement presented for the data in the current study, not just cited from previous work?

Analysis and Power
In examining power and data analysis, the following questions are relevant. What power was there to detect the effect being studied—that is, were there enough subjects studied so that there was a reasonable chance of detecting the effect of interest? If not, any negative results must be regarded with caution and suspicion. Regarding data analysis, these are apposite questions. Is the method of analysis congruent with the type of variable? Are the basic assumptions about the statistical method met? Does the author present effect sizes along with the significance of the statistical tests? Does the author present the actual values of the variables being compared (e.g., means and standard deviations) in addition to just the test statistic (e.g., t-test)? Is there concern with experimentwise alpha inflation and has the author been judicious in his or her use of significance tests? Is there a logical relationship between the analyses conducted and the questions asked—are the analyses appropriate to answer the question?

If the answer to many or most, if not all, of the questions regarding each of the sections of a research report is in the affirmative, then it is likely that the results can be depended on. To the degree that the answers to the questions are negative is the degree to which the results of the study are questionable and might not be considered definitive or even particularly informative.

Conclusion
Research methodology and statistics are complex areas in which expert consultation is always more helpful prior to starting a research project than it is after the project has begun. This chapter has only scratched the surface of a few of the areas and has left many untouched. Probably the most important advice to give the psychiatric researcher is to consult a professional methodologist, biostatistician, or other experienced person in these arenas before diving into a research project. Although the software and computers are available at relatively small cost, they cannot provide the in-depth knowledge that is required to do things properly and correctly from the start. It is unfortunate, but many research projects have borne no fruit because choices made without prior consultation have rendered the results of the study beyond help even from the most sophisticated and complex statistical rescue strategies. Consequently, many individuals have expended a great deal of effort that did not lead to a desired result. Like all other domains of psychiatry, research method is a specialized area in which training and experience are valuable and for which assistance from a mentor is a prudent investment.
